

ECONOMICS

TENTH EDITION

JOHN SLOMAN, DEAN GARRATT AND JON GUEST

Pearson

At Pearson, we have a simple mission: to help people make more of their lives through learning.

We combine innovative learning technology with trusted content and educational expertise to provide engaging and effective learning experiences that serve people wherever and whenever they are learning.

From classroom to boardroom, our curriculum materials, digital learning tools and testing programmes help to educate millions of people worldwide – more than any other private enterprise.

Every day our work helps learning flourish, and wherever learning flourishes, so do people.

About the Authors

John Sloman is Visiting Fellow at the University of Bristol and Associate of the Economics Network (www.economicsnetwork.ac.uk), a UK-wide organisation, where, until his retirement in 2012, he was Director. The Economics Network is based at the University of Bristol and provides a range of services designed to promote and share good practice in learning and teaching economics. The Network is supported by grants from the Royal Economic Society, the Scottish Economic Society and university economic departments and units from across the UK.

John is also Visiting Professor at the University of the West of England, Bristol, where, from 1992 to 1999, he was Head of School of Economics. He taught at UWE until 2007.

John has taught a range of courses, including economic principles on Economics, Social Science and Business Studies degrees, development economics, comparative economic systems, intermediate macroeconomics and managerial economics. He has also taught economics on various professional courses.

John is the co-author with Dean Garratt of *Essentials of Economics* (Pearson Education, 7th edition 2016), with Dean Garratt; Elizabeth Jones of the University of Warwick

and Jon Guest of *Economics for Business* (Pearson Education, 7th edition 2016); and with Elizabeth Jones of *Essential Economics for Business* (Pearson Education, 5th edition 2017). Translations or editions of the various books are available for a number of different countries with the help of co-authors around the world.

John is very interested in promoting new methods of teaching economics, including group exercises, experiments, role playing, computer-aided learning and the use of audience response systems and podcasting in teaching. He has organised and spoken at conferences for both lecturers and students of economics throughout the UK and in many other countries.

As part of his work with the Economics Network he has contributed to its two sites for students and prospective students of economics: *Studying Economics* (www.studyingeconomics.ac.uk/) and *Why Study Economics?* (<http://whystudyeconomics.ac.uk>).

From March to June 1997, John was a visiting lecturer at the University of Western Australia. In July and August 2000, he was again a visiting lecturer at the University of Western Australia and also at Murdoch University in Perth.

In 2007, John received a Lifetime Achievement Award as 'outstanding teacher and ambassador of economics', presented jointly by the Higher Education Academy, the Government Economic Service and the Scottish Economic Society.

Dr Dean Garratt is a Principal Lecturer in Economics at Nottingham Business School (NBS) and the Course Leader for MSc Economics, MSc Economics and Investment Banking and MSc International Finance.

Dean teaches economics at a variety of levels, including modules in macroeconomics, applied economics and career development for economists. He is passionate about encouraging students to communicate economics more intuitively, to deepen their interest in economics and to apply economics to a range of issues.

Earlier in his career Dean worked as an economic assistant at both HM Treasury and at the Council of Mortgage Lenders. While at these institutions he was researching and briefing on a variety of issues relating to the household sector and to the housing and mortgage markets.

Dean is a Senior Fellow of the Higher Education Academy and an Associate of the Economics Network which aims to promote high-quality teaching practice. He has been involved in several projects promoting a problem-based learning (PBL) approach in the teaching of economics.

In 2006, Dean was awarded the Outstanding Teaching Prize by the Economics Network. The award recognises

exemplary teaching practice that deepens and inspires interest in economics. In 2013, he won the student-nominated Nottingham Business School teacher of the year award.

Dean is an academic assessor for the Government Economic Service (GES) helping to assess candidates at Economic Assessment Centres (EACs). In this role he assesses candidates looking to join the GES, the UK's largest employer of professional economists.

Jon Guest is a Senior Teaching Fellow at Aston Business School and a Teaching Associate at Warwick Business School. He joined Aston University in September 2017 having previously been a Senior Lecturer at Nottingham Business School, a

Principal Teaching Fellow at Warwick Business School and a Senior Lecturer at Coventry University.

Jon has taught on a range of courses including Principles of Microeconomics, Intermediate Microeconomics, Economic Issues and Behavioural Economics. He has also taught economics on various professional courses for the Government Economic Service and HM Treasury.

Jon has worked on developing teaching methods that promote a more active learning environment in the classroom. In particular, he has published journal articles and carried out a number of funded research projects on the impact of games and experiments on student learning. These include an online version of the TV show *Deal or No Deal* and games that involve students acting as buyers and sellers in the classroom. He has recently included a series of short videos on economics topics and implemented elements of the flipped classroom into his teaching. Jon is also interested in innovative ways of providing students with feedback on their work.

Dean runs sessions on HM Treasury's Graduate Development Programme (GDP). These sessions cover principles in policy making, applying economics principles and ideas to analyse policy issues and contemporary developments in macroeconomics.

Outside of work, Dean is an avid watcher of many sports. Having been born in Leicester, he is a season ticket holder at both Leicester City Football Club and Leicestershire County Cricket Club.

Through his work as an Associate of the Economics Network, Jon has run sessions on innovative pedagogic practices at a number of universities and major national events. He is also an academic assessor for the Economics Assessment Centres run by the Government Economic Service. This involves interviewing candidates and evaluating their ability to apply economic reasoning to a range of policy issues. He has also acted as an External Examiner for a number of UK universities.

The quality of his teaching was formally recognised when he became the first Government Economic Service Approved Tutor in 2005 and won the student-nominated award from the Economics Network in the same year. Jon was awarded the prestigious National Teaching Fellowship by the Higher Education Academy in 2011.

Jon is a regular contributor and editor of the *Economic Review* and is a co-author of the 7th edition of the textbook, *Economics for Business*. He has published chapters in books on the economics of sport and regularly writes cases for the 'Sloman in the News' website. He has also published research on the self-evaluation skills of undergraduate students.

Outside of work Jon is a keen runner and has completed the London Marathon. However, he now has to accept that he is slower than both of his teenage sons – Dan and Tom. He is also a long-suffering supporter of Portsmouth Football Club.

Part A INTRODUCTION

Why Economics is Good for You 2

What is economics?	3
Puzzles and stories	4
Applying the principles	5

1 Economics and Economies 6

1.1 What do economists study?	7
1.2 Different economic systems	18
1.3 The nature of economic reasoning	27

Boxes

1.1 <i>Looking at macroeconomic data</i>	10
1.2 <i>The opportunity costs of studying</i>	13
1.3 <i>Scarcity and abundance</i>	14
1.4 <i>Command economies</i>	22
1.5 <i>Adam Smith (1723–90)</i>	25
1.6 <i>Ceteris paribus</i>	28

Part B FOUNDATIONS OF MICROECONOMICS

2 Supply and Demand 34

2.1 Demand	35
2.2 Supply	42
2.3 Price and output determination	45
2.4 Elasticity	56
2.5 The time dimension	70

Boxes

*2.1 <i>The demand for lamb</i>	40
2.2 <i>UK house prices</i>	50
2.3 <i>Stock market prices</i>	54

3 Government and the Market 79

3.1 The control of prices	80
3.2 Indirect taxes and subsidies	88
3.3 Government rejection of market allocation	93
3.4 Agriculture and agricultural policy	95

Boxes

3.1 <i>A minimum unit price for alcohol</i>	83
3.2 <i>The rise in illegal lending</i>	84
3.3 <i>How can ticket touts make so much money?</i>	86
3.4 <i>Ashes to ashes?</i>	90
3.5 <i>The fallacy of composition</i>	97

Part C MICROECONOMIC THEORY

4 Background to Demand: the Rational Consumer 104

4.1 Marginal utility theory	105
4.2 The timing of costs and benefits	113
*4.3 Indifference analysis	115

Boxes

*4.1 <i>Using calculus to derive a marginal utility function</i>	107
4.2 <i>The marginal utility revolution: Jevons, Menger, Walras</i>	111
4.3 <i>Taking account of time</i>	112
*4.4 <i>Love and caring</i>	120
*4.5 <i>Consumer theory: a further approach</i>	125

5 Consumer Behaviour in an Uncertain World 128

5.1 Demand under conditions of risk and uncertainty	129
5.2 Behavioural economics	136

Supporting Resources

Visit www.pearsoned.co.uk/sloman to find valuable online resources:

MyLab Economics

For students

- Study guide with exercises, quizzes and tests, arranged chapter by chapter
- Multiple-choice questions to test your learning
- Glossary with Flashcards to check your understanding
- Link to Sloman Economics News site
- Online textbook chapters
- Link to additional resources on the companion website (listed below)

For lecturers

- MyLab's gradebook, which automatically tracks student performance and progress
- Extensive test bank, allowing you to generate your own tests, assessments and homework assignment
- Access to a wealth of lecturer resources on the companion website (listed below)

Companion website

For students

- Answers to all in-chapter questions in the book
- Over 200 case studies with questions and activities, organised by chapter
- Over 130 audio animations explaining all the key models used in the book
- Regularly updated and searchable blog, featuring current news items with discussion of the issue, questions and links to articles and data
- Hotlinks to 285 sites relevant to the study of economics
- Maths case studies illustrating the key mathematical concepts used in the book

For lecturers

- Comprehensive range of PowerPoint slides, including figures and tables from the book, as well as animated slide shows for use in lectures, organised chapter by chapter. There are various versions of these slide shows, some including questions that can be used with 'clickers'
- Animated key models in PowerPoint
- Teaching and learning case studies, discussing ways of increasing student engagement and improving student learning
- 20 workshops in Word for use in large or small classes, plus a guide on ways of using the workshops. These can easily be customised to suit lecturers' needs. Answers are given to all the workshop questions.
- Over 200 case studies with questions and student activities (as on student website). Answers to all questions in case studies
- Answers to all questions in the book (end-of-chapter questions, box questions and in-text questions) and to questions in maths case studies

Also: The companion website provides the following features:

- Search tool to help locate specific items of content
- Online help and support to assist with website usage and troubleshooting

For more information please contact your local Pearson Education sales representative or visit www.pearsoned.co.uk/sloman.

Preface

A NOTE TO THE STUDENT FROM THE AUTHORS

Economics affects all our lives. As consumers we try to make the best of our limited incomes. As workers – or future workers – we take our place in the job market. As citizens of a country our lives are affected by the decisions of our government and other policy makers: decisions over taxes, decisions over spending on health and education, decisions on interest rates, decisions that affect unemployment, inflation and growth. As dwellers on the planet Earth we are affected by the economic decisions of each other: the air we breathe, the water we drink and the environment we leave to our children are all affected by the economic decisions taken by the human race.

Economics thus deals with some of the most challenging issues we face. It is this that still excites us about economics after many years of teaching the subject. We hope that some of this excitement rubs off on you.

The first nine editions of *Economics* have been widely used in Britain and throughout the world. Like them, this new edition is suitable for all students of economics at first-year degree level, A level or on various professional courses where a broad grounding in both principles and applications is required. It is structured to be easily understood by those of you who are new to the subject, with various sections and boxes that can be left out on first reading or on shorter courses; yet it also has sufficient depth to challenge those of you who have studied the subject before, with starred sections (appearing on a grey background) and starred case studies that will provide much that is new. There are also optional short mathematical sections for those of you studying a more quantitatively focused course.

The book gives a self-contained introduction to the world of economics and is thus ideal for those who will not study the subject beyond introductory level. But by carefully laying a comprehensive foundation and by the inclusion of certain materials in starred sections that bridge the gap between introductory and second-level economics, it provides the necessary coverage for those of you going on to specialise in economics.

The book looks at the world of the early twenty-first century. Despite huge advances in technology and despite the comfortable lives led by many people in the industrialised

world, we still suffer from unemployment, poverty and inequality, and in many countries (the UK included) the gap between rich and poor has grown much wider; our environment is polluted; our economy still goes through periodic recessions; conflict and disagreement often dominate over peace and harmony.

In today's world there are many challenges that face us, including:

- A growing interdependence of the economies of the world, with a seemingly inexorable process of 'globalisation', which links us all through a web of telecommunications and international trade into a world of Amazon, Facebook, Coca-Cola, Nike trainers, Google, Netflix and the English Premier League.
- New challenges for the UK arising from the Brexit vote.
- A rise in populism as the lower paid and unemployed see their incomes stagnating while the wealthy get richer. This has led to many people calling for policies to protect their jobs and communities from cheap imports.
- Large-scale migration of people across and within continents placing pressures on resources, but also creating new economic opportunities.
- Evidence that economic problems spread like a contagion around the world, tying domestic economic growth to global events.
- The effects of financialisation, by which we mean the increasing economic importance of the financial sector, and its impact on the financial health of people, businesses and governments as well as its potential to destabilise economies.
- The continuing hangover from the turmoil on international financial markets that culminated in the banking crisis of 2007–8, with many countries today still trying to tackle high levels of public and private debt and with austerity policies acting as a brake on growth.
- Rapid economic growth of some developing countries, such as India and China, which are increasingly influential in the global economy.
- A move away from the ideological simplicity of a 'free-market' solution to all economic problems.

- An EU struggling to reform its institutions and processes and to stimulate economic growth.
- An ever-deepening crisis for many of the poorest developing countries, often ravaged by disease, conflict and famines, and seemingly stuck in a cycle of poverty.

Economists are called on to offer solutions to these and many other problems. We shall be seeing what solutions economists can offer as the book progresses.

But despite our changing environment, there are certain economic fundamentals that do not change. Although there are disagreements among economists – and there are plenty – there is a wide measure of agreement on how to analyse these fundamentals.

Critical thinking and employability

When you are approaching graduation and start applying for jobs, you will need to demonstrate to potential employers that you have the range of skills necessary for analysing and solving problems and for communicating ideas and solutions to colleagues and clients. This requires the ability to think critically and to apply core concepts and ideas to new situations. Universities recognise this and ‘employability’ is a key objective of courses nowadays.

Employability is a core focus of this book. Critical thinking is developed through questions positioned throughout the text to encourage you to reflect on what you have just read and thereby improve and deepen your learning. Answers to these questions are freely available on the website to enable you to check your progress. Critical thinking is also developed through the use of Boxes of case studies and applications occurring several times in each chapter. These apply the economics you’re learning to a variety of real-world issues and data. There are many additional case studies with questions on the student website.

If your lecturer recommends the use of MyEconLab to accompany the text, you will find there large banks of additional questions and the ability to monitor your progress. These questions enable you to reflect on your learning and on where additional work is required.

Critical thinking is also encouraged through the use of fifteen ‘threshold concepts’. These are core ideas and concepts that recur throughout economics. Understanding and being able to apply these core economic concepts helps you to ‘think like an economist’ and to relate the different parts of the subject to each other. An icon appears in the margin

wherever the concept recurs so that you can easily recognise its use in a new context.

In addition there are 40 ‘Key ideas’ that encourage you to relate new material to a toolkit of ideas. Again, there are icons in the margin to help you identify the relevant idea.

The whole way through the book, you are encouraged to reflect on your learning, to apply it to the real world and to use real-world data to make sense of economic issues and problems.

In addition to the book, there is a news blog with new news items added several times per month. Each blog post discusses economic issues in the news and relates these news items to key economic concepts and theories. Links are given to a range of articles, videos, podcasts, data and reports and each blog post finishes with a set of discussion questions. You can access the blog from the book’s website at www.pearsoned.co.uk/sloman. Archived articles go back many months. You can also search the news articles by key word, chapter of this book or by month. Again, the use of real-world news topics, questions and data help you apply the theories and ideas you will learn in this book and develop these all-important critical thinking skills that are so central to employability.

In terms of employability, employees who can think flexibly and apply concepts and theories in new and perhaps strange situations to analyse and solve problems will be much more valuable to their employer. This book helps you to develop these skills. What is more, the use of data in the book and in the blogs and other web resources, and the hyperlinks in the e-text to data sources and relevant articles, will allow you to gain experience in using evidence to support and assess arguments.

Employers value these problem-solving skills. Indeed, they like to employ graduates with an economics degree, or some element of economics in their degree, because of the skills you will develop. And it’s not just for jobs as economists, but for a large number of professions where studying economics is seen to equip you with a valuable set of skills that are transferable to a range of non-economics situations.

We hope that this book will give you an enjoyable introduction to the economist’s world and that it will equip you with the tools to understand and criticise the economic policies that others pursue.

Good luck and have fun.

John, Dean and Jon

TO LECTURERS AND TUTORS

In the light of the financial crisis and the struggle of many countries to tackle its aftermath, there has been much soul-searching amongst economists about the appropriateness of the models we use and what should be taught to our students. These concerns were debated at an international conference at the Bank of England in 2012. One outcome of this was the publication of a book, *What's the Use of Economics?*¹ This considers how undergraduate courses could be reformed to meet the needs of employers and how economic models and syllabuses could be revised to reflect the real world and to provide a foundation for devising effective economic policy. A second, follow-up conference, *Revisiting the State of Economics Education*, took place at the Bank of England in 2015 and the debate continues.²

We have attempted to address these concerns in the past two editions of this book and have gone further still in this new edition. In particular, we have incorporated recent developments in macroeconomics, including stressing the importance of balance sheets, credit cycles, financial instability and systemic risk, the increased use of the *DAD/DAS* framework and the integration of the expectations-augmented Phillips curve and the *IS/MP* model. But these have been treated at a level wholly suitable for first-year students.

We have also given further weight to behavioural economics in analysing the behaviour of both consumers, firms and workers. In particular, there is more detailed discussion of loss aversion and the endowment effect, present bias and self-control issues, reference points and biases when making decisions under conditions of uncertainty. More weight is given to the importance of institutional structures and culture and we have also strengthened microeconomic analysis in several places, such as game theory and price discrimination.

We have also thoroughly revised the applied chapters and sections to reflect changes in policies. For example, we have included the implications of the Brexit vote and also of the Trump administration's policies in several parts of the book.

In addition, we show how many of the theories developed to explain the problems that existed at the time and how they have evolved to reflect today's issues. We have thus continued to emphasise the link between the history of economic thought and economic history.

This new edition also retains many of the popular features of the previous edition:

- A style that is direct and to the point, with the aim all the time to provide maximum clarity. There are numerous examples to aid comprehension.
- All economic terms highlighted in the text where they first appear and defined at the foot of that page. Each term is also highlighted in the index, so that the student can simply look up a given definition as required. By defining them on the page where they appear, the student can also see the terms used in context in the text.
- Key ideas highlighted and explained when they first appear. There are 40 of these ideas, which are fundamental to the study of economics. Students can see them recurring throughout the book, and an icon appears in the margin to refer back to the page where the idea first appears.
- Fifteen 'threshold concepts'. Understanding and being able to relate and apply these core economic concepts helps students to 'think like an economist' and to relate the different parts of the subject to each other. Again, an icon appears in the margin wherever the concept recurs.
- A wealth of applied material in boxes (177 in all), making learning more interesting for students and, by relating economics to the real world, bringing the subject alive. The boxes allow the book to be comprehensive without the text becoming daunting and allow more advanced material to be introduced where appropriate. Many of the boxes can be used as class exercises and virtually all have questions at the end.
- Extensive use of data, with links in the online version to general data sources and individual datasets, with many opportunities for students to explore data to help them reflect on policy choices.
- Full-page chapter introductions. These set the scene for the chapter by introducing the students to the topics covered and relating them to the everyday world. The introductions also include a 'chapter map'. This provides a detailed contents listing, helping students to see how the chapter is structured and how the various topics relate to each other.
- A consistent use of colour in graphs and diagrams, with explanations in panels where appropriate. These features make them easier to comprehend and more appealing.
- Starred sections and boxes for more advanced material (appearing with a grey background). These can be omitted without interrupting the flow of the argument. This allows the book to be used by students with different abilities and experience, and on courses of different levels of difficulty.
- 'Looking at the maths' sections. These short sections express a topic mathematically. Some use calculus; some do not. They are designed to be used on more quantitatively focused courses and go further than other textbooks at introductory level in meeting the needs of students on such courses. Most refer students to worked examples in Maths Cases on the student website. Some

¹ Diane Coyle (ed.), *What's the Use of Economics?* (London Publishing Partnership, 2012).

² Peter Day, 'Are economics degrees fit for purpose', *BBC News*, 5 February 2016.

of these use simultaneous equations; some use simple unconstrained optimisation techniques; others use constrained optimisation, using both substitution and Lagrange multipliers. The 'Looking at the maths' sections are short and can be omitted by students on non-mathematical courses without any loss of continuity.

- An open learning approach, with questions incorporated into the text so as to test and reinforce students' understanding as they progress. This makes learning a much more active process.
- End-of-chapter questions. These can be set as work for students to do in class or at home. Alternatively, students can simply use them to check their comprehension at the end of a topic.
- Summaries given at the end of each section, thus providing a point for reflection and checking on comprehension at reasonably frequent intervals.
- An even micro/macro split.
- The book is divided into seven parts. This makes the structure transparent and makes it easier for the student to navigate.

Despite retaining these popular features, there have been many changes to this tenth edition.

Extensive revision

Economics (10th edition) uses a lot of applied material, both to illustrate theory and policy, and to bring the subject alive for students by relating it to contemporary issues. This has meant that, as with the previous edition, much of the book has had to be rewritten to reflect contemporary issues. Specifically this means that:

- Many new boxes have been included on topical and controversial issues, including the secondary ticket market, the dominance of Google, the Financial Accelerator and primary surpluses/sustainable debt. Existing boxes have been extensively revised.
- There are many new examples given in the text.

- Theoretical coverage has been strengthened at various points in the book to reflect developments in the subject. This includes:
 - an increased emphasis on the role of borrowing, debt, financial markets, balance sheets and risk at the government, corporate and household levels;
 - the development of macroeconomic models, including the interaction between the *IS/MP* model, the *DAD/DAS* model and the expectations-augmented Phillips curve models;
 - increased emphasis on behavioural economics at the level of both the consumer and the firm, including the impact of present bias, loss aversion, preferences for fairness and biases when making decisions in an uncertain environment;
 - a deepening of the exposition of game theory and more detailed analysis of price discrimination, externalities and public goods.
- The text provides extensive coverage of the recent developments in money and banking and their impact on the economy.
- All policy sections reflect the changes that have taken place since the last edition, including changes to the regulation of businesses and the protection of the environment, and the continuing international responses to the financial crisis and policies adopted in various countries to reduce levels of public-sector deficits and debt. The text enables students to see how they can apply fundamental economic concepts to gain a better understanding of these important issues. Hence, students will be in a better position to analyse the actual responses of policy makers as well as the alternatives that could perhaps have been pursued.
- All tables and charts have been updated, as have factual references in the text.
- Most importantly, every single section and every single sentence of the book has been carefully considered, and if necessary redrafted, to ensure both maximum clarity and contemporary relevance. The result, we hope, is a text that your students will find exciting and relevant to today's world.

SUGGESTIONS FOR SHORTER OR LESS ADVANCED COURSES

The book is designed to be used on a number of different types of course. Because of its comprehensive nature, the inclusion of a lot of optional material and the self-contained nature of many of the chapters and sections, it can be used very flexibly.

It is suitable for one-year principles courses at first-year degree level, two-year economics courses on non-economics degrees, A level, HND and professional courses. It is also highly suitable for single-semester courses, either with a micro or a macro focus, or giving a broad outline of the subject.

The following suggests chapters which are appropriate to different types of course and gives some guidance on chapters that can be omitted while retaining continuity:

Alternative 1: Less advanced but comprehensive courses

Omit all starred sections, starred sub-sections and starred boxes.

Example of a comprehensive course, omitting some of these chapters: Chapters 1–8, 10, 12–14, 15, 17–22, 24–25.

Alternative 2: Economics for Business courses

Chapters 1–3, 5–9, 12–15, 18, 21, 23–6.

Example of an Economics for Business course, omitting some of these chapters: Chapters 1–3, 6–10, 14, 15, 18, 22, 24–25.

Alternative 3: Introduction to microeconomics

Chapters 1–14, 24. The level of difficulty can be varied by including or omitting starred sections and boxes from these chapters.

Example of an Introduction to Microeconomics course, omitting some of these chapters: Chapters 1–4, 6–8, 10, 12, 24.

Alternative 4: Introduction to macroeconomics

Chapters 1, 2, 15–26. The level of difficulty can be varied by including or omitting starred sections and boxes from these chapters.

Example of an Introduction to Macroeconomics course, omitting some of these chapters: Chapters 1, 2, (if microeconomics has not previously been covered) 15, 17–23, 25.

Alternative 5: Outline courses

Chapters 1, 2, 6, 7, 15, 17, 18, 22, 24, 25 (section 25.1). Omit boxes at will.

Alternative 6: Courses with a theory bias

Chapters 1, 2, 4–10, 12, 15–21, 23, 24, 25. The level of difficulty can be varied by including or omitting starred sections and boxes from these chapters.

Alternative 7: Courses with a policy bias (and only basic theory)

Chapters 1–3, 6, 7, 11–15, (17), 22–6.

COMPANION RESOURCES

MyEconLab (for students)

MyEconLab is a comprehensive set of online resources developed for the tenth edition of *Economics*. The book is available with an access card, but if your book did not come with one, you can purchase access to the resources online at www.MyEconLab.com.

MyEconLab provides a variety of tools to enable students to assess their own learning, including exercises, quizzes and tests, arranged chapter by chapter. There are many new questions in this edition and each question has been carefully considered to reflect the learning objectives of the chapter. A personalised Study Plan identifies areas to concentrate on to improve grades, and specific tools are provided to each student to direct their studies in the most efficient way.

Student website

In addition to the materials on MyEconLab, there is an open-access companion website for students with a large range of other resources, including:

- Animations of key models with audio explanations. These can be watched online or downloaded to a computer, MP4 player, smart phone, etc.;

- Links to the Sloman Economics news blog with news items added several times each month by a small team of authors;
- 201 case studies with questions for self study and a range of activities for individual students or groups. These case studies are ordered chapter by chapter and referred to in the text;
- Maths cases with exercises, related to the 'Looking at the Maths' sections in the book;
- Updated list of 285 hotlinks to sites of use for economics;
- Answers to all in-chapter questions;

Note that the companion website, news blog and hotlinks can also be accessed directly from www.pearsoned.co.uk/sloman.

See the Student resources chart on page xxi.

MyEconLab (for lecturers)

You can register online at www.myeconlab.com to use MyEconLab, which is a complete virtual learning environment for your course or embedded into Blackboard, WebCT or Moodle. You can customise its look and feel and its

availability to students. You can use it to provide support to your students in the following ways:

- MyEconLab's gradebook automatically records each student's time spent and performance on the tests and Study Plan. It also generates reports you can use to monitor your students' progress.
- You can use MyEconLab to build your own tests, quizzes and homework assignments from the question base provided to set for your students' assessment.
- Questions are generated algorithmically so that they use different values each time they are used.
- You can create your own exercises by using the econ exercise builder.

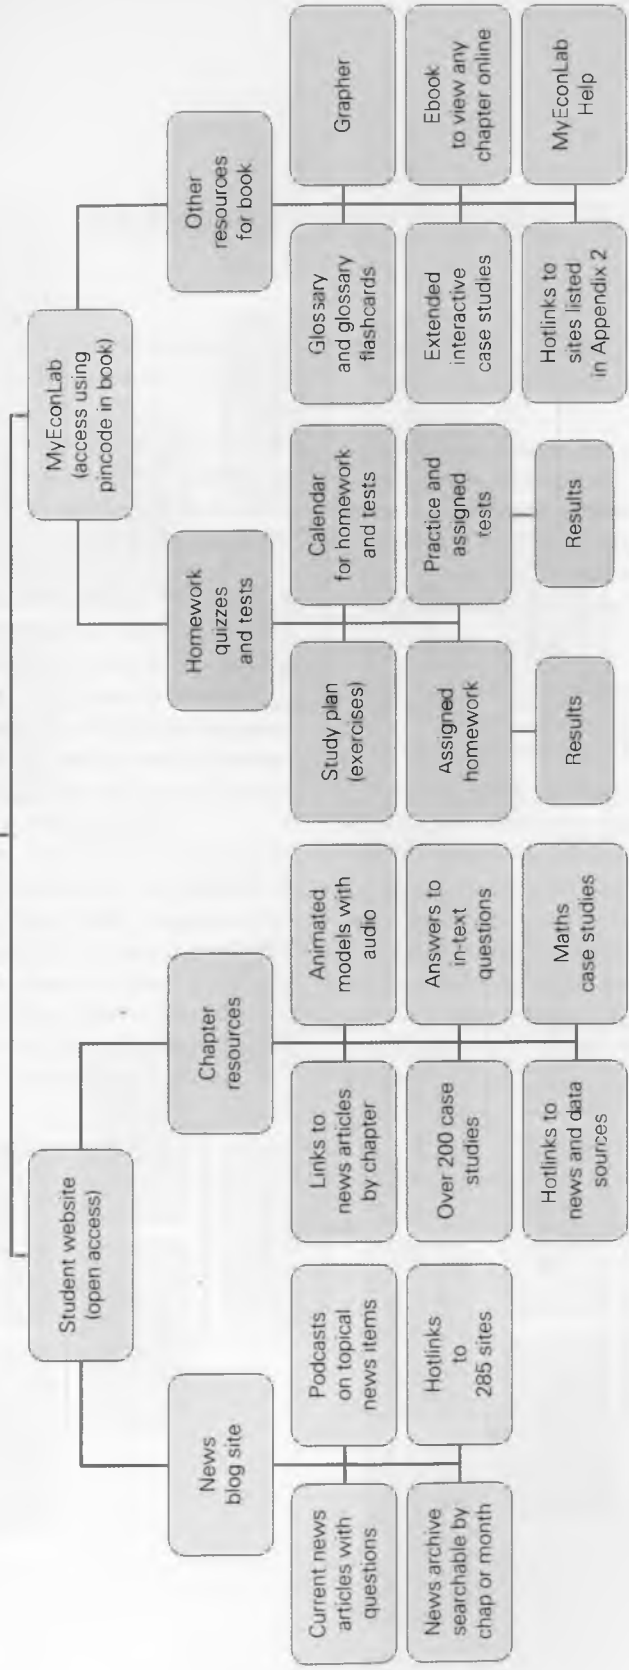

Additional resources for lecturers

There are also many additional resources for lecturers and tutors that can be downloaded from the lecturer section of MyEconLab or from the separate lecturer website. These have been thoroughly revised from the tenth edition. These include:

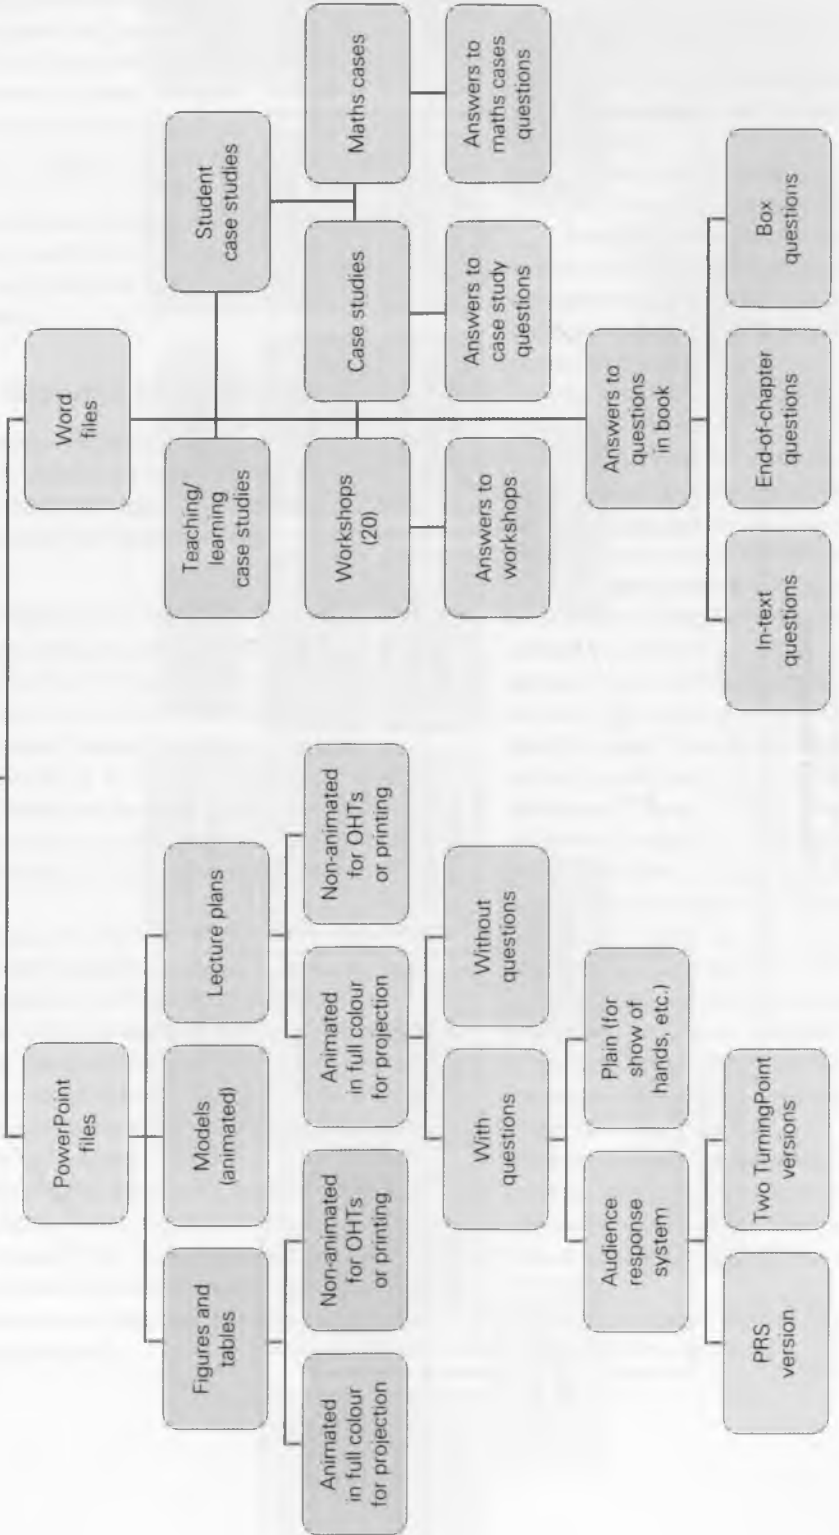

- PowerPoint® slideshows in full colour for use with a data projector in lectures and classes. These can also be made available to students by loading them on to a local network. There are several types of these slideshows:
 - All figures from the book and most of the tables. Each figure is built up in a logical sequence, thereby allowing them to be shown in lectures in an animated form. They are also available in a simple version suitable for printing for handouts or display on an OHP or visualiser.
 - A range of models. There are 41 files, each containing one of the key models from the book, developed in an animated sequence of between 20 and 80 screens.
 - Customisable lecture slideshows. There is one for each chapter of the book. Each one can be easily edited, with points added, deleted or moved, so as to suit particular lectures. A consistent use of colour is made to show how the points tie together. It is not intended that all the material is covered in a single lecture; you can break at any point. It's just convenient to organise them by chapter. They come in various versions:
 - Lecture slideshows with integrated diagrams. These include animated diagrams, charts and tables at the appropriate points.
 - Lecture slideshows with integrated diagrams and questions. These include multiple-choice questions to allow lectures to become more interactive and can be used with or without an audience response system (ARS). ARS versions are available for InterWrite PRS® and for two versions of Turning-Point® and are ready to use with the appropriate 'clickers'.
 - Lecture plans without the diagrams. These allow you to construct your own diagrams on the blackboard, whiteboard or visualiser.
- Answers to all questions in *Economics* (10th edition): i.e. questions embedded in the text, box questions and end-of-chapter questions. These can be edited as desired and distributed to students.
- Answers to the case studies and maths cases found in MyEconLab.
- Case studies. These 201 cases, also available to students on the student website, can be reproduced and used for classroom exercises or for student assignments. Most cases have questions, to which answers are also provided (not available to students). Each case also has an activity for individual students or for groups, and most would be suitable for seminars.
- Extended case studies. These have a range of student activities, questions, data and multimedia, and can be used for project work, group work, work for and during seminars and as part of assessment.
- Maths cases. These 27 maths cases with exercises, also available to students in MyEconLab, relate to the 'Looking at the Maths' sections in the book. Answers to the exercises are also provided (not available to students).
- Workshops. There are 20 of these (10 micro and 10 macro/international). They are in Word® and can be reproduced for use with large groups of students (up to 200). They can also be amended to suit your course. Suggestions for use are given in an accompanying file. Answers to all workshop questions are given in separate Word® files.
- Teaching/learning case studies. These 20 case studies examine various ways to improve student learning of introductory economics. They have been completely revised with new hyperlinks where appropriate.

The following two pages show in diagrammatic form all the student and lecturer resources.

Lecturer Resources

Acknowledgements

As with previous editions, we owe a debt to various people. The whole team from Pearson has, as always, been very helpful and supportive. Thanks in particular to Natalia Jaszczuk and Catherine Yates, the editors, who have offered great support throughout the long process of bringing the book to print. Thanks also to Joan Dale Lace, who, as previously, meticulously copyedited the manuscript and to Sue Gard who carefully proofread everything.

A huge thanks goes to Alison Wride from EML Learning who co-authored the previous three editions. She has decided to concentrate her efforts on her work with the Government Economic Service, but many of her ideas are still retained in this edition. And a special thanks, as previously, to Mark Sutcliffe from the Cardiff School of Management. He provided considerable help and support for the first few editions and it's still much appreciated.

Thanks too to colleagues and students from many universities who have been helpful and encouraging and, as in previous editions, have made useful suggestions for improvement. We have attempted to incorporate their ideas wherever possible. Please do write or email if you have any suggestions. Especially we should like to thank the following reviewers of the previous editions. Their analysis and comments have helped to shape this new edition.

Review of the 9th Edition:

Professor Francesco Feri, Royal Holloway, University of London, UK.

Helen Arce Salazar, The Hague University of Applied Sciences, Netherlands.

Dr Marie Wong, Middlesex University, UK.

Professor Peter Schmidt, Hochschule Bremen, City University of Applied Sciences, Germany.

Dr Sambit Bhattacharyya, University of Sussex, UK.

Review of 10th Edition:

Dr Giorgio Motta, Lancaster University, UK.

Dr Eric Golson, University of Surrey, UK.

Dr Giancarlo Ianulardo, University of Exeter, UK.

A special thanks to Peter Smith from the University of Southampton who has again thoroughly revised and updated the MyEconLab online course. It's been great over the editions to have his input and ideas for improvements to the books and supplements.

Finally, our families have been remarkably tolerant and supportive throughout the writing of this new edition. A massive thanks to Alison, Pat and Helen, without whose encouragement the project would not have been completed.

Part

Introduction

Why Economics is Good for You

2

1 Economics and Economies

6

This opening part of the book introduces you to economics – what it is, some of the fundamental concepts and, most of all, why it is a great subject to study. Economics is not a set of facts or theories to be memorised; it is both more interesting and more useful than that. Studying economics enables you to think about the world in a different way; it helps you to make sense of the decisions people make: decisions about what to buy or what job to do; decisions governments make about how much to tax or what to spend those taxes on; decisions businesses make about what to produce, what prices to charge and what wages to pay. This makes economics relevant for everyone, not only those who are going on to further study.

After studying economics you will be able to apply this ‘way of thinking’ to your life both now and in the future. You will be able to think more analytically and to problem-solve more effectively; this helps explain why economics graduates are so highly valued by employers. Studying economics therefore opens up a variety of career opportunities.

Economics contains some simple core ideas which can be applied to a wide range of economic problems. We will start examining these ideas in Chapter 1, but we begin on the next four pages, in ‘Why Economics is Good for You’, with a look at some interesting questions and puzzles that make the subject such a rich one. By the time you have studied the book, you’ll be able to answer these and more.

Why Economics is Good for You

CHAPTER MAP

What is economics?	3
An island economy	3
Books and media	3
Puzzles and stories	4
A pay-rise, how exciting	4
Do we have too much debt?	4
Of course I want to know	4
We need to save more; we need to spend more	4
Applying the principles	5
Thinking like an economist – a word of warning	5

You may never have studied economics before, and yet when you open a newspaper what do you read? – a report from ‘our economics correspondent’. Turn on the television news and what do you see? – an item on the state of the economy. Talk to friends and often the topic will turn to the price of this or that product, or whether you have got enough money to afford to do this or that.

The fact is that economics affects our daily lives. We are continually being made aware of local, national and international economic issues, such as price increases, interest rate changes, fluctuations in exchange rates, unemployment, economic recessions or the effects of globalisation.

We are also continually faced with economic problems and decisions of our own. What should I buy for lunch? Should I save up for a summer holiday, or spend more on day-to-day living? Should I go to university, or should I try to find a job now? If I go to university, should I work part-time?

This ‘mini chapter’ is an easy read to get you started on the road to thinking like an economist.

WHAT IS ECONOMICS?

If we told you that economics is a problem of maximisation subject to constraints, you'd probably drop this book and find something else to do. So let's put it a different way. Economics is a way of answering some of the most important questions societies face. It's also a way of answering much 'smaller' questions: ones that affect all of us. We are going to set out some of these questions, and start you off on your economics journey. But be warned – once you start thinking like an economist, you probably won't be able to stop.

An island economy

In Chapter 1 we will introduce various core economic concepts and some formal definitions of the economic problems faced by individuals and society. But let's start with a flight of fancy.

Let's suppose that we wake up tomorrow and find ourselves in charge of an island economy. Who is 'we' in this case? Well perhaps it is the authors, plus the reader. Or perhaps it is your economics tutorial group, or a group of random strangers. It really doesn't matter, since it is just an imaginary problem.

Once we got over the excitement of being in charge of a whole economy, we might begin to appreciate that it's not going to be all palm trees and days at the beach. An economy has people who need to eat, be housed and will need access to health care. It may have other islands, nearby, that are friendly and want to trade – or are not friendly and may want to invade.

Being in charge suddenly seems to involve quite a few decisions. What is this island going to produce so that people can live? Is it going to be self-sufficient, or to 'swap' goods with other countries? How are people going to know what to produce? How will the products be shared out? Will they be allocated to everyone, even those who do not work? What will we do if some people are too old to work and haven't got savings or families? What should we do if the island bank runs out of money? How can we be sure that we will have enough resources to support the people next year, as well as this?

At the end of the book (page 862) you will see a poem about people cast away on a desert island. Hopefully, after reading this book, you will understand their plight better. But you might find it interesting to read it now before embarking on your studies.

Of course, we are never actually going to be parachuted in to be in charge of an island, except, perhaps, in a reality TV show – although some of you reading this book may aspire to go into politics. But the questions we have posed above are a reflection of the real challenges countries face. We will look

at the role of government throughout this book: choices that need to be made, decisions that need to be taken, different approaches policy makers can take, and what happens when governments need to work together.

Books and media

Economics has undergone something of a makeover in the past few years. There are two main reasons.

In 2007–8 there was a major financial crisis, which led to the collapse of banks across the world and a downturn in the global economy. It also led to a close scrutiny of why economists had not predicted the crisis. The outcome was a great deal more coverage of economics and economists than had been seen previously – an interesting example of the Oscar Wilde saying, 'There is only one thing worse than being talked about, and that is not being talked about.' Indeed, it stimulated a lot of interest in studying economics at university!

The second reason has less to do with actual economics and more to do with the way it has been written about. The first decade of the century saw the publication of a number of books which presented economics as a series of thought-provoking puzzles, rather than as a purely academic subject. These included *The Undercover Economist*¹ by Tim Harford and the *Freakonomics*² titles, which resulted from collaboration between University of Chicago economist Steven Levitt and New York Times journalist Stephen J. Dubner.

Today, coverage of economics is widespread: in papers, on the Internet, in blogs and radio and television programmes. If you are reading this book because you are studying for a degree or other qualification, you may feel that you are just too busy to read more than the recommended reading list. But try to think more broadly than that. You will find that you can develop your 'economics' brain by spotting the issues. Whether you read papers, or look at news sites online, if you get into the habit of identifying economic issues and puzzles, you will be going a long way towards being an economist.

You could start by Googling the Sloman Economics News site.³ This not only gives you links to up-to-date articles, with some analysis and questions, it also links through to chapters in this book.

1 Tim Harford, *The Undercover Economist* (Little, Brown, 2005).

2 Steven D. Levitt and Stephen J. Dubner, *Freakonomics: A Rogue Economist Explores the Hidden Side of Everything* (William Morrow and Company, 2005).

PUZZLES AND STORIES

Let's look at some examples of economic puzzles and ideas. The ones we discuss below are just a few that you might find interesting.

A pay rise, how exciting

Do you work? By which we mean, do you work for money? If so, make a note of your hourly pay and how many hours you work per week.

Let's assume you are earning £7.50 per hour. Would you like a pay rise to £15 per hour? You would? And what will you do with the extra money you earn? You might go on holiday, or save more, or perhaps you'll simply go out for an extra evening per week, or buy nicer food when you go shopping.

But before we start talking about that, we need to go back to that note of yours. If your rate of pay doubled, how many hours would you work now? You might work the same number of hours; you might think it's worth working more hours; or, you might decide that you can work fewer hours and have more time for other things. It's an interesting puzzle for you to think about. You could ask your friends how they might react in this situation. Perhaps you, or some of your friends, aren't working at the moment, but might do so if higher rates of pay were on offer.

We've thought about this from your point of view. Who else might be interested in the puzzle? Employers are obviously involved. If they want people to do more work, they might consider whether offering higher hourly rates will achieve that. Imagine how annoying it would be if instead people want to work fewer hours, not more. We will see in Chapters 10 and 11 that governments might be interested, too.

Do we have too much debt?

If you are thinking about your student loan or credit card debt, then you will probably immediately say yes. Debt arises from borrowing – the more you borrow and the less you pay back the bigger your debt will be. But borrowing is not always a bad thing. You might not like having to borrow to go to university, but you probably thought it was your best option. You hope that, by getting a degree, you will get a higher salary and that this will more than compensate for the extra debt. It is the same when people buy a house or apartment. People are willing to take out a mortgage so that they can have a place of their own now and 'get on the housing ladder'.

But what about governments? After the financial crisis of 2007–8, governments around the world borrowed large amounts of money to support their economies. They used the money to fund ailing banks and to spend on infrastructure, such as roads, hospitals and broadband. But then, as government debt rocketed, many governments decided they were borrowing too much. They did an about-turn. They started an austerity drive of cutting government expenditure and raising taxes. But was this the right thing to do? Was the debt

too high, or should they have continued borrowing to invest in infrastructure and boost the economy? This is something that economists and politicians are still debating to this day.

Of course I want to know

One thing that economists spend a lot of time talking and thinking about is information. We will see in the rest of this book how important it is when making decisions. And, as you've already seen, most of economics is about making decisions. For example, how can you decide which university to apply for? You need to have all sorts of information: what the entry requirements are, what the structure of the course is, how good the lecturers are at teaching and making the subject interesting, how many people get good jobs at the end of the course, how good the social life is, what the accommodation is like. You can probably think of at least three or four other questions you would want answering.

Let's take another example. Suppose you are trying to decide whether to see a film that's just been released. You can get information about the plot, the actors, the special effects, the rating, etc. You can talk to friends who've seen it. You can also read opinions of critics and reviewers on the quality of the film. Hopefully all this information will help you choose whether to spend money and time going to see it.

Similarly, you can get information about many of the other goods and services you might want to buy, by talking to friends or family, researching on the Internet or browsing in shops.

What about a bigger piece of information? Suppose someone could tell you exactly how long you will live if you continue with your current lifestyle? Would that be a useful piece of information? How would it change your day-to-day choices? Would you behave differently right away? Does your answer depend on who gives the information? You might be more inclined to believe a scientist than an astrologer!

In practice, no one is going to be able to tell you your exact life expectancy (to the day). Accidents can happen and medicine moves on. So the best you could currently expect is an informed prediction based, usually, on statistical probability. But such informed predictions about life expectancy are crucial for insurance companies deciding on premiums.

Information is all around us – in fact, we are said to live in the information age. So the problem is often not one of a lack of information, but one of selecting what information is reliable. We hope, by reading this book, you will be better able to assess information and its usefulness for making economic decisions.

We need to save more; we need to spend more

Puzzles like the two above involve decisions of individual people and these are probably the easiest type to identify. But there are some which apply to a whole economy or country. The second half of this book, Chapters 15 onwards,

looks at ‘whole economy’ economics, so let’s identify an issue in that area.

How much do you save? The answer is likely to depend on your income, your spending habits and probably on things that are hard to pin down, such as your current level of confidence or how ‘good’ you are at saving.

Now let’s think about saving on a national basis. You may have heard people say that we need to save more. There are all sorts of reasons why saving is a ‘good thing’. We are living longer and, unless we save more, we may not have enough to be comfortable in our old age. When we save, we have a buffer against emergencies. When we save, we are not (generally) borrowing, so we don’t have to pay interest; instead, we receive interest and so our income is higher.

All of these reasons can be scaled up to the whole economy. You have probably heard politicians say that the country needs to save for the future, especially if we are all going to live longer. The nation, they argue, needs to reduce its debts so that we can reduce the interest we have to pay, leaving more over for the things people want, such as a better health service and better education. And if emergencies arise (the financial crisis of 2007–8 is a really good example) the country will be in a better position if banks have plenty of money. It’s

also true that saving by individuals provides a source of funds for businesses that want and need to borrow for investment.

You might be wondering why this is a puzzle, since it seems pretty straightforward.

Let’s think about the opposite of saving. If you don’t save, what do you do with your money? You spend it and, hopefully, enjoy it. Imagine the opposite – that you saved a lot of your income, much more than you do now. Imagine that you only bought the barest of necessities, grew your own food, wore the same clothes for years and didn’t buy any new technology, or even have an occasional night out. You might have a pretty miserable life.

Now scale this up to the whole economy again. If people start spending less, what will happen? Businesses will very quickly be in trouble. The banks will be full of our savings, but no one will be borrowing. With spending falling, many firms won’t be able to make profits and will have to close. The economy will move into recession and very soon could be in severe crisis.

Of course this is an exaggerated example. But you can see the puzzle, can’t you? Saving is good, but so is spending. What should we do? What should the government encourage us to do?

APPLYING THE PRINCIPLES

Thinking like an economist – a word of warning

As you go through the rest of this book, whether you study all of it or just some sections, try to spot the puzzles we have talked about above. And look out for other puzzles and issues. You can do this outside formal study. Economics is about people and society. It isn’t a dry subject; it is something that is all around us. Try to get into the habit of thinking like an economist on a daily basis. If there’s a decision to be made, there’s an economic way of thinking about it.

To help you think like an economist, we’ve identified 15 ‘threshold concepts’. Understanding these concepts and being able to apply them in various contexts helps you gain a deeper understanding of economic problems and choices. We describe each concept when we first come across it and then,

each time we use it, there is an icon in the margin to remind you and to refer you back to the page where it’s described.

Where will this approach of ‘thinking like an economist’ take you? It will make you more analytical; it will help you make better decisions. There’s evidence that it can get you a better job and it will certainly make you better at your job.

We’d like to offer one word of warning though. Once you’re thinking like an economist, there’s no turning back. It’s a skill that will be with you for life. Just bear in mind that the non-economists around you may need convincing about the beauty of the subject.

Enjoy the book, but, more importantly, enjoy your journey through economics and the new light it will shed on the world around you.

BOX A.1 WHAT’S THE LATEST ECONOMICS NEWS? CASE STUDIES AND APPLICATIONS

- Government says that the UK cannot remain in the EU single market or customs union when it leaves the EU.
- The Bank of Japan engages in another round of quantitative easing to boost the ailing Japanese economy.
- Severe droughts cause crops to fail across sub-Saharan Africa: higher grain prices expected soon.
- There is widespread criticism of Donald Trump’s policies on trade, with fears that US exports might suffer if America cuts back on imports.
- Unemployment falls and economic growth accelerates, leading to expectations of higher interest rates.

- The age at which UK workers can draw their state pension is raised further. Many predict that those currently under 30 will be working until at least the age of 70.
- Lack of training helps to explain low levels of productivity.
- Oil prices set to remain low for many years as more and more countries engage in fracking.
- Interest rates likely to rise; house prices likely to fall.

1. What is it that makes each one of the above news items an economics item?
2. In each case identify two different individuals or groups who might be affected by the news item.

Economics as a science	27
Economics as a social science	29
Economics and policy	29

In the introductory chapter we discussed some of the questions and puzzles that make economics such an interesting subject to study. Now we turn to explaining those ideas in a bit more detail. We also introduce some of the tools you will need to help you analyse the puzzles posed and answer the questions.

Economics contains some core ideas. These ideas are simple, but can be applied to a wide range of economic problems. We start examining these ideas in this chapter. We begin on the journey to help you to ‘think like an economist’ – a journey that we hope you will find fascinating and will give you a sound foundation for many possible future careers.

In the introductory chapter, we asked what economics is about. In this chapter, we will attempt to answer that question and give you greater insight into the subject you are studying. We will see how the subject is divided up and we will distinguish between the two major branches of economics: microeconomics and macroeconomics.

We will also look at the ways in which different types of economy operate, from the centrally planned economies of the former communist countries to the more free-market economies of most of the world today. We will ask just how ‘markets’ work.

1.1 WHAT DO ECONOMISTS STUDY?

Many people think that economics is about *money*. Well, to some extent this is true. Economics has a lot to do with money: with how much money people earn; how much they spend; what various items cost; how much money firms make; the total amount of money there is in the economy. But, as we shall see later in the book, money is only important because of what it allows us to do; money is a tool and economics is more than just the study of money.

It is concerned with the following:

- The **production** of goods and services: how much an economy produces, both in total and of individual items; how much each firm or person produces; what techniques of production are used; how many people are employed.
- The **consumption** of goods and services: how much people spend (and how much they save); how much people buy of particular items; what individuals choose to buy; how consumption is affected by prices, advertising, fashion, people's incomes and other factors.

Could production and consumption take place without money? If you think they could, give some examples.

But we still have not got to the bottom of what economics is about. Is there one crucial ingredient that makes a problem an economic one? The answer is that there is a central problem faced by all individuals and all countries, no matter how rich. It is the problem of *scarcity* – an issue underlying all other economic problems. For an economist, scarcity has a very specific definition.

Before reading on, how would you define 'scarcity'? Must goods be at least temporarily unattainable to be scarce?

The problem of scarcity

Ask people if they would like more money, and the vast majority would answer 'Yes'. But they don't want more money for its own sake. Rather they want to be able to buy more goods and services, either today or in the future.

These 'wants' will vary according to income levels and tastes. In a poor country 'wants' might include clean water, education and suitable housing. In richer nations 'wants' might involve a second car, longer holidays and more time with friends and family. As countries get richer, human wants may change but they don't disappear. Wants are virtually unlimited.

Yet the means of fulfilling wants are limited. At any point, the world can only produce a finite amount of goods and services because the world has a limited amount of *resources*. These resources, or **factors of production** as they are often called in economics, are of three broad types:

- Human resources: **labour**. The labour force is limited in number, but also in skills. This limits the productivity of labour: i.e. the amount labour can produce.
- Natural resources: **land and raw materials**. The world's land area is limited, as are its raw materials.
- Manufactured resources: **capital**. Capital consists of all those inputs that have themselves had to be produced. The world has a limited stock of factories, machines, transportation and other equipment. The productivity of this capital is limited by the current state of technology.

Could each of these types of resources be increased in quantity or quality? Is there a time dimension to your answer?

So this is the fundamental economic problem: human wants are virtually unlimited, whereas the resources available to meet those wants are limited. We can thus define scarcity as follows:

Scarcity is the excess of human wants over what can actually be produced. Because of scarcity, various choices have to be made between alternatives.

If we would all like more money, why does the government not print a lot more? Could it not thereby solve the problem of scarcity 'at a stroke'?

Definitions

Production The transformation of inputs into outputs by firms in order to earn profit (or to meet some other objective).

Consumption The act of using goods and services to satisfy wants. This will normally involve purchasing the goods and services.

Factors of production (or resources) The inputs into the production of goods and services: labour, land and raw materials, and capital.

Labour All forms of human input, both physical and mental, into current production.

Land and raw materials Inputs into production that are provided by nature: e.g. unimproved land and mineral deposits in the ground.

Capital All inputs into production that have themselves been produced: e.g. factories, machines and tools.

Scarcity The excess of human wants over what can actually be produced to fulfil these wants.

Of course, we do not all face the problem of scarcity to the same degree. A poor family who may not be able to afford enough to eat, or a decent place to live, will hardly see it as a 'problem' that a rich family cannot afford a second skiing holiday. But economists do not claim that we all face an equal problem of scarcity. In fact this is one of the major issues economists study: how resources are distributed, whether between different individuals, different regions of a country or different countries of the world.

This economic problem – limited resources but limitless wants – makes people, both rich and poor, behave in certain ways. Economics studies that behaviour. It studies people at work, producing goods that people want. It studies people as consumers, buying the goods that they want. It studies governments influencing the level and pattern of production and consumption. It even studies why people get married and what determines the number of children they have! In short, it studies anything to do with the process of satisfying human wants.

Demand and supply

We have said that economics is concerned with consumption and production. Another way of looking at this is in terms of *demand* and *supply*. Demand and supply and the relationship between them lie at the very centre of economics. How does this relate to the problem of scarcity?

Demand is related to wants. If every good and service were free, people would simply demand whatever they wanted. In total, such wants are likely to be virtually boundless, perhaps only limited by people's imaginations. *Supply*, on the other hand, is limited. It is related to resources. The amount that firms can supply depends on the resources and technology available.

Given the problem of scarcity – that human wants exceed what can actually be produced – *potential* demands will exceed *potential* supplies. Society has to find some way of dealing with this problem, to try to match demand with supply. This applies at the level of the economy overall: total or '*aggregate*' demand needs to be balanced against total or *aggregate* supply. In other words, total spending in the economy should balance total production. It also applies at the level of individual goods and services. The demand and supply of cabbages should balance, and so should the demand and supply of cars, houses, tablets and holidays.

But if potential demand exceeds potential supply, how are *actual* demand and supply made equal? Either demand has to be reduced, or supply has to be increased, or a combination of the two. Economics studies this process. It studies how demand adjusts to available supplies, and how supply adjusts to consumer demands.

Dividing up the subject

Economics is traditionally divided into two main branches – *macroeconomics* and *microeconomics*, where 'macro' means big and 'micro' means small.

Macroeconomics is concerned with the economy as a whole. It is concerned with *aggregate demand* and *aggregate supply*. By 'aggregate demand' we mean the total amount of spending in the economy, whether by consumers, by customers outside the country for our exports, by the government, or by firms when they buy capital equipment or stock up on raw materials. By 'aggregate supply' we mean the total national output of goods and services.

Microeconomics is concerned with the individual parts of the economy. It is concerned with the demand and supply of particular goods, services and resources such as cars, butter, clothes, haircuts, plumbers, accountants, blast furnaces, computers and oil.

Which of the following are macroeconomic issues, which are microeconomic ones and which could be either depending on the context?

- Inflation.
- Low wages in certain sectors.
- The rate of exchange between the pound and the euro.
- Why the prices of fresh fruit and vegetables fluctuate more than that of cars.
- The rate of economic growth this year compared with last year.
- The decline of traditional manufacturing industries.
- Immigration of workers.

Macroeconomics

Because scarcity exists, societies are concerned that their resources should be used *as fully as possible* and that over time their national output should grow.

Why should resources be used as fully as possible? If resources are 'saved' in one time period surely they can be used in the next time period? The answer is that not all resources can be saved. For example, if a worker doesn't go to work one week then that resource is lost: labour can't be saved up for the future.

Why do societies want growth? To understand this, think back to the discussion of endless wants: if our output grows, then more of our wants can be satisfied. Individuals and society can be made better off.

Definitions

Macroeconomics The branch of economics that studies economic aggregates (grand totals): e.g. the overall level of prices, output and employment in the economy.

Aggregate demand The total level of spending in the economy.

Aggregate supply The total amount of output in the economy.

Microeconomics The branch of economics that studies individual units: e.g. households, firms and industries. It studies the interrelationships between these units in determining the pattern of production and distribution of goods and services.

The achievement of growth and the full use of resources are not easy. This is demonstrated by periods of high unemployment and stagnation that have occurred from time to time throughout the world (for example, in the recessions of the 1930s, the early 1980s and the period following the financial crisis of 2007–8). Furthermore, attempts by governments to stimulate growth and employment can result in inflation and rising imports. Economies have often experienced cycles where periods of growth alternate with periods of recession, such periods varying from a few months to a few years. This is known as the 'business cycle'.

Macroeconomic problems are closely related to the balance between aggregate demand and aggregate supply.

If aggregate demand is too *high* relative to aggregate supply, inflation and trade deficits are likely to result.

- **Inflation** refers to a general rise in the level of prices throughout the economy. If aggregate demand rises substantially, firms are likely to respond by raising their prices. If demand is high, they can probably still sell as much as before (if not more) even at the higher prices, and make higher profits. If firms in general put up their prices, inflation results. By comparing price levels between different periods we can measure the *rate of inflation*. Typically, the rate of inflation reported is the *annual* rate of inflation: the percentage increase in prices over a 12-month period.
- **Balance of trade** deficits are the excess of imports over exports. If aggregate demand rises, people are likely to buy more imports. So part of the extra spending will go on goods from overseas, such as Japanese TVs, Chinese computers, German cars, etc. Also, if the rate of inflation is high, home-produced goods will become uncompetitive with foreign goods. We are likely to buy more foreign imports and people abroad are likely to buy fewer of our exports.

If aggregate demand is too low relative to aggregate supply, unemployment and recession may well result.

- **Recession** is where output in the economy declines for two successive quarters or longer. In other words, during this period growth becomes negative. Hence, not all periods during which the economy contracts are termed 'recessions'. It is the duration and persistence of the contraction that distinguishes a recession. Recessions are associated with low levels of consumer spending. If people spend less, shops are likely to find themselves with unsold stock. Then they will buy less from the manufacturers; they will cut down on production; and buy fewer capital goods such as machinery.
- **Unemployment** is likely to result from cutbacks in production. If firms are producing less, they will need to employ fewer people.

Macroeconomic policy, therefore, tends to focus on the balance of aggregate demand and aggregate supply. It can be

Definitions

Inflation A general rise in the level of prices throughout the economy

(Annual) Rate of inflation The percentage increase in the level of prices over a 12-month period.

Balance of trade Exports of goods and services minus imports of goods and services. If exports exceed imports, there is a 'balance of trade surplus' (a positive figure). If imports exceed exports, there is a 'balance of trade deficit' (a negative figure).

Recession A period where national output falls for two or more successive quarters.

Unemployment The number of people of working age who are actively looking for work but are currently without a job. (Note that there is much debate as to who should officially be counted as unemployed.)

Demand-side policy Government policy designed to alter the level of aggregate demand, and thereby the level of output, employment and prices.

Supply-side policy Government policy that attempts to alter the level of aggregate supply directly.

demand-side policy, which seeks to influence the level of spending in the economy. This in turn will affect the level of production, prices and employment. Or it can be *supply-side policy*. This is designed to influence the level of production directly: for example, by trying to create more incentives for firms to innovate.

Microeconomics

Microeconomics and choice

Because resources are scarce, choices have to be made. There are three main categories of choice that must be made in any society:

- *What* goods and services are going to be produced and in what quantities, since there are not enough resources to produce everything people want? How many cars, how much wheat, how much insurance, how many iPhones, etc. will be produced?
- *How* are things going to be produced? What resources are going to be used and in what quantities? What techniques of production are going to be adopted? Will cars be produced by robots or by assembly-line workers? Will electricity be produced from coal, oil, gas, nuclear fission, renewable resources such as wind farms or a mixture of these?
- *For whom* are things going to be produced? In other words, how will the country's income be distributed? After all, the higher your income, the more you can consume of the total output. What will be the wages of shop workers, MPs, footballers and accountants? How much will pensioners receive? How much of the country's income will go to shareholders or landowners?

BOX 1.1

LOOKING AT MACROECONOMIC DATA

CASE STUDIES AND APPLICATIONS

Assessing different countries' macroeconomic performance

Rapid economic growth, low unemployment, low inflation and the avoidance of current account deficits¹ are major macroeconomic policy objectives of most governments around the world. To help them achieve these objectives they employ economic advisers. But when we look at the

performance of various economies, the success of governments' macroeconomic policies seems decidedly 'mixed'.

The table shows data for the USA, Japan, Germany² and the UK from 1961 to 2018.

Macroeconomic performance of four industrialised economies (average annual figures)

	Unemployment (% of workforce)				Inflation (annual %)				Economic growth (annual %)				Balance on current account (% of national income)			
	USA	Japan	Germany	UK	USA	Japan	Germany	UK	USA	Japan	Germany	UK	USA	Japan	Germany	UK
1961–70	4.8	1.3	0.6	1.7	2.4	5.6	2.7	3.9	4.2	10.1	4.4	3.0	0.5	0.6	0.7	0.2
1971–80	6.4	1.8	2.2	3.8	7.0	8.8	5.1	13.2	3.2	4.4	2.8	2.0	0.9	0.5	1.1	-0.7
1981–90	2.5	2.5	6.0	9.6	4.5	2.2	2.5	6.2	3.2	3.9	2.3	2.6	-1.7	2.3	2.6	-1.4
1991–2000	3.3	3.3	7.9	7.9	2.2	0.4	2.3	3.3	3.3	1.5	1.9	2.4	-1.6	2.5	-0.7	-1.5
2001–07	5.3	4.6	9.2	5.2	2.8	-0.1	1.9	1.9	2.1	1.0	2.3	2.5	-4.8	3.3	3.8	-2.1
2008–18	6.9	3.9	5.3	6.6	1.6	0.3	1.3	2.3	1.7	0.7	1.3	1.2	-2.7	2.7	7.1	-3.5

Note: Years 2017 and 2018 are forecasts.

Source: *Statistical Annex of the European Economy* (Commission of the European Communities, various tables and years) and *World Economic Outlook* (IMF, April 2017).

1. Has the UK generally fared better or worse than the other three countries?
2. Was there a common pattern in the macroeconomic performance of each of the four countries over these 58 years?

If the government does not have much success in managing the economy, it could be for the following reasons:

- Economists have incorrectly analysed the problems and hence have given the wrong advice.
- Economists disagree and hence have given conflicting advice.

- Economists have based their advice on inaccurate statistics or incorrect forecasts.
- Governments have not listened to the advice of economists. This could be for political reasons, such as the electoral cycle.
- There is little else that governments could have done: the problems were insoluble or could not have been predicted.

1 The current account balance is the trade balance plus any incomes earned from abroad minus any incomes paid abroad. These incomes could be wages, investment incomes or government revenues (see section 15.7 for details).
2 West Germany from 1961 to 1991.

All societies have to make these choices, whether they are made by individuals, groups or the government. They can be seen as microeconomic choices, since they are concerned not with the total amount of national output, but with the individual goods and services that make it up: what they are, how they are made, and who gets to consume them.

Choice and opportunity cost

Choice involves sacrifice. The more food you choose to buy, the less money you will have to spend on other goods. The more food a nation produces, the fewer resources there will be for producing other goods. In other words, the production or consumption of one thing involves the sacrifice of alternatives. This sacrifice of alternatives in the production (or consumption) of a good is known as its *opportunity cost*.

If the workers on a farm can produce either 1000 tonnes of wheat or 2000 tonnes of barley, then the opportunity cost

of producing 1 tonne of wheat is the 2 tonnes of barley forgone. The opportunity cost of buying a textbook is the new pair of jeans that you have had to go without. The opportunity cost of saving for your old age is the consumption you sacrifice while younger.

KEY
IDEA
2

The *opportunity cost* of any activity is the sacrifice made to do it. It is the best thing that could have been done as an alternative.

Definition

Opportunity cost The cost of any activity measured in terms of the best alternative forgone.

THRESHOLD CONCEPT 1

CHOICE AND OPPORTUNITY COST

THINKING LIKE AN ECONOMIST

KT 1
p7

Scarcity, as we have seen, is at the heart of economics.

We all face scarcity. With a limited income we cannot buy everything we want. And even if we had the money, with only 24 hours in a day, we would not have time to enjoy all the things we would like to consume. The same applies at a national level. A country has limited resources and so cannot produce everything people would like. Of course, this is also true on a global scale: our planet has finite resources, and the technology and our abilities to exploit these resources are also limited.

With limited resources and endless wants, we have to make choices. In fact, virtually every time we do something, we are making a choice between alternatives. If you choose to watch television, you are choosing not to go out. If you buy a pair of trainers for £70, you are choosing not to spend that £70 on something else. Likewise, if a country devotes more of its resources to producing manufactured goods, there will be less to devote to the provision of services. If we devote more resources to producing a cleaner environment, we may have to produce less of the material goods that people want to consume.

What we give up in order to do something is known as its **opportunity cost**. Opportunity cost is the cost of doing something measured in terms of the best alternative forgone. It's what you would have chosen to do with your time or money if you had not made the choice you did. This is one of the most fundamental concepts in economics. It is a threshold concept: once you have seen its importance, it affects the way you look at economic problems. When you use the concept of opportunity cost, you are thinking like an economist. And this may be different from thinking like an accountant or from the way you thought before.

It may sound deceptively simple, but in some cases working out the opportunity cost of an activity can be a tricky process. We will come across this concept many times throughout this book.

By looking at opportunity cost we are recognising that we face trade-offs. To do more of one thing involves doing less of something else. For example, we trade off work and leisure. The more we work, the less leisure time we will have. In other words, the opportunity cost of working is the leisure we have sacrificed. Nations trade off producing one good against others. The more a country spends on defence, the less it will have to spend on consumer goods and services. This has become known as the 'guns versus butter' trade-off. In other words, if a country decides to use more of its resources for defence, the opportunity cost is the consumer goods sacrificed. We examine such trade-offs at a national level on pages 15–17, when we look at the 'production possibility curve'.

We therefore have to make decisions between alternatives. To make sensible decisions we must weigh up the benefits of doing something against its opportunity cost. This is known in economics as 'rational decision making'. It is another of our threshold concepts (no. 8): see page 109.

1. Think of three things you did last week. What was the opportunity cost of each one?
2. Assume that a supermarket has some fish that has reached its sell-by date. It was originally priced at £10, but yesterday was marked down to £5 'for quick sale'. It is now the end of the day and it still has not been sold. The supermarket is about to close and there is no one in the store who wants fish. What is the opportunity cost for the store of throwing the fish away?

TC 1
p11

Opportunity cost as the basis for choice is the first of our 'Threshold concepts' (see above). There are 15 of these threshold concepts, which we shall be exploring throughout the book. Once you have grasped these concepts and seen their significance, they will affect the way that you understand and analyse economic problems. They will help you to 'think like an economist'.

Rational choices

Economists often refer to **rational choices**. This simply means that people are weighing up the *costs* and *benefits* of different activities and picking the option that allows them to maximise their objective. For consumers and workers this means making choices that maximise their happiness. For a firm it may mean choosing what and how much to produce to maximise profits.

Definition

Rational choices Choices that involve weighing up the benefit of any activity against its opportunity cost so that the decision maker successfully maximises their objective: i.e. happiness or profits.

Imagine you are doing your shopping in a supermarket and you want to buy a chicken. Do you spend a lot of money and buy a free-range organic chicken, or do you buy a cheap bird instead? To make a rational (i.e. sensible) decision, you will need to weigh up the costs and benefits of each alternative. The free-range chicken may taste better and it may meet your concerns about animal welfare, but it has a high opportunity cost: because it is expensive, you will need to sacrifice quite a lot of consumption of other goods if you decide to buy it. If you buy the intensively farmed chicken, however, although you will not enjoy it so much, you will have more money left over to buy other things: it has a lower opportunity cost.

Thus rational decision making, as far as consumers are concerned, involves choosing those items that give you the best value for money – i.e. the *greatest benefit relative to cost*.

The same principles apply to firms when deciding what to produce. For example, should a car firm open up another production line? A rational decision will again involve weighing up the benefits and costs. The benefits are the revenues the firm will earn from selling the extra cars. The costs will include the extra labour costs, raw material costs, costs of component parts, etc. It will be profitable to open

up the new production line only if the revenues earned exceed the costs entailed: in other words, if it increases profits.

In the more complex situation of deciding which model of car to produce, or how many of each model, the firm must weigh up the relative benefits and costs of each – i.e. it will want to produce the most profitable product mix.

Assume that you are looking for a job and are offered two. One is more enjoyable, but pays less. How would you make a rational choice between the two jobs?

Marginal costs and benefits

In economics we argue that rational choices involve weighing up **marginal costs** and **marginal benefits**. These are the costs and benefits of doing a little bit more or a little bit less of a specific activity. They can be contrasted with the total costs and benefits of the activity.

Take a familiar example. What time will you set your alarm to go off tomorrow morning? Let us say that you have to leave home at 8:30. Perhaps you will set the alarm for 7:00. That will give you plenty of time to get ready, but it will mean less sleep. Perhaps you will decide to set it for 8:00. That will give you a longer lie-in, but more of a rush in the morning to get ready.

So how do you make a rational decision about when the alarm should go off? What you have to do is to weigh up the costs and benefits of **additional** sleep. Each extra minute in bed gives you more sleep (the marginal benefit), but means you'll be more rushed when you get up (the marginal cost). The decision is therefore based on the costs and benefits of **extra** sleep, not on the total costs and benefits of a whole night's sleep.

This same principle applies to rational decisions made by consumers, workers and firms. For example, the car firm we were considering just now will weigh up the marginal costs and benefits of producing cars: in other words, it will compare the costs and revenue of producing **additional** cars. If additional cars add more to the firm's revenue than to its costs, it will be profitable to produce them.

Rational decision making, then, involves weighing up the marginal benefit and marginal cost of any activity. If the

marginal benefit exceeds the marginal cost, it is rational to do the activity (or to do more of it). If the marginal cost exceeds the marginal benefit, it is rational not to do it (or to do less of it).

Rational decision making is Threshold Concept 8 and this is examined in Chapter 4, page 109.

TC 8
p109

How would the principle of weighing up marginal costs and benefits apply to a worker deciding how much overtime to work in a given week?

Microeconomic objectives

Microeconomics is concerned with the allocation of scarce resources: with the answering of the *what, how and for whom* questions. But how satisfactorily will these questions be answered? Clearly this depends on society's objectives. There are two major objectives that we can identify: **efficiency** and **equity**.

Efficiency. If altering what was produced or how it was produced could make us all better off (or at least make some of us better off without anyone losing), then it would be efficient to do so. For a society to achieve full **economic efficiency**, three conditions must be met:

- Efficiency in production (**productive efficiency**). This is where production of each item is at minimum cost. Producing any other way would cost more.
- Efficiency in consumption. This is where consumers allocate their expenditures so as to get maximum satisfaction from their income. Any other pattern of consumption would make people feel worse off.
- Efficiency in specialisation and exchange. This is where firms specialise in producing goods for sale to consumers, and where individuals specialise in doing jobs in order to buy goods, so that everyone maximises the benefits they achieve relative to the costs of achieving them.

These last two are collectively known as **allocative efficiency**. In any economic activity, allocative efficiency will be increased as long as doing more of that activity (and hence less of an alternative) involves a greater marginal benefit than marginal cost. Full efficiency will be achieved when all such improvements have been made.

Definitions

Marginal costs The additional cost of doing a little bit more (or 1 unit more if a unit can be measured) of an activity.

Marginal benefits The additional benefits of doing a little bit more (or 1 unit more if a unit can be measured) of an activity.

Rational decision making Doing more of an activity if its marginal benefit exceeds its marginal cost and doing less if its marginal cost exceeds its marginal benefit.

Economic efficiency A situation where each good is produced at the minimum cost and where individual

people and firms get the maximum benefit from their resources.

Productive efficiency A situation where firms are producing the maximum output for a given amount of inputs, or producing a given output at the least cost.

Allocative efficiency A situation where the current combination of goods produced and sold gives the maximum satisfaction for each consumer at their current levels of income. Note that a redistribution of income would lead to a different combination of goods that was allocatively efficient.

BOX 1.2

THE OPPORTUNITY COSTS OF STUDYING

CASE STUDIES AND
APPLICATIONS

What are you sacrificing?

You may not have realised it, but you probably consider opportunity costs many times a day. We are constantly making choices: what to buy, what to eat, what to wear, whether to go out, how much to study, and so on. Each time we make a choice to do something, we are in effect rejecting doing some alternative. This alternative forgone is the opportunity cost of the action we choose.

Sometimes the opportunity costs of our actions are the direct monetary costs we incur. Sometimes it is more complicated.

Take the opportunity costs of your choices as a student.

Buying a textbook costing £59.99

This choice does involve a direct money payment. What you have to consider are the alternatives you could have bought with the £59.99. You then have to weigh up the benefit from the best alternative against the benefit of the textbook.

1. What might prevent you from making the best decision?

Coming to lectures

Even though students now pay fees for their degrees in many countries, there is no extra (marginal) monetary cost in coming to classes once the fees have been paid. You will not get a refund by missing a lecture. The fees, once you've paid them, are what we call a 'sunk cost'.

So are the opportunity costs zero? No: by coming to a lecture you are not working in the library; you are not sleeping; you are not undertaking paid work during that time. If you are making a rational decision to come to classes, then you will consider such possible alternatives.

2. If there are several other things you could have done, is the opportunity cost the sum of all of them?
3. What factors would make the opportunity cost of attending a class relatively high?

Revising for an economics exam

Again, the opportunity cost is the best alternative to which you could have put your time. This might be revising for some

other exam. You will probably want to divide your time sensibly between your subjects. A *sensible* decision is not to revise economics on any given occasion if you will gain a greater benefit from revising another subject. In such a case the (marginal) opportunity cost of revising economics exceeds the (marginal) benefit.

Choosing to study at university or college

What are the opportunity costs of being a student in higher education?

At first it might seem that the costs of higher education would include the following:

- Tuition fees.
- Books, stationery, etc.
- Accommodation, food, entertainment, travel and other living expenses.

But adding these up does not give the opportunity cost. The opportunity cost is the *sacrifice* entailed by going to university or college *rather than* doing something else. Let us assume that the alternative is to take a job that has been offered. The correct list of opportunity costs of higher education would include:

- Books, stationery, etc.
- Additional accommodation and travel expenses over what would have been incurred by taking the job.
- Wages that would have been earned in the job, less any income received as a student.
- The tuition fees paid by the student.

4. Why is the cost of food not included? Should the cost of clothing be included?
5. What impact would it have on the calculation of opportunity costs if you really disliked the nature of the work in the best alternative job?
6. Is the opportunity cost to the individual of attending higher education different from the opportunity costs to society as a whole? Do the benefits of higher education for society differ from those for the individual?

KEY
IDEA
3

Economic efficiency is achieved when each good is produced at the minimum cost and where individual people and firms get the maximum benefit from their resources.

Equity. Even though the current levels of production and consumption might be efficient, they could be regarded as unfair, if some people are rich while others are poor. Another microeconomic goal, therefore, is that of *equity*.

Income distribution is regarded as equitable if it is considered to be fair or just. The problem with this objective, however, is that people have different notions of fairness. A rich person may well favour a much higher degree of inequality than will a poor person. Likewise, socialist governments will generally be in favour of a greater redistribution of income from the rich to the poor than will Conservative governments. Equity is therefore described as a value judgement: notions of equity will depend on the values of individuals or society.

Equity is where income is distributed in a way that is considered to be fair or just. Note that an equitable distribution is not the same as an equal distribution and that different people have different views on what is equitable.

Would it be desirable to have total equality in an economy, so that everyone receives the same share of resources?

The social implications of choice

In practice, the choices that people make may be neither efficient nor equitable. Firms may use inefficient techniques or be poorly managed; people often make wrong decisions about what to buy or what job to take; governments may be wasteful or inefficient in their use of tax revenues; there may be considerable inequality and injustice.

What is more, the effects of people's choices often spill over to other people. Take the case of pollution. It might be profitable for a firm to tip toxic waste into a river. But what is profitable for the firm will not necessarily be 'profitable' for society. Such an action may have serious environmental consequences.

Throughout the book we will be considering how well the economy meets various economic and social objectives, whether micro or macro. We will examine why problems occur and what can be done about them.

Illustrating economic issues: the production possibility curve

Economics books and articles frequently contain diagrams. The reason is that diagrams are very useful for illustrating economic relationships. Ideas and arguments that might take a long time to explain in words can often be expressed clearly and simply in a diagram.

Two of the most common types of diagram used in economics are graphs and flow diagrams. In this and the next section we will look at one example of each. These examples are chosen to illustrate the distinction between microeconomic and macroeconomic issues.

We start by having a look at a **production possibility curve**. This diagram is a graph. Like many diagrams in economics it shows a simplified picture of reality – a picture stripped of all details that are unnecessary to illustrate the points being made. Of course, there are dangers in this.

Definitions

Equity A distribution of income that is considered to be fair or just. Note that an equitable distribution is not the same as an equal distribution and that different people have different views on what is equitable.

Production possibility curve A curve showing all the possible combinations of two goods that a country can produce within a specified time period with all its resources fully and efficiently employed.

BOX 1.3

SCARCITY AND ABUNDANCE

CASE STUDIES AND APPLICATIONS

Is lunch ever free?

The central economic problem is scarcity. But are *all* goods and services scarce? Is anything we desire truly abundant?

First, what do we mean by *abundance*? In the economic sense we mean something where supply exceeds demand at a *zero* price. In other words, even if it is free, there is no shortage. What is more, there must be no opportunity cost in supplying it. For example, if the government supplies health care free to the sick, it is still scarce in the economic sense because there is a cost to the government (and hence the taxpayer).

Two things that might seem to be abundant are air and water.

Air

In one sense air is abundant. There is no shortage of air to breathe for most people for most of the time. But if we define air as clean, unpolluted air, then in some parts of the world it is scarce. It costs money to clean polluted air. We may not pay directly – the cleaned-up air may be free to the

'consumer' – but the taxpayer or industry (and hence its customers) will have to pay.

Even if you live in a non-polluted part of the country, you may well have spent money moving there to escape the pollution. Again there is an opportunity cost to obtain the clean air.

Water

Whether water is abundant depends again on where you live. It also depends on what the water is used for.

Water for growing crops in a country with plentiful rain is abundant. In drier countries, resources have to be spent on irrigation. Water for drinking is not abundant. Reservoirs have to be built. The water has to be piped, purified and pumped.

1. There is a saying in economics, 'There is no such thing as a free lunch' (hence the subtitle for this box). What does this mean?
2. Are any other (desirable) goods or services truly abundant?

Figure 1.1 A production possibility curve

Table 1.1 Maximum possible combinations of food and clothing that can be produced in a given time period

Units of food (millions)	Units of clothing (millions)
8.0	0.0
7.0	2.2
6.0	4.0
5.0	5.0
4.0	5.6
3.0	6.0
2.0	6.4
1.0	6.7
0.0	7.0

In the attempt to make a diagram simple enough to understand, we run the risk of oversimplifying. If this is the case, the diagram may be misleading.

A production possibility curve is shown in Figure 1.1. The graph is based on the data shown in Table 1.1.

Assume that some imaginary nation devotes all its resources – land, labour and capital – to producing just two goods: food and clothing. Various possible combinations that could be produced over a given period of time (e.g. a year) are shown in the table. Thus the country, by devoting all its resources to producing food, could produce 8 million units of food but no clothing. Alternatively, by producing, say, 7 million units of food it could release enough resources – land, labour and capital – to produce 2.2 million units of clothing. At the other extreme, it could produce 7 million units of clothing with no resources at all being used to produce food.

The information in the table can be transferred to a graph (Figure 1.1). We measure units of food on one axis (in this case the vertical axis) and units of clothing on the other. The curve shows all the combinations of the two goods that can

be produced with all the nation's resources fully and efficiently employed. For example, production could take place at point *x*, with 6 million units of food and 4 million units of clothing being produced. Production cannot take place beyond the curve. For example, production is not possible at point *w*: the nation does not have enough resources to do this.

Note that there are two simplifying assumptions in this diagram. First, it is assumed that there are just two types of good that can be produced. We have to assume this because we only have two axes on our graph. The other assumption is that there is only one type of food and one type of clothing. This is implied by measuring their output in particular units (e.g. tonnes). If food differed in type, it would be possible to produce a greater tonnage of food for a given amount of clothing simply by switching production from one food-stuff to another.

These two assumptions are obviously enormous simplifications when we consider the modern complex economies of the real world. But despite this, the diagram still allows important principles to be illustrated simply. In fact, this is one of the key advantages of using diagrams.

Microeconomics and the production possibility curve

A production possibility curve illustrates the microeconomic issues of choice and opportunity cost.

If the country chose to produce more clothing, it would have to sacrifice the production of some food. This sacrifice of food is the opportunity cost of the extra clothing.

The fact that to produce more of one good involves producing less of the other is illustrated by the downward-sloping nature of the curve. For example, the country could move from point *x* to point *y* in Figure 1.2. In doing so it would be producing an extra 1 million units of clothing, but 1 million units less of food. Thus the opportunity cost of the 1 million extra units of clothing would be the 1 million units of food forgone.

It also illustrates the phenomenon of *increasing opportunity costs*. By this we mean that as a country produces more

Figure 1.2 Increasing opportunity costs**Definition**

Increasing opportunity costs of production When additional production of one good involves ever-increasing sacrifices of another.

of one good it has to sacrifice ever-increasing amounts of the other. The reason for this is that different factors of production have different properties. People have different skills; land varies across different parts of the country; raw materials differ one from another; and so on. Thus, as a country concentrates more on the production of one good, it has to start using resources that are less suitable – resources that would have been better suited to producing other goods. In our example, then, the production of more and more clothing will involve a growing *marginal cost*: ever-increasing amounts of food have to be sacrificed for each additional unit of clothing produced.

It is because opportunity costs increase that the production possibility curve is bowed outward rather than being a straight line. Thus in Figure 1.2, as production moves from point *x* to *y* to *z*, so the amount of food sacrificed rises for each additional unit of clothing produced. The opportunity cost of the fifth million units of clothing is 1 million units of food. The opportunity cost of the sixth million units of clothing is 2 million units of food.

1. What is the opportunity cost of the seventh million units of clothing?
2. If the country moves upward along the curve and produces more food, does this also involve increasing opportunity costs?
3. Under what circumstances would the production possibility curve be (a) a straight line; (b) bowed in towards the origin? Are these circumstances ever likely?

Macroeconomics and the production possibility curve

There is no guarantee that resources will be fully employed, or that they will be used in the most efficient way possible. The nation may thus be producing at a point inside the curve: for example, point *v* in Figure 1.3.

What we are saying here is that the economy is producing less of both goods than it is possible for it to produce, either because some resources are not being used (for example, workers may be unemployed), or because it is not using the most efficient methods of production possible, or a combination of the two. By using its resources to the full, the nation could move out onto the curve: to point *x* or *y*, for example. It could produce more clothing *and* more food.

Here we are concerned not with the combination of goods produced (a microeconomic issue), but with whether the total amount produced is as much as it could be (a macroeconomic issue).

Figure 1.3 Making a fuller use of resources

Figure 1.4 Growth in actual and potential output

Over time, the production possibilities of a nation are likely to increase. **Investment** in new plant and machinery will increase the stock of capital; new raw materials may be discovered; technological advances are likely to take place; through education and training, labour is likely to become more productive. This growth in potential output is illustrated by an outward shift in the production possibility curve. This will then allow actual output to increase: for example, from point x to point x' in Figure 1.4.

Will economic growth always involve a parallel outward shift of the production possibility curve?

Illustrating economic issues: the circular flow of goods and incomes

The process of satisfying human wants involves producers and consumers. The relationship between them is two-sided and can be represented in a flow diagram (see Figure 1.5).

The consumers of goods and services are labelled 'households'. Some members of households, of course, are also workers, and in some cases are the owners of other factors of production too, such as land. The producers of goods and services are labelled 'firms'.¹

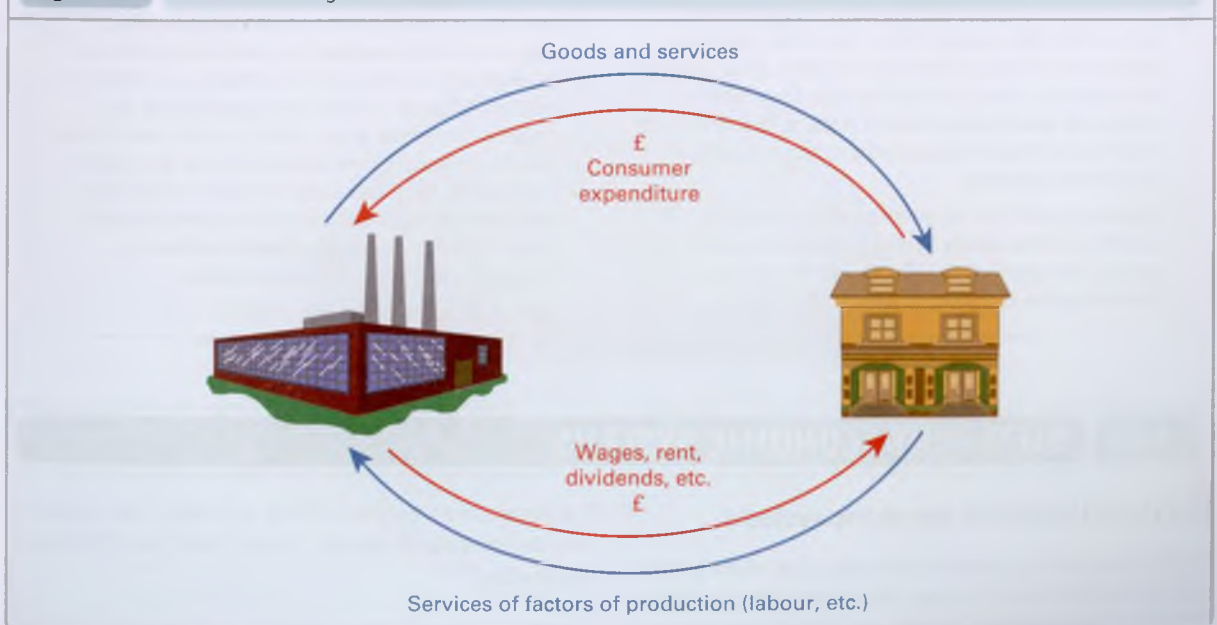

Firms and households are in a twin 'demand and supply' relationship with each other.

First, in the top part of the diagram, households demand goods and services, and firms supply goods and services. In the process, exchange takes place. In a money economy (as opposed to a **barter economy**), firms exchange goods and services for money. In other words, money flows from households to firms in the form of consumer expenditure, while

Definition

Investment The production of items that are not for immediate consumption.

¹ In practice, much of society's production takes place within the household for its members' own consumption. Examples include cooking, cleaning, growing vegetables, decorating and childcare. Also, firms buy from and sell to each other – whether it be raw materials, capital goods or semi-finished goods. Nevertheless, it is still useful to depict the flows of goods and services and money between households and firms when explaining the operation of markets.

Figure 1.5 Circular flow of goods and incomes

goods and services flow the other way – from firms to households.

This coming together of buyers and sellers is known as a **market** – it could be a street market, a shop or a website offering online shopping. Thus we talk about the market for apples, for oil, for houses, for televisions, and so on.

Second, firms and households come together in the market for factors of production. This is illustrated in the bottom half of Figure 1.5. This time the demand and supply roles are reversed. Firms demand the use of factors of production owned by households – labour, land and capital. Households supply them. Thus the services of labour and other factors

flow from households to firms, and in exchange firms pay households money – namely, wages, rent, dividends and interest. Just as we referred to particular goods markets, so we can also refer to particular factor markets – the market for bricklayers, for footballers, for land, and so on.

So there is a circular flow of incomes. Households earn incomes from firms and firms earn incomes from households. The money circulates. There is also a circular flow of goods and services, but in the opposite direction. Households supply factor services to firms, which then use them to supply goods and services to households.

This flow diagram, like the production possibility curve, can help us to distinguish between microeconomics and macroeconomics.

Microeconomics is concerned with the composition of the circular flow: what combinations of goods make up the goods flow; how the various factors of production are combined to produce these goods; for whom the wages, dividends, rent and interest are paid out.

Macroeconomics is concerned with the total size of the flow and what causes it to expand and contract.

Definitions

Barter economy An economy where people exchange goods and services directly with one another without any payment of money. Workers would be paid with bundles of goods.

Market The interaction between buyers and sellers.

Section summary

1. The central economic problem is that of scarcity. Given that there is a limited supply of factors of production (labour, land and capital), it is impossible to provide everybody with everything they want. Potential demands exceed potential supplies.
2. The subject of economics is usually divided into two main branches: macroeconomics and microeconomics.
3. Macroeconomics deals with aggregates such as the overall levels of unemployment, output, growth and prices in the economy.
4. Microeconomics deals with the activities of individual units within the economy: firms, industries, consumers, workers, etc. Because resources are scarce, people have to make choices. Society has to choose by some means or other *what* goods and services to produce, *how* to produce them and *for whom* to produce them. Microeconomics studies these choices.
5. Rational choices involve weighing up the marginal benefits of each activity against its marginal opportunity costs. If the marginal benefits exceed the marginal costs, it is rational to choose to do more of that activity.
6. The production possibility curve shows the possible combinations of two goods that a country can produce in a given period of time. Assuming that the country is already producing on the curve, the production of more of one good will involve producing less of the other. This opportunity cost is illustrated by the slope of the curve. If the economy is producing within the curve as a result of idle resources or inefficiency, it can produce more of both goods by taking up this slack. In the longer term, it can only produce more of both by shifting the curve outwards through investment, technological progress, etc.
7. The circular flow of goods and incomes shows the interrelationships between firms and households in a money economy. Firms and households come together in markets. In goods markets, firms supply goods and households demand goods. In the process, money flows from households to firms in return for the goods and services that the firms supply. In factor markets, firms demand factors of production and households supply them. In the process, money flows from firms to households as incomes for factor services.

1.2 DIFFERENT ECONOMIC SYSTEMS

The classification of economic systems

All societies face the problem of scarcity. They differ considerably, however, in the way they tackle the problem. One important difference between societies is in the degree

of government control of the economy: the extent to which government decides ‘what’, ‘how’ and ‘for whom’ to produce.

At the one extreme lies the completely **planned or command economy**, where all the economic decisions are taken by the government.

At the other extreme lies the completely **free-market economy**. In this type of economy there is no government intervention at all. All decisions are taken by individuals and firms. Households decide how much labour and other factors to supply, and what goods to consume. Firms decide what goods to produce and what factors to employ. The pattern of production and consumption that results depends on the interactions of all these individual demand and supply decisions in free markets.

In practice, all economies are a mixture of the two; it is the *degree* of government intervention that distinguishes different economic systems. In China, the government plays a large role, whereas in the USA, the government plays a much smaller role.

It is still useful to analyse the extremes, in order to put the different **mixed economies** of the real world into perspective. The mixture of government and the market can be shown by the use of a spectrum diagram such as Figure 1.6. It shows where particular economies of the real world lie along the spectrum between the two extremes.

The diagram is useful in that it provides a simple picture of the mixture of government and the market that exists in various economies. It can also be used to show changes in the mixture over time.

The problem with this type of classification is that it is one-dimensional and oversimplified. Countries differ in the *type* of government intervention as well as the level. For example, governments can intervene through planning, public ownership, regulation, taxes and subsidies, partnership schemes with private industry, and so on. Two countries

could be in a similar position along the spectrum but have very different types of government intervention.

Notice that there has been a general movement to the right along the spectrum since the 1980s. In former communist countries this has been a result of the abandonment of central planning and the adoption of private enterprise. In Western economies it has been a result of deregulation of private industry and privatisation (the selling of nationalised industries to the private sector).

How do you think the positions of these eight countries will change over the next decade?

The informal sector: a third dimension

In all societies, many economic decisions are made, whether individually or in groups, which involve neither the government nor the market. For example, many of the activities taking place in the home, such as cooking, cleaning, gardening and care for children or the elderly, can be seen

Definitions

Centrally planned or command economy An economy where all economic decisions are taken by the central authorities.

Free-market economy An economy where all economic decisions are taken by individual households and firms and with no government intervention.

Mixed economy An economy where economic decisions are made partly by the government and partly through the market. In practice all economies are mixed.

Figure 1.6 Classifying economic systems

as 'economic' activities. There is an output (such as a meal or a service provided) and there is an opportunity cost to the provider (in terms of alternative activities forgone). And yet no money changes hands. Similarly, many of the activities done in groups, such as clubs and charities, involve the provision of goods and/or services, but again, no money changes hands.

These activities are taking place in the *informal sector*. The relative size of the informal sector varies from one country to another and over time. In rich countries, as more women continue to work after having children, and as working hours have increased, many people employ others to do the jobs, such as cleaning and childcare, that they once did themselves. What was once part of the informal sector is now part of the market sector.

In many developing countries, much of the economic activity in poorer areas involves *subsistence production*. This is where people grow their own food, build their own shelter, etc. While some of the inputs (e.g. building materials) may have to be purchased through the market, much of this production is in the informal sector and involves no exchange of money. The importance of the informal sector, particularly to developing countries, should not be underestimated. This is an area of increasing interest to many economists, particularly those interested in the downsides of economic growth.

The command economy

The command economy is usually associated with a socialist or communist economic system, where land and capital are collectively owned. The state plans the allocation of resources at three levels:

- It plans the allocation of resources between current consumption and investment for the future. By sacrificing some present consumption and diverting resources into investment, it could increase the economy's growth rate.

The amount of resources it chooses to devote to investment will depend on its broad macroeconomic strategy: the importance it attaches to growth as opposed to current consumption.

- At a microeconomic level, it plans the output of each industry and firm, the techniques that will be used, and the labour and other resources required by each industry and firm.

In order to ensure that the required inputs are available, the state would probably conduct some form of *input-output analysis*. All industries are seen as users of inputs from other industries and as producers of output for consumers or other industries. For example, the steel industry uses inputs from the coal and iron-ore industries and produces output for the vehicle and construction industries. Input-output analysis shows, for each industry, the sources of all its inputs and the destination of all its output. By using such analysis the state attempts to

Definitions

Informal sector The parts of the economy that involve production and/or exchange, but where there are no money payments.

Subsistence production Where people produce things for their own consumption.

Input-output analysis This involves dividing the economy into sectors, where each sector is a user of inputs from and a supplier of outputs to other sectors. The technique examines how these inputs and outputs can be matched to the total resources available in the economy.

match up the inputs and outputs of each industry so that the planned demand for each industry's product is equal to its planned supply.

- It plans the distribution of output between consumers. This will depend on the government's aims. It may distribute goods according to its judgement of people's needs; or it may give more to those who produce more, thereby providing an incentive for people to work harder. It may distribute goods and services directly (for example, by a system of rationing); or it may decide the distribution of money incomes and allow individuals to decide how to spend them. If it does the latter, it may still seek to influence the pattern of expenditure by setting appropriate prices: low prices to encourage consumption, and high prices to discourage consumption.

Assessment of the command economy

With central planning, the government could take an overall view of the economy. It could direct the nation's resources in accordance with specific national goals.

High growth rates could be achieved if the government directed large amounts of resources into investment. Unemployment could be largely avoided if the government carefully planned the allocation of labour in accordance with production requirements and labour skills. National income could be distributed more equally or in accordance with needs. The social repercussions of production and consumption (e.g. the effects on the environment) could be taken into account, provided the government was able to predict these effects and chose to take them into account.

In practice, a command economy could achieve these goals only at considerable social and economic cost. The reasons are as follows:

- The larger and more complex the economy, the greater the task of collecting and analysing the information essential to planning, and the more complex the plan. Complicated plans are likely to be costly to administer and involve cumbersome bureaucracy.

- If there is no system of prices, or if prices are set arbitrarily by the state, planning is likely to involve the inefficient use of resources. It is difficult to assess the relative efficiency of two alternative techniques that use different inputs if there is no way in which the value of those inputs can be ascertained. For example, how can a rational decision be made between an oil-fired and a coal-fired furnace if the prices of oil and coal do not reflect their relative scarcity?
- It is difficult to devise appropriate incentives to encourage workers and managers to be more productive without a reduction in quality. For example, if bonuses are given according to the quantity of output produced, a factory might produce shoddy goods, since it can probably produce a larger quantity of goods by cutting quality. To avoid this problem, a large number of officials may have to be employed to check quality.
- Complete state control over resource allocation would involve a considerable loss of individual liberty. Workers would have no choice where to work; consumers would have no choice what to buy.
- If production is planned, but consumers are free to spend money incomes as they wish, there will be a problem if the wishes of consumers change. Shortages will occur if consumers decide to buy more; surpluses will occur if they decide to buy less.

Most of these problems were experienced in the former Soviet Union and the other Eastern bloc countries, and were part of the reason for the overthrow of their communist regimes (see Box 1.4).

The free-market economy

Free decision making by individuals

In a free market, individuals are free to make their own economic decisions. Consumers are free to decide what to buy with their incomes: free to make demand decisions. Firms are free to choose what to sell and what production methods to use: free to make supply decisions. The demand and supply decisions of consumers and firms are transmitted to each other through their effect on prices: through the **price mechanism**. The prices that result are the prices that firms and consumers have to accept.

The price mechanism

The price mechanism works as follows. Prices respond to shortages and surpluses. Shortages result in prices rising. Surpluses result in prices falling. Let us take each in turn.

If consumers want more of a good (or if producers decide to cut back supply), demand will exceed supply. The resulting shortage will cause the price of the good to rise. This will act as an incentive to producers to supply more, since production will now be more profitable. At the same time it will discourage consumers from buying so much. *The price will continue rising until the shortage has been eliminated.*

If, on the other hand, consumers decide they want less of a good (or if producers decide to produce more), then supply will exceed demand. The resulting surplus will cause the price of the good to fall. This will act as a disincentive to producers, who will supply less, since production will now be less profitable. It will encourage consumers to buy more. *The price will continue falling until the surplus has been eliminated.*

This price, where demand equals supply, is called the **equilibrium price**. By **equilibrium** we mean a point of balance or a point of rest: in other words, a point towards which there is a tendency to move.

1. Try using the same type of analysis in the labour market to show what will happen if there is an increase in demand for labour. What is the 'price' of labour?
2. Can you think of any examples where prices and wages do not adjust very rapidly to a shortage or surplus? For what reasons might they not do so?

The response of demand and supply to changes in price illustrates a very important feature of how economies work: *people respond to incentives*. It is important, therefore, that incentives are appropriate and have the desired effect. This is the fifth of our 15 threshold concepts (see Chapter 2, page 50).

The effect of changes in demand and supply

How will the price mechanism respond to changes in consumer demand or producer supply? Patterns of consumer demand will change over time: for example, people may decide they want more fixed gear bikes and fewer mountain bikes. Likewise the pattern of supply changes: for example, changes in technology may allow the mass production of microchips at lower cost, while the production of hand-built furniture becomes relatively expensive.

In all cases of changes in demand and supply, the resulting changes in price act as both signals and incentives.

A change in demand. A rise in demand is signalled by a rise in price, which then acts as an incentive for supply to rise. The high price of these goods relative to their costs of production signals that consumers are willing to see resources diverted from other uses. This is just what firms do. They divert resources from goods with lower prices relative to

Definitions

Price mechanism The system in a market economy whereby changes in price in response to changes in demand and supply have the effect of making demand equal to supply.

Equilibrium price The price where the quantity demanded equals the quantity supplied: the price where there is no shortage or surplus.

Equilibrium A position of balance. A position from which there is no inherent tendency to move away.

BOX 1.4

COMMAND ECONOMIES

The rise and fall of planning

Russia

The Bolsheviks under the leadership of Lenin came to power in Russia with the October revolution of 1917. Communism was introduced and the market economy abolished.

Industries were nationalised; workers were told what jobs to do; food was taken from peasants to feed the towns; workers were allocated goods from distribution depots.

With the ending of the civil war in 1921, the economy was in bad shape and Lenin embarked on the New Economic Policy. This involved a return to the use of markets. Smaller businesses were returned to private hands and peasants were able to sell their crops. The economy began to recover; however Lenin died in 1924 and Stalin came to power.

The Russian economy underwent a radical transformation from 1928 onwards. The key features of the Stalinist approach were collectivisation, industrialisation and central planning. Peasant farms were abolished and replaced by large-scale collective farms where land was collectively owned and worked, and by state farms, owned by the state and run by managers. This caused disruption and famine, with peasants slaughtering their animals rather than giving them up. However, in the longer term more food was produced. Both collective and state farms were given quotas of output that they were supposed to deliver, for which the state would pay a fixed price.

Alongside the agricultural reforms a drive to industrialisation took place and a vast planning apparatus was developed. At the top was *Gosplan*, the central planning agency. This prepared five-year plans, which specified the general direction in which the economy was to move, and annual plans, which gave details of what was to be produced and with what resources for some 200 or so key products. The system operated without either the price mechanism or the profit motive, although incentives existed with bonuses paid to managers and workers if targets were achieved.

Stalin died in 1953, but the planning system remained largely unchanged throughout the Soviet Union until the late 1980s. Initially, high growth rates had been achieved, though at a cost of low efficiency. Poor flows of information led to inconsistencies in the plans. Targets were often unrealistic,

and as a result there were frequent shortages and sometimes surpluses. There was little product innovation and goods were frequently of poor quality. A large 'underground economy' flourished in which goods were sold on the illegal market and in which people did second 'unofficial' jobs.

Moves to the market

By the time Gorbachev came to power in 1985 many people were pressing for economic reform. Gorbachev responded with his policy of *perestroika* (economic reconstruction), which involved managers preparing their own plans and managers and workers being rewarded for becoming more efficient. Under the new system, one-person businesses and larger co-operatives were allowed, while the price mechanism was reintroduced with the state raising prices if there were substantial shortages.

These reforms, however, did not halt the economic decline. Managers resented the extra responsibilities and people were unclear as to what to expect from the state. Queues lengthened in the shops and people became disillusioned with *perestroika*.

Communism fell apart in 1989 and both the Soviet Union and the system of central planning came to an end. Russia embarked upon a radical programme of market reforms in which competition and enterprise were intended to replace state central planning (see Case Studies 1.5, Free-market medicine in Russia; 14.9, Privatisation in transition economies; and 14.10, Forms of transition in transition countries, on the student website).

Initially, the disruption of the move to the market led to a sharp decline in the Russian economy. GDP fell by an average of 5.5 per cent per annum between 1993 and 1998. This was followed by a period of rapid economic growth, which averaged 7 per cent from 2000 to 2008. But the economy declined by nearly 8 per cent in the 2009 recession. Although this was followed by growth rates of 4.5 and 4.3 per cent in 2010 and 2011, since then growth has been around 2 per cent. Many commentators point to decades of underinvestment in industry and in road and rail infrastructure, corruption, disillusionment and continuing political uncertainty as root causes of this sluggish growth rate. From 2014, the economy was further dampened by Western

costs (and hence lower profits) to those goods that are more profitable.

A fall in demand is signalled by a fall in price. This then acts as an incentive for supply to fall. The goods are now less profitable to produce.

A change in supply. A rise in supply is signalled by a fall in price. This then acts as an incentive for demand to rise. A fall in supply is signalled by a rise in price. This then acts as an incentive for demand to fall.

The fact that markets adjust so as to equate demand and supply is our fourth 'Threshold Concept', which is discussed in Chapter 2, page 47.

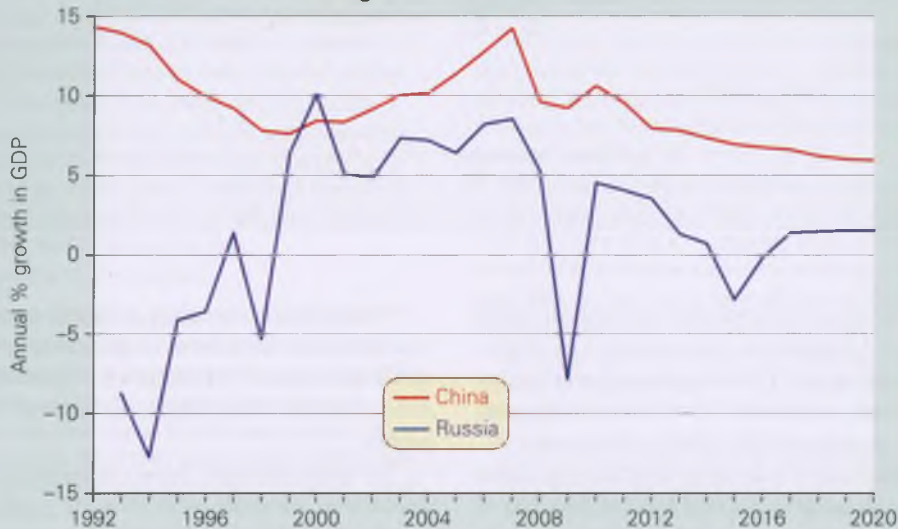

Changes in demand or supply cause markets to adjust. Whenever such changes occur, the resulting 'disequilibrium' will bring an automatic change in prices, thereby restoring equilibrium (i.e. a balance of demand and supply).

1. Why do the prices of fresh vegetables fall when they are in season? Could an individual farmer prevent the price falling?
2. If you were the manager of a supermarket, how would you set about deciding what prices to charge for food approaching its sell-by date?
3. Demand for downloaded music has grown rapidly, yet the prices of downloads have fallen. Why?

Economic growth in China and Russia

Note: Figures from 2017 based on forecasts.

Source: Data drawn from World Economic Outlook Database (IMF, April 2017).

economic sanctions in response to Russia's annexation of Crimea and the continuing conflict in Eastern Ukraine. Russia went into recession in 2015, but rebounded in 2017.

China

In contrast to the Soviet Union, China's move towards a more market-based economy has been carefully managed by the ruling Communist Party. From the 1940s to the 1970s central planning, combined with the removal of all property rights, resulted in low productivity, a creaking infrastructure and famine.

But after the death of Party Chairman Mao Zedong in 1976, a new breed of Chinese leaders came to power, and they were increasingly pragmatic. There was a focus on making use of aspects of capitalism alongside government control of the economy. Productivity was valued equally with political stability, while consumer welfare was considered as important as the elimination of unemployment. Economic zones were set

up, where foreign investment was encouraged, and laws on patents and other intellectual property encouraged innovation. This approach was developed further over the following decades and from 1992 to 2010 China averaged growth of 10.5 per cent per annum – the highest in the world.

Today, China is the world's second largest economy and, although growth has slowed somewhat to around 6.5 per cent, is poised to overtake the USA by 2020 albeit with much lower output *per head*. Yet its human rights record remains a concern to many around the world; economic liberalisation and growth have not been accompanied by political freedom. Furthermore, it is experiencing some of the problems of capitalism: pollution, income inequality and potential instability of the financial system. It remains unclear how long the combination of capitalist economics alongside tight political control can continue to deliver.

The interdependence of markets

The interdependence of goods and factor markets. A rise in demand for a good will raise its price and profitability. Firms will respond by supplying more. But to do this they will need more inputs. Thus the demand for the inputs (factors of production) will rise, which in turn will raise the price of the inputs. The suppliers of inputs will respond to this incentive by supplying more. This can be summarised as follows:

1. Goods market

- Demand for the good rises.
- This creates a shortage.

- This causes the price of the good to rise.
- This eliminates the shortage by reducing demand and encouraging firms to produce more.

2. Factor market

- The increased supply of the good causes an increase in the demand for factors of production (i.e. inputs) used in making it.
- This causes a shortage of those inputs.
- This causes their prices to rise.
- This eliminates their shortage by reducing demand and encouraging the suppliers of inputs to supply more.

Figure 1.7 The price mechanism: the effect of a rise in demand

So changes in goods markets will lead to changes in factor markets. Figure 1.7 summarises this sequence of events, where the subscripts 'g' and 'f' refer to the good and the factors used in making it respectively. (It is common in economics to summarise an argument like this by using symbols.)

Interdependence exists in the other direction too: factor markets affect goods markets. For example, the discovery of raw materials will lower their price. This will lower the costs of production of firms using these raw materials and will increase the supply of the finished goods. The resulting surplus will lower the price of the good, which will encourage consumers to buy more.

? Summarise this last paragraph using symbols like those in Figure 1.7.

The interdependence of different goods markets. A rise in the price of one good will encourage consumers to buy alternatives. This will drive up the price of alternatives. This in turn will encourage producers to supply more of the alternatives.

? Are different factor markets similarly interdependent? What would happen if the price of capital equipment rose?

Conclusion

Even though all individuals are merely looking to their own self-interest in the free-market economy, they are in fact being encouraged to respond to the wishes of others through the incentive of the price mechanism. (See Case Study 1.4, The interdependence of markets, on the student website; see also Box 1.5.)

Assessment of the free-market economy

The fact that a free-market economy functions automatically is one of its major advantages. There is no need for costly and complex bureaucracies to co-ordinate economic decisions. The economy can respond quickly to changing demand and supply conditions.

When markets are highly competitive, no one has great power. Competition between firms keeps prices down and acts as an incentive for efficiency. The more firms there are competing, the more responsive they will be to consumer wishes.

The more efficiently firms can combine their factors of production, the more profit they will make. The more efficiently workers work, the higher their wages are likely to be. The more carefully consumers decide what to buy, the greater the value for money they will receive.

Thus people pursuing their own self-interest through buying and selling in competitive markets helps to minimise the central economic problem of scarcity, by encouraging the efficient use of society's resources in line with consumer wishes. From this type of argument, the following conclusion is often drawn by defenders of the free market: 'The pursuit of private gain results in the social good.' This claim is the subject of much debate and has profound moral implications (see Threshold Concept 2).

Problems of the free market

In practice, however, markets do not achieve maximum efficiency in the allocation of scarce resources, and governments therefore feel it necessary to intervene to rectify this and other problems of the free market. The problems of a free market include:

- Power and property may be unequally distributed. Those who have power and/or property (e.g. big business, unions and landlords) will gain at the expense of those without power and property.
- Competition between firms is often limited. A few firms may dominate an industry, charging high prices and making large profits.
- Consumers and firms may not have full information about the costs and benefits associated with different goods and factor inputs and may thus make the wrong decisions.
- Rather than responding to consumer wishes, firms may attempt to persuade consumers by advertising.

BOX 1.5

ADAM SMITH (1723–90)

EXPLORING ECONOMICS

The 'invisible hand' of the market

Many economists would argue that modern economics dates from 1776, the year in which Adam Smith's *An Inquiry into the Nature and Causes of the Wealth of Nations* was published – one of the most important books on economics ever written.

The work, in five books, is very wide-ranging, but the central argument is that market economies generally serve the public interest well. Markets guide production and consumption like an *invisible hand*. Even though everyone is looking after their own private self-interest, their interaction in the market will lead to the social good.

In book I, chapter 2, Smith writes:

Man has almost constant occasion for the help of his brethren and it is in vain for him to expect it from their benevolence only . . . It is not from the benevolence of the butcher, the brewer, or the baker that we expect our dinner, but from their regard to their own interest. We address ourselves, not to their humanity but to their self-love, and never talk to them of our own necessities, but of their advantages.

Later, in book IV, chapter 2, he continues:

Every individual is continually exerting himself to find out the most advantageous employment of whatever capital he can command. It is his own advantage, indeed, and not that of the society, which he has in view. But the study of his own advantage naturally, or rather necessarily, leads him to prefer that employment which is most advantageous to the society . . . he intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. Nor is it always the worse for the society that it

was no part of it. By pursuing his own interest he frequently promotes that of society more effectually than when he really intends to promote it.

He argued, therefore, with one or two exceptions, that the state should not interfere with the functioning of the economy. It should adopt a *laissez-faire* or 'hands-off' policy. It should allow free enterprise for firms and free trade between countries.

This praise of the free market has led many on the political right to regard him as the father of the 'libertarian movement' – the movement that advocates the absolute minimum amount of state intervention in the economy (see Box 12.7 on page 388). In fact, one of the most famous of the libertarian societies is called the Adam Smith Institute.

But Smith was not blind to the drawbacks of unregulated markets. In book I, chapter 7, he looks at the problem of monopoly:

A monopoly granted either to an individual or to a trading company has the same effect as a secret in trade or manufactures. The monopolists, by keeping the market constantly under-stocked, by never fully supplying the effectual demand, sell their commodities much above the natural price, and raise their emoluments, whether they consist in wages or profit, greatly above their natural rate.

Later on he looks at the dangers of firms getting together to pursue their mutual interest:

People of the same trade seldom meet together, even for merriment or diversion, but the conversation ends in a conspiracy against the public or in some contrivance to raise prices.

- Lack of competition and high profits may remove the incentive for firms to be efficient.
- The practices of some firms may be socially undesirable. For example, a chemical works may pollute the environment.
- Some socially desirable goods would simply not be produced by private enterprise. Who would carry out counter-terrorism activities if this were not funded by governments?
- A free-market economy may lead to macroeconomic instability. There may be periods of recession with high unemployment and falling output, and other periods of rising prices.
- Finally, there is the ethical objection, that a free-market economy, by rewarding self-interested behaviour, may encourage selfishness, greed, materialism and the acquisition of power.

The fact that free markets may fail to meet various social objectives is Threshold Concept 3.

The mixed economy

Because of the problems of both free-market and command economies, all real-world economies are a mixture of the two systems.

In *mixed market economies*, the government may control the following:

- **Relative prices** of goods and inputs, by taxing or subsidising them or by direct price controls.
- Relative incomes, by the use of income taxes, welfare payments or direct controls over wages, profits, rents, etc.

Definitions

Mixed market economy A market economy where there is some government intervention.

Relative price The price of one good compared with another (e.g. good X is twice the price of good Y).

THRESHOLD CONCEPT 2

PEOPLE GAIN FROM VOLUNTARY ECONOMIC INTERACTION

THINKING LIKE AN ECONOMIST

Economic interaction between people can take a number of different forms. Sometimes it takes place in markets. For example, when goods are exchanged, there is interaction between the consumer and the shop. When someone is employed, there is interaction between the employer and the employee. When a firm buys raw materials, there is interaction between the purchasing firm and the selling firm.

In each case there is expected to be a mutual gain. If there wasn't, the interaction would not take place. If you go on a holiday costing £400, then assuming the holiday turns out as you expected, you will have gained. You would rather have the holiday than spend the £400 on something else. The marginal benefit to you exceeds the marginal cost. The travel agent and tour operator also gain. They make a profit on selling you the holiday. It is a 'win-win situation'. This is sometimes called a *positive sum game*: an interaction where there is a positive net gain.

Another example is international trade (the subject of Chapter 24). If two countries trade with each other, there will be a net gain to both of them. If there wasn't, they would not trade. Both countries will end up consuming a greater value of products than they could without trade. The reason is that each country can specialise in the products it is relatively good at producing (compared to the other country) and export them, and import from the other country the goods it is relatively poor at producing.

That there is a net gain from voluntary interaction is a *threshold concept* because realising this tends to change the way we look at economic activity. Often it is important to identify what these overall gains are so that we can compare them with alternative forms of interaction. For example, even though both workers and their employer respectively gain from the wages currently paid and the output currently produced, it might still be possible to reorganise the workforce in a way that increases production. This could allow the employer to pay higher wages and still gain an increase in profits. Both sides could thus gain from constructive negotiation about wages and new work practices.

Sometimes it may appear that voluntary interaction results in one side gaining and the other losing. For example, a firm may raise its price. It gains and the consumer loses. But is this strictly true? Consumers are certainly worse off than before, but as long as they are still prepared to buy the product, they must consider that they are still gaining more by buying it than by not. There is still a gain to both sides: it's just that the firm is gaining more and the consumer is gaining less.

1. *Would you ever swap things with friends if both of you did not gain? Explain your answer.*
2. *Give one or two examples of involuntary (i.e. compulsory) economic interaction, where one side gains but the other loses.*

THRESHOLD CONCEPT 3

MARKETS MAY FAIL TO MEET SOCIAL OBJECTIVES

THINKING LIKE AN ECONOMIST

We have seen that market forces can automatically equate demand and supply. The outcomes of the process may be desirable, but they are by no means always so. Unrestrained market forces can result in severe problems for individuals, society and the environment.

Markets tend to reflect the combined actions of individual consumers and firms. But when consumers and firms make their decisions, they may act selfishly and fail to take account of the broader effects of their actions. If people want to buy guns, market forces will make their supply profitable. If people want to drive fuel-hungry cars, then this will create the market for firms to supply them. Market forces are not kind and caring. They mechanically reflect human behaviour.

And it's not just selfish behaviour that markets reflect, but ignorance too. You may be unaware that a toy you buy for a child is dangerous, but by buying it, you encourage unscrupulous firms to supply them. A firm may not realise that a piece of machinery it uses is dangerous until an accident happens. In the meantime, it continues using it because it is profitable to do so.

If wages are determined purely by demand and supply, then some people, such as footballers and bankers, may be very well

paid. Others, such as cleaners and shop workers, may be very poorly paid. If the resulting inequality is seen as unfair, then market forces alone will not be enough to achieve a fair society.

Recognising the limitations and failings of markets is a *threshold concept*. It helps us to understand how laws or taxes or subsidies could be framed to counteract such failings. It helps us to relate the mechanical operation of demand and supply to a whole range of social objectives and ask whether the market system is the best way of meeting such objectives.

But to recognise market failures is only part of the way to finding a solution. Can the government put things right, and if so, how? Or do the limitations of government mean that the solution is sometimes worse than the problem? We examine these issues in many parts of the book. We set the scene in Threshold Concept 7 on page 81.

1. *If global warming affects all of us adversely, why in a purely market economy would individuals and firms continue with activities that contribute towards global warming?*
2. *In what ways do your own consumption patterns adversely affect other people?*

- The pattern of production and consumption, by the use of legislation (e.g. making it illegal to produce unsafe goods), by direct provision of goods and services (e.g. education and defence) or by taxes and subsidies.
- The macroeconomic problems of unemployment, inflation, lack of growth, balance of trade deficits and exchange rate fluctuations, by the use of taxes and government expenditure, the control of bank lending and

interest rates, the direct control of prices and the control of foreign exchange rates.

The fact that government intervention can be used to rectify various failings of the market is Threshold Concept 7 (see Chapter 3, page 81). It is important to realise, however, that government actions may bring adverse as well as beneficial consequences. For more on government intervention in the mixed economy see Chapters 11 to 14.

TC 7
p81

Section summary

1. The economic systems of different countries vary according to the extent to which they rely on the market or the government to allocate resources.
2. At the one extreme, in a command economy, the state makes all the economic decisions. It plans amounts of resources to allocate for present consumption and amounts for investment for future output. It plans the output of each industry, the methods of production it will use and the amount of resources it will be allocated. It plans the distribution of output between consumers.
3. A command economy has the advantage of being able to address directly various national economic goals, such as rapid growth and the avoidance of unemployment and inequality. A command economy, however, is likely to be inefficient and bureaucratic; prices and the choice of production methods are likely to be arbitrary; incentives may be inappropriate; shortages and surpluses may result.
4. At the other extreme is the free-market economy. In this economy, decisions are made by the interaction of demand and supply. Price changes act as the mechanism whereby demand and supply are balanced. If there is a shortage, price will rise until the shortage is eliminated. If there is a surplus, price will fall until that is eliminated.
5. A free-market economy functions automatically and if there is plenty of competition between producers this can help to protect consumers' interests. In practice, however, competition may be limited; there may be great inequality; there may be adverse social and environmental consequences; there may be macroeconomic instability.
6. In practice, all economies are some mixture of the market and government intervention. It is the degree and form of government intervention that distinguishes one type of economy from another.

1.3 THE NATURE OF ECONOMIC REASONING

Economics is one of the social sciences. So in what sense is it a *science*? Is it like the natural sciences such as physics and astronomy? What is the significance of the word 'social' in social science? What can economists do, and what is their role in helping governments devise economic policy?

Economics as a science

The methodology employed by economists has a lot in common with that employed by natural scientists. Both attempt to construct theories or **models** which are then used to *explain* and *predict*. An astronomer, for example, constructs models of planetary movements to *explain* why planets are in the position they are and to *predict* their position in the future.

Models in economics

In order to explain and predict, the economist constructs models which show simplified relationships between various economic phenomena. The simplification is deliberate – economists know their models look nothing like the real

world they hope to explain. It is referred to as abstraction. An example of a model is one showing the relationships between demand, supply and price of a product. Although most models can be described verbally, they can normally be represented more precisely in graphical or mathematical form.

Building models

Models are constructed by making general hypotheses about the causes of economic phenomena: for example, that consumer demand will rise when consumer incomes rise. These hypotheses will often be based on observations. This process of making general statements from particular observations is known as **induction**.

Definitions

Economic model A formal presentation of an economic theory.

Induction Constructing general theories on the basis of specific observations.

Using models

Explanation. Models explain by showing how things are caused: what the causes of inflation are, why workers in some industries earn more than others, and so on. A model is constructed to help explain a particular relationship or set of phenomena. An economic model might be really useful for one purpose but not very useful for another.

Prediction. Models are sometimes used to make simple forecasts: for example, inflation will be below 5 per cent next year. Usually, however, predictions are of the 'If... then...' variety: for example, if demand for good x rises, its price will rise. This process of drawing conclusions from models is known as **deduction**.

When making such deductions it has to be assumed that nothing else that can influence the outcome has changed in the meantime. For example, if demand for good x rises, its price will rise *assuming* the cost of producing good x has not fallen. This is known as the ***ceteris paribus*** assumption. *Ceteris paribus* is Latin for 'other things being equal'.

Assessing models

Models can be judged according to how successful they are in explaining and predicting. They are not judged by how closely they resemble the real world.

If the predictions are wrong, the first thing to do is to check whether the deductions were correctly made. If they were, the model must be either adapted or abandoned in favour of an alternative model with better predictive ability. But in economics, as with many other disciplines, academics are often unwilling to abandon their models. Instead they prefer the minimum adaptation necessary. This can lead to lively debates between different 'schools of thought', each claiming that their models paint a more accurate picture of the economy.

There has been a great deal of debate recently about why economic models failed to forecast the financial crisis of 2007–8. In September 2010, Ben Bernanke, the then Federal Reserve Board Chairman, said the failure of the economic models did not mean that they were irrelevant or significantly flawed. Rather than throwing out the models, more

work was needed to capture how the financial system impacts on growth and stability. Some people argued that the models were simply misused: i.e. used for a purpose they were not designed for. John Kay argued it was like using a London Underground map to work out the best walking route!²

Others disagreed. They claimed that many of the main models that had failed to predict the crisis were fundamentally flawed and needed replacing with other models – perhaps amended versions of older ones; perhaps new ones.

We look at these debates in Parts E and F of the book.

Economists as detectives

Because of a lack of conclusive evidence about just how many parts of the economy function, economists also need the skills of detectives. This involves a third type of reasoning (in addition to induction and deduction), known as **abduction**. This involves making informed guesses or estimates from limited evidence. It is using the scraps of evidence as clues to what might be really going on. It is how many initial hypotheses are formed. Then the researcher (or detective) will use the clues to search for more evidence that can be used for induction that will yield a more robust theory. The clues may lead to a false trail, but sometimes they may allow the researcher to develop a new theory or amend an existing one. A good researcher will be alert to clues; to seeing patterns in details that might previously have been dismissed or gone unnoticed.

Before the banking crisis of 2007–8 and the subsequent credit crunch and recession in the developed world, many

Definitions

Deduction Using a theory to draw conclusions about specific circumstances.

Ceteris paribus Latin for 'other things being equal'. This assumption has to be made when making deductions from theories.

Abduction Using pieces of evidence to develop a plausible explanation. This can then be tested by gathering more evidence.

BOX 1.6

CETERIS PARIBUS

CASE STUDIES AND APPLICATIONS

Because of the complexities of the real world, economic models have to make various simplifying assumptions. Sometimes, however, economists are criticised for making unrealistic assumptions, assumptions that make their models irrelevant. The following joke illustrates the point.

There were three people cast away on a desert island: a chemist, an engineer and an economist. There was no food on the island and their plight seemed desperate.

Then they discovered a crate of canned food that had been washed up on the island. When they realised that they had no

means of opening the cans, they decided that each of them should use their expertise to find a solution.

The chemist searched around for various minerals that could be heated up to produce a compound that would burn through the lids of the cans.

The engineer hunted around for rocks and then worked out what height of tree they would have to be dropped from in order to smash open the cans.

Meanwhile the economist sat down and thought 'Assuming we had a can opener...'

economists were picking up clues and trying to use them to develop a theory of systemic risk in financial markets. They were using the skills of an economic detective to try to discover not only what was currently going on but also what might be the consequences for the future. Some used abductive reasoning successfully to predict the impending crisis; most did not.

Economics as a social science

Economics concerns human behaviour. One problem here is that individuals often behave in very different ways. People have different tastes and different attitudes. This problem, however, is not as serious as it may seem at first sight. The reason is that people *on average* are likely to behave more predictably. For example, if the price of a product goes up by 5 per cent, we might be able to predict, *ceteris paribus*, that the quantity demanded will fall by approximately 10 per cent. This does not mean that every single individual's demand will fall by 10 per cent, only that *total* demand will. Some people may demand a lot less; others may demand the same as before.

Even so, there are still things about human behaviour that are very difficult to predict, even when we are talking about whole groups of people. How, for example, will firms react to a rise in interest rates when making their investment decisions? This will depend on things such as the state of business confidence, something that is notoriously difficult to predict. How will a business respond to price changes by its rivals? This will often depend on how it thinks its rivals themselves will react to its own response. How will people respond to a crisis, such as the global banking and credit crisis of 2007–8? This depends very much on the mood of financial and other companies and individuals. A mood of pessimism (or optimism for that matter) can quickly spread, but not to a degree that is easily predictable.

For these reasons there is plenty of scope for competing models in economics, each making different assumptions and leading to different policy conclusions. As a result, economics can often be highly controversial. As we shall see later on in the book, different political parties may adhere to different schools of economic thought. Thus the political left may adhere to a model which implies that governments must intervene if unemployment is to be cured, whereas the political right may adhere to a model which implies that unemployment will be reduced if the government intervenes less and relies more on the free market.

One branch of economics that has seen considerable growth in recent years is behavioural economics, which adds elements of psychology to traditional models in an attempt to gain a better understanding of decision making by investors, consumers and other economic participants. Much of the early evidence in support of behavioural economics came from laboratory experiments where people made decisions in simulated environments – normally a computer room. More recent evidence has come from field

experiments, where people make decisions in a more natural environment and do not know their behaviour is being observed. For more on behavioural economics see Chapters 4, 5, 9, 10, 13 and 14.

The fact that there are different economic theories does not mean that economists always disagree. Despite the popular belief that 'if you laid all the economists of the world end to end they would still not reach a conclusion', there is in fact a large measure of agreement between economists about how to analyse the world and what conclusions to draw.

Economics and policy

Economists play a major role in helping governments to devise economic policy. In order to understand this role, it is necessary to distinguish between 'positive' and 'normative' statements.

A **positive statement** is a statement of fact. It may be right or wrong, but its accuracy can be tested by appealing to the facts. 'Unemployment is rising', 'Inflation will be over 6 per cent by next year' and 'If the government cuts taxes, imports will rise' are all examples of positive statements.

A **normative statement** is a statement of value: a statement about what ought or ought not to be, about whether something is good or bad, desirable or undesirable. 'It is right to tax the rich more than the poor', 'The government ought to reduce inflation' and 'State pensions ought to be increased' are all examples of normative statements. They cannot be proved or disproved by a simple appeal to the facts.

Economists can only contribute to questions of policy in a positive way. That is, they can analyse the consequences of following certain policies. They can say which of two policies is more likely to achieve a given aim, but they should not, as economists, say whether the aims of the policy are desirable. For example, economists may argue that a policy of increasing government expenditure will reduce unemployment and raise inflation, but they cannot, as economists, decide whether such a policy is desirable.

The importance of the positive/normative distinction

Economics can only contribute to policy issues in a positive way. Economists, as scientists, should not make normative judgements. They can make them only as individual people, with no more moral right than any other individual.

Definitions

Positive statement A value-free statement which can be tested by an appeal to the facts.

Normative statement A value judgement.

Which of the following are positive statements and which are normative?

- (a) Cutting the higher rates of income tax will redistribute incomes from the poor to the rich.
 (b) It is wrong that inflation should be targeted if the consequence is higher unemployment.

- (c) It is incorrect to state that putting up interest rates will reduce inflation.
 (d) The government should introduce road pricing to address the issue of congestion.
 (e) Current government policies should be aimed at reducing the deficit rather than stimulating growth.

Section summary

- The methodology used by economists is similar to that used by natural scientists. Economists construct models, which they use to explain and predict economic phenomena. These models can be tested by appealing to facts and seeing how successfully they have been predicted or explained by the model. Unsuccessful models can be either abandoned or amended.
- Being a social science, economics is concerned with human actions. Making accurate predictions in economics is very difficult given that economics has to deal with a constantly changing environment.
- Economists can help governments to devise policy by examining the consequences of alternative courses of action. In doing this, it is important to separate positive questions about what the effects of the policies are from normative ones as to what the goals of policy should be. Economists in their role as economists have no superior right to make normative judgements. They do, however, play a major role in assessing whether a policy meets the political objectives of government (or opposition).

END OF CHAPTER QUESTIONS

1. Imagine that a country can produce just two things: goods and services. Assume that over a given period it could produce any of the following combinations:

Units of goods

0	10	20	30	40	50	60	70	80	90	100
---	----	----	----	----	----	----	----	----	----	-----

Units of services

80	79	77	74	70	65	58	48	35	19	0
----	----	----	----	----	----	----	----	----	----	---

- Draw the country's production possibility curve.
 - Assuming that the country is currently producing 40 units of goods and 70 units of services, what is the opportunity cost of producing another 10 units of goods?
 - Explain how the figures illustrate the principle of increasing opportunity cost.
 - Now assume that technical progress leads to a 10 per cent increase in the output of goods for any given amount of resources. Draw the new production possibility curve. How has the opportunity cost of producing extra units of services altered?
2. Imagine that you won millions of pounds on the National Lottery. Would your 'economic problem' be solved?
- Assume that in a household one parent currently works full-time and the other stays at home to look after the family. How would you set about identifying and calculating the opportunity costs of the second parent now taking a full-time job? How would such calculations be relevant in deciding whether it is worth taking that job?
 - When you made the decision to study economics, was it a 'rational' decision (albeit based on the limited information you had available at the time)? What additional information would you like to have had in order to ensure that your decision was the right one?
 - In what way does specialisation reduce the problem of scarcity?
 - Would redistributing incomes from the rich to the poor reduce the overall problem of scarcity?
 - Assume that fracking becomes common across the UK. The result is that supplies of shale gas and oil increase sharply. Trace through the effects of this on the market for oil, gas and the market for other fuels.
 - Give two examples of positive statements about the economy, and two examples of normative ones. Now give two examples that are seemingly positive, but which have normative implications or undertones.

Foundations of Microeconomics

2 Supply and Demand 34

3 Government and the Market 79

In the first half of the book, we focus on microeconomics. Despite being ‘small economics’ – in other words, the economics of the individual parts of the economy, rather than the economy as a whole – it is still concerned with many of the big issues of today. To understand how the economy works at this micro level, we must understand how markets work. This involves an understanding of demand and supply.

In Chapter 2, we look at how demand and supply interact to determine prices (and so allocate resources) in a free-market economy. We will also see just how responsive they are to changing circumstances.

Markets, however, are not always free: governments frequently intervene in markets. In Chapter 3, we look at some of the reasons why governments may choose to reject the free market and examine the methods they use to influence prices, output and allocation.

We look at markets, their efficiency and government intervention in more detail in Parts C and D.

Price expectations and speculation	70
Dealing with uncertainty and risk	73

As we saw in Chapter 1, in a free-market economy prices play a key role in transmitting information from buyers to sellers and from sellers to buyers. This chapter examines this 'price mechanism' in more detail.

We examine what determines demand, what determines supply and what the relationship is between demand, supply and price. We see how the price mechanism transmits information both from consumers to producers, and from producers to consumers; and how prices act as incentives – for example, if consumers want more European city breaks, how this increased demand leads to an increase in their price and hence to an incentive for firms to increase their production.

What we will see is the mechanism whereby the free market responds to changes in demand or supply – and responds in a way that balances demand and supply at a position of 'equilibrium'.

But we will also need to see just how much prices and output respond to changes in demand and supply. How much will the demand for music downloads go up if their price comes down? How much will the supply of new houses go up if the price of houses rises? In section 2.4 we develop the concept of elasticity of demand and supply to examine this responsiveness.

Finally, we look at how quickly markets adjust and also examine how people's expectations of price changes affect what actually happens to prices. In particular, we look at speculation – people attempting to gain from anticipated price changes.

The markets we will be examining are highly competitive ones, with many firms competing against each other. In economics we call this *perfect competition*. This is where consumers and producers are too numerous to have any control over prices: they are *price takers*.

In the case of consumers, this means that they have to accept the prices as given for the things that they buy. On most occasions this is true; when you get to the supermarket checkout you cannot start haggling with the checkout operator over the price of a can of beans or a tub of ice cream.

In the case of firms, perfect competition means that producers are small and face too much competition from other firms to be able to raise prices. Take the case of foreign exchange traders selling euros. They have to sell the currency at the current market price. If individually they try to sell at a higher price, no one will buy, since purchasers of currency can get all the euros they want at the market price.

Of course, many firms *do* have the power to choose their prices. This does not mean that they can simply charge whatever they like. They will still have to take account of overall consumer demand and their competitors' prices. Hewlett-Packard (HP), when setting the price of its laptop

computers, will have to ensure that they remain competitive with those produced by Dell, Toshiba, Lenovo, etc. Nevertheless, most firms have some flexibility in setting their prices: they have a degree of 'market power'.

If this is the case, then why do we study *perfect markets*, where firms are price takers? One reason is that they provide a useful approximation to the real world and give us many insights into how a market economy works. Many markets, such as those in agriculture and finance, do function very similarly to those we shall be describing.

Another is that perfect markets provide an ideal against which to compare the real world, since in perfect markets we see resources being used and allocated efficiently. Economists can therefore use them as a benchmark when comparing the prices, output, profit, etc. in different types of market. For example, will the consumer end up paying higher prices in a market dominated by just a few firms than in one operating under perfect competition? Will Sky respond to an increase in demand for television services in the same way as a farmer does to an increase in the demand for cauliflowers?

Markets with powerful firms are examined in Chapters 7 and 8. For now we concentrate on price takers.

2.1 DEMAND

The relationship between demand and price

The headlines announce 'Major crop failures in Brazil and East Africa: coffee prices soar'. Shortly afterwards you find that coffee prices have increased sharply in the shops. What do you do? You will probably cut back on the amount of coffee you drink. Perhaps you will reduce it from, say, six cups per day to four. Perhaps you will give up drinking coffee altogether.

This is simply an illustration of the general relationship between price and consumption: *when the price of a good rises, the quantity demanded will fall*. This relationship is known as the *law of demand*. There are two reasons for this law:

- People will feel poorer. They will not be able to afford to buy as much of the good with their money.

The purchasing power of their income (their *real income*) has fallen. This is called the *income effect* of a price rise.

- The good will now cost more than alternative or 'substitute' goods, and people will switch to these. This is called the *substitution effect* of a price rise.

Similarly, when the price of a good falls, the quantity demanded will rise. People can afford to buy more (the income effect), and they will switch away from consuming alternative goods (the substitution effect).

Therefore, returning to our example of the increase in the price of coffee, we will not be able to afford to buy as much as before, and we will probably drink more tea, cola, fruit juices or even water instead.

Definitions

Perfect competition (preliminary definition) A situation where the consumers and producers of a product are price takers. (There are other features of a perfectly competitive market; these are examined in Chapter 7.)

Price taker A person or firm with no power to be able to influence the market price.

Law of demand The quantity of a good demanded per period of time will fall as price rises and will rise as price falls, other things being equal (*ceteris paribus*).

Income effect The effect of a change in price on quantity demanded arising from the consumer becoming better or worse off as a result of the price change.

Substitution effect The effect of a change in price on quantity demanded arising from the consumer switching to or from alternative (substitute) products.

The income and substitution effects are useful concepts as they help to explain why people react to a price rise by buying less. The size of these effects depends on a range of factors. These factors determine the shape of the demand curve.

A word of warning: be careful about the meaning of the words **quantity demanded**. They refer to the amount that consumers are willing and able to purchase at a given price over a given period (e.g. a week, or a month, or a year). They do not refer to what people would simply *like* to consume. You might like to own a luxury yacht, but your demand for luxury yachts will almost certainly be zero at the current price. Quantity demanded may also be different from the quantity actually purchased. A consumer may be willing and able to purchase the good but cannot find a supplier willing to sell at that price.

The demand curve

Consider the hypothetical data in Table 2.1, which shows how many kilograms of potatoes per month would be purchased at various prices.

Columns (2) and (3) show the **demand schedules** for two individuals, Kate and Simon. Column (4) shows the total **market demand schedule**. This is the total demand by all consumers. To obtain the market demand schedule for potatoes, we simply add up the quantities demanded at each price

by *all* consumers: i.e. Kate, Simon and everyone else who demands potatoes. Notice that we are talking about demand *over a period of time* (not at a point in time). Thus we could talk about daily demand or weekly demand or annual demand.

Assume that there are 200 consumers in the market. Of these, 100 have schedules like Kate's and 100 have schedules like Simon's. What would be the total market demand schedule for potatoes now?

The demand schedule can be represented graphically as a **demand curve**. Figure 2.1 shows the market demand curve for potatoes corresponding to the schedule in Table 2.1. The price of potatoes is plotted on the vertical axis. The quantity demanded is plotted on the horizontal axis.

Point *E* shows that at a price of 100p per kilo, 100 000 tonnes of potatoes are demanded each month. When the price falls to 80p we move down the curve to point *D*. This shows that the quantity demanded has now risen to 200 000 tonnes per month. Similarly, if the price falls to 60p we move down the curve again to point *C*: 350 000 tonnes are now demanded. The five points on the graph (*A–E*) correspond to the figures in columns (1) and (4) of Table 2.1. The graph also enables us to read off the likely quantities demanded at prices other than those in the table.

- How much would be demanded at a price of 30p per kilogram?
- Assuming that demand does not change from month to month, plot the annual market demand for potatoes.

Table 2.1 The demand for potatoes (monthly)

	Price (pence per kg) (1)	Kate's demand (kg) (2)	Simon's demand (kg) (3)	Total market demand (tonnes: 000s) (4)
<i>A</i>	20	28	16	700
<i>B</i>	40	15	11	500
<i>C</i>	60	5	9	350
<i>D</i>	80	1	7	200
<i>E</i>	100	0	6	100

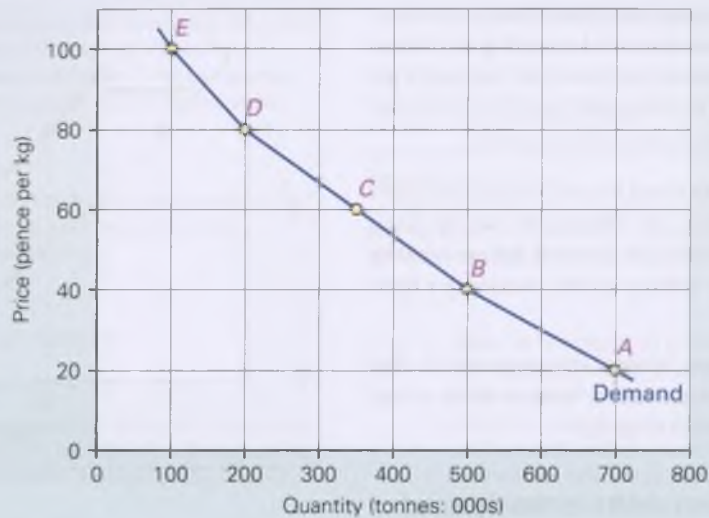

Definitions

Quantity demanded The amount of a good that a consumer is willing and able to buy at a given price over a given period of time.

Demand schedule for an individual A table showing the different quantities of a good that a person is willing and able to buy at various prices over a given period of time.

Market demand schedule A table showing the different total quantities of a good that consumers are willing and able to buy at various prices over a given period of time.

Demand curve A graph showing the relationship between the price of a good and the quantity of the good demanded over a given time period. Price is measured on the vertical axis; quantity demanded is measured on the horizontal axis. A demand curve can be for an individual consumer or group of consumers, or more usually for the whole market.

Figure 2.1 Market demand curve for potatoes (monthly)

A demand curve could also be drawn for an individual consumer. Like market demand curves, individuals' demand curves generally slope downwards from left to right: they have negative slope. The lower the price of the product, the more a person is likely to buy.

1. Draw Kate's and Simon's demand curves for potatoes on one diagram. Note that you will use the same vertical scale as in Figure 2.1, but you will need a quite different horizontal scale.
2. At what price is their demand the same?
3. What explanations could there be for the quite different shapes of their two demand curves? (This question is explored in section 3.1 below.)
4. Assume that Kate and Simon are the only two consumers in the market. Show how the market demand curve can be derived from their individual demand curves.

Two points should be noted at this stage:

- In textbooks, demand curves (and other curves too) are only occasionally used to plot specific data. More frequently they are used to illustrate general theoretical arguments. In such cases the axes will simply be price and quantity, with the units unspecified.
- The term 'curve' is used even when the graph is a straight line. In fact when using demand curves to illustrate arguments we frequently draw them as straight lines – it's easier.

Other determinants of demand

Price is not the only factor that determines how much of a good people will buy. Demand is also affected by the following.

Tastes. The more desirable people find the good, the more they will demand. Tastes are affected by advertising, by trends and fashion, by observing other consumers, by considerations of health and by the experience of consuming the good on previous occasions. For example, the recent fashion for men to grow beards has had a negative impact on the demand for razors.

The number and price of substitute goods (i.e. competitive goods). The higher the price of **substitute goods**, the higher will be the demand for this good as people switch from the substitutes. For example, the demand for e-cigarettes will be influenced by the price of cigarettes. If the price of cigarettes increases, the demand for e-cigarettes will rise.

The number and price of complementary goods. **Complementary goods** are those that are consumed together; cars and petrol, paper and ink cartridges, fish and chips. The higher the price of complementary goods, the fewer of them will be bought and hence the less will be the demand for the good under consideration. For example, the demand for games will depend on the price of games consoles, such as the Sony PlayStation® and Microsoft Xbox®. If the price of games

Definitions

Substitute goods A pair of goods which are considered by consumers to be alternatives to each other. As the price of one goes up, the demand for the other rises.

Complementary goods A pair of goods consumed together. As the price of one goes up, the demand for both goods will fall.

consoles comes down, so that more are purchased, the demand for games will rise.

Income. As people's incomes rise, their demand for most goods will rise. Such goods are called **normal goods**. There are exceptions to this general rule, however. As people get richer, they spend less on **inferior goods**, such as supermarket 'value' ranges, and switch to better quality goods.

Distribution of income. If national income were redistributed from the poor to the rich, the demand for luxury goods would rise. At the same time, as the poor got poorer they might have to buy more inferior goods; demand for these would rise too.

Expectations of future price changes. If people think that prices are going to rise in the future, they are likely to buy more now before the price does go up.

Movements along and shifts in the demand curve

A demand curve is constructed on the assumption that 'other things remain equal' (*ceteris paribus*). In other words, it is assumed that none of the determinants of demand, other than price, changes. The effect of a change in price is then simply illustrated by a movement along the demand curve: for example, from point *B* to point *D* in Figure 2.1 when the price of potatoes rises from 40p to 80p per kilo.

What happens, then, when one of these other determinants does change? The answer is that we have to construct a whole new demand curve: the curve shifts. If a change in one of the other determinants causes demand to rise – say, income rises – the whole curve will shift to the right. This shows that at each price more will be demanded than before. Thus, in Figure 2.2, at a price of *P*, a quantity of Q_0 was originally demanded. But now, after the increase in demand, Q_1 is demanded. (Note that D_1 is not necessarily parallel to D_0 .)

If a change in a determinant other than price causes demand to fall, the whole curve will shift to the left.

To distinguish between shifts in and movements along demand curves, it is usual to distinguish between a change in *demand* and a change in the *quantity demanded*. A shift in the demand curve is referred to as a **change in demand**, whereas a movement along the demand curve as a result of a change in price is referred to as a **change in the quantity demanded**.

1. Assume that in Table 2.1 the total market demand for potatoes increases by 20 per cent at each price – due, say, to substantial increases in the prices of bread and rice. Plot the old and the new demand curves for potatoes. Is the new curve parallel to the old one?
2. The price of blueberries rises and yet it is observed that the sales of blueberries increase. Does this mean that the demand curve for blueberries is upward sloping? Explain.

Definitions

Normal good A good whose demand rises as people's incomes rise.

Inferior good A good whose demand falls as people's incomes rise.

Change in demand The term used for a shift in the demand curve. It occurs when a determinant of demand other than price changes.

Change in the quantity demanded The term used for a movement along the demand curve to a new point. It occurs when there is a change in price.

* LOOKING AT THE MATHS

We can represent the relationship between the market demand for a good and the determinants of demand in the form of an equation. This is called a **demand function**. It can be expressed either in general terms or with specific values attached to the determinants.

Simple demand functions

Demand equations are often used to relate quantity demanded to just one determinant. Thus an equation relating quantity demanded to price could be in the form

$$Q_d = a - bP \quad (1)$$

For example, the actual equation might be:

$$Q_d = 10\,000 - 200P \quad (2)$$

From this can be calculated a complete demand schedule or demand curve, as shown in the table and diagram. As price (P) changes, the equation tells us how much the quantity demanded (Q_d) changes.

Demand schedule for equation (2)

P	Q_d
5	9000
10	8000
15	7000
20	6000
25	5000

Demand curve for equation (2)

1. Complete the demand schedule in the table up to a price of 50.
2. What is it about equation (2) that makes the demand curve (a) downward sloping; (b) a straight line?

Definitions

Demand function An equation which shows the mathematical relationship between the quantity demanded of a good and the values of the various determinants of demand.

Regression analysis A statistical technique which allows a functional relationship between two or more variables to be estimated.

Econometrics The science of applying statistical techniques to economic data in order to identify and test economic relationships.

This equation is based on a *ceteris paribus* assumption: it is assumed that all the other determinants of demand remain constant. If one of these other determinants changed, the equation itself would change. There would be a shift in the curve: a change in demand. If the a term alone changed, there would be a parallel shift in the curve. If the b term changed, the slope of the curve would change.

Simple equations can be used to relate demand to other determinants too. For example, an equation relating quantity demanded to income would be in the form

$$Q_d = a + bY \quad (3)$$

1. Referring to equation (3), if the term ' a ' has a value of $-50\,000$ and the term ' b ' a value of 0.001 , construct a demand schedule with respect to total income (Y). Do this for incomes between £100 million and £300 million at £50 million intervals.
2. Now use this schedule to plot a demand curve with respect to income. Comment on its shape.

More complex demand functions

In a similar way, we can relate the quantity demanded to two or more determinants. For example, a demand function could be of the form:

$$Q_d = a - bP + cY + dP_s - eP_c \quad (4)$$

This equation says that the quantity demanded (Q_d) will fall as the price of the good (P) rises, will rise as the level of consumer incomes (Y) rises, will rise as the price of a particular substitute (P_s) rises and will fall as the price of a particular complement (P_c) rises, by amounts b , c , d and e respectively.

Estimated demand equations

Surveys can be conducted to show how demand depends on each one of a number of determinants, while the rest are held constant. Using statistical techniques called **regression analysis**, a demand equation can be estimated.

For example, assume that it was observed that the demand for butter (measured in 250g units) depended on its price (P_b), the price of margarine (P_m) and total annual consumer incomes (Y). The estimated weekly demand equation may then be something like

$$Q_d = 2\,000\,000 - 50\,000P_b + 20\,000P_m + 0.01Y \quad (5)$$

Thus if the price of butter were 50p, the price of margarine were 35p and consumer incomes were £200 million, and if P_b and P_m were measured in pence and Y was measured in pounds, then the demand for butter would be 2 200 000 units. This is calculated as follows:

$$\begin{aligned} Q_d &= 2\,000\,000 - (50\,000 \times 50) + (20\,000 \times 35) \\ &\quad + (0.01 \times 200\,000\,000) \\ &= 2\,000\,000 - 2\,500\,000 + 700\,000 + 2\,000\,000 \\ &= 2\,200\,000 \end{aligned}$$

The branch of economics that applies statistical techniques to economic data is known as **econometrics**. Econometrics is beyond the scope of this book. It is worth noting, however, that econometrics, like other branches of statistics, cannot produce equations and graphs that allow totally reliable predictions to be made. The data on which the equations are based are often incomplete or unreliable, and the underlying relationships on which they are based (often ones of human behaviour) may well change over time.

*BOX 2.1 THE DEMAND FOR LAMB

A real-world demand function¹

Source: Based on data in *Family food Datasets* Table 2.1 (Defra).

The diagram shows what happened to the consumption of lamb in the UK over the period 1974–2015. How can we explain this dramatic fall in consumption? One way of exploring this issue is to make use of a regression model, which should help us to see which variables are relevant and how they are likely to affect demand.

The following is an initial model fitted² (using *Gretl*, a free, open source, statistical software package) to annual data for the years 1974–2010.

$$Q_L = 144.0 - 0.137P_L - 0.034P_B + 0.214P_P - 0.00513Y + \varepsilon \quad (1)$$

where:

Q_L is the quantity of lamb sold in grams per person per week;

P_L is the 'real' price of lamb (in pence per kg, 2000 prices);³

P_B is the 'real' price of beef (in pence per kg, 2000 prices);

P_P is the 'real' price of pork (in pence per kg, 2000 prices);

Y is households' real disposable income per head (£ per year, 2000 prices);

ε is the error term that attempts to capture the impact of any other variables that have an impact on the demand for lamb.

This model makes it possible to predict what would happen to the demand for lamb if any one of the four explanatory variables changed, assuming that the other variables remained constant. We will assume that the estimated coefficients used throughout this box are all statistically significant.

Using equation (1), calculate what would happen – ceteris paribus – to the demand for lamb if:

- the real price of lamb went up by 10p per kg;
- the real price of beef went up by 10p per kg;
- the real price of pork fell by 10p per kg;
- real disposable income per head rose by £100 per annum.

Are the results as you would expect?

There is a serious problem with estimated demand functions like these if there are unobserved factors that change over time and have an impact on the demand for lamb. By omitting explanatory variables, we can say that the model is mis-specified and this introduces a bias into the estimated coefficients. For example, the estimated coefficient on Y is negative and quite close to zero. This suggests that household income has little effect on demand. Is this what we would expect? Also, the coefficient on P_B is negative which suggests that lamb and beef are complements in consumption. Once again this appears to be a counterintuitive result.

One factor that did change over time was tastes. During the 37-year period covered by the data there was a shift in demand away from lamb and other meats, partly for health reasons, and partly because of an expansion in the availability of and demand for vegetarian and low-meat alternatives.

On the assumption that this shift in taste took place steadily over time, a new demand equation was estimated for the same years:

$$Q_L = 121.4 - 0.151P_L - 0.0213P_B + 0.180P_p - 0.000391Y - 1.728 \text{ TIME} \quad (2)$$

where $\text{TIME} = 1$ in 1974, 2 in 1975, 3 in 1976, etc.

1. How does the introduction of the variable TIME affect the relationship between the demand for lamb and (a) its real price; (b) real disposable income per head?
2. Does lamb appear to be a normal good or an inferior good?
3. What does the negative coefficient of P_B indicate?

It can be argued that model (2) is a better model than model (1) because it appears to have a better 'goodness of fit'. This is indicated by something called the ' R -squared' statistic. If $R^2 = 1$ this suggests the model can explain all the variation in the data on the demand for lamb, whereas if $R^2 = 0$ this indicates that the model cannot explain any of the variation in the data.

In model (2), $R^2 = 0.913$ compared with 0.908 for model (1). This means that model (2) can explain 91.3 per cent of the variation in the consumption of lamb during the period 1974 to 2010, whereas model (1) can explain 90.8 per cent.

Whilst model (2) appears to be a small improvement on model (1),⁴ it still has problems. The estimated coefficient of Y remains negative and is very close to zero while the

coefficient on P_B remains negative. The model might still be mis-specified because of other omitted variables. For example, consumers' purchases of lamb in any given year might be influenced by what they were consuming the previous year. The model also includes the real price of two substitutes for lamb, but does not include the real prices of any complements.

To take the above points into account, the following third model was estimated, using data for 1975 to 2010.

$$Q_L = -37.520 - 0.128P_L + 0.0757P_B + 0.122P_p + 0.00415Y - 1.529\text{TIME} + 0.679LQ_L - 0.0519P_C \quad (3)$$

where LQ_L is the lagged consumption of lamb (i.e. consumption in the previous year) and P_C is the real price of a complement (potatoes). $R^2 = 0.958$ and all the coefficients are significant.

1. To what extent is model (3) an improvement on model (2)? (Hint: is lamb now a normal or inferior good?)
2. Use the three equations and also the data given in the table below to estimate the demand for lamb in 2000 and 2010. Which model works the best in each case? Why? Explain why the models are all subject to error in their predictions.
3. Use model (3) and the data given in the table to explain why the demand for lamb fell so dramatically between 1980 and 2010.

	Q_L	LQ_L	P_L	P_B	P_p	Y	TIME	P_C
1980	128	121	421.7	546.0	414.6	10 498	7	26.7
2000	54	56	467.0	480.5	381.1	17 797	27	44.9
2010	44	46	506.2	470.1	381.1	19 776	37	53.5

1 Thanks to Tony Flegg, John's 'office mate' at UWE, for contributing to this box and to Andrew Hunt from Plymouth University for updating the figures.

2 Nominal food prices were calculated by dividing expenditure by consumption. These nominal prices in pence per kg were then adjusted to 'real' prices by dividing by the RPI (retail price index) for total food (2000 = 100) and multiplying by 100. See www.gov.uk/government/statistical-data-sets/family-food-datasets (expenditure and consumption).

3 The R^2 must be adjusted for the number of variables because simply adding more variables will always cause the unadjusted R^2 figure to increase.

4 Care must be taken not to judge a model by simply looking at the R^2 figure, which is sometimes called 'the most over-used and abused of all statistics'.

Section summary

1. When the price of a good rises, the quantity demanded per period of time will fall. This is known as the 'law of demand'. It applies both to individuals' demand and to the whole market demand.
2. The law of demand is explained by the income and substitution effects of a price change.
3. The relationship between price and quantity demanded per period of time can be shown in a table (or 'schedule') or as a graph. On the graph, price is plotted on the vertical axis and quantity demanded per period of time on the horizontal axis. The resulting demand curve is downward sloping (negatively sloped).
4. Other determinants of demand include tastes, the number and price of substitute goods, the number and price of complementary goods, income, distribution of income and expectations of future price changes.
5. If price changes, the effect is shown by a movement along the demand curve. We call this effect 'a change in the quantity demanded'.
6. If any other determinant of demand changes, the whole curve will shift. We call this effect 'a change in demand'. A rightward shift represents an increase in demand; a leftward shift represents a decrease in demand.
- *7. The relationship between the quantity demanded and the various determinants of demand (including price) can be expressed as an equation.

2.2 SUPPLY

Supply and price

Imagine you are a farmer deciding what to do with your land. Part of your land is in a fertile valley, while part is on a hillside where the soil is poor. Perhaps, then, you will consider growing vegetables in the valley and keeping sheep on the hillside.

Your decision will depend to a large extent on the price that various vegetables will fetch in the market and the price you can expect to get for meat and wool. As far as the valley is concerned, you will plant the vegetables that give the best return. If, for example, the price of potatoes is high, you might use a lot of the valley for growing potatoes. If the price gets higher, you may well use the whole of the valley. If the price is very high indeed, you may even consider growing potatoes on the hillside, even though the yield per acre is much lower there.

In other words, the higher the price of a particular farm output, the more land will be devoted to it. This illustrates the general relationship between supply and price: *when the price of a good rises, the quantity supplied will also rise*. There are three reasons for this:

- As firms supply more, they are likely to find that beyond a certain level of output, costs rise more and more rapidly. In the case of the farm just considered, if more and more potatoes are grown, then the land which is less suitable for potato cultivation has to be used. This raises the cost of producing extra potatoes. It is the same for manufacturers. Beyond a certain level of output, costs are likely to rise rapidly as workers have to be paid overtime and as machines approach capacity working. If higher output involves higher costs of producing each unit, producers

will need to get a higher price if they are to be persuaded to produce extra output.

- The higher the price of the good, the more profitable it becomes to produce. Firms will thus be encouraged to produce more of it by switching from producing less profitable goods.
- Given time, if the price of a good remains high, new producers will be encouraged to enter the industry. Total market supply thus rises.

The first two determinants affect supply in the short run. The third affects supply in the long run. We distinguish between short-run and long-run supply in section 2.5 on page 70.

The supply curve

The amount that producers would like to supply at various prices can be shown in a *supply schedule*. Table 2.2 shows a monthly supply schedule for potatoes, both for an individual farmer (farmer X) and for all farmers together (the whole market). (Note, however, that the amount they supply at a given price may not be the same as the amount they actually sell. Some supply may remain unsold.)

Definition

Supply schedule A table showing the different quantities of a good that producers are willing and able to supply at various prices over a given time period. A supply schedule can be for an individual producer or group of producers, or for all producers (the market supply schedule).

Table 2.2 The supply of potatoes (monthly)

	Price of potatoes (pence per kg)	Farmer X's supply (tonnes)	Total market supply (tonnes: 000s)
a	20	50	100
b	40	70	200
c	60	100	350
d	80	120	530
e	100	130	700

The supply schedule can be represented graphically as a **supply curve**. A supply curve may be an individual firm's supply curve or a market curve (i.e. that of the whole industry).

Figure 2.3 shows the *market* supply curve of potatoes. As with demand curves, price is plotted on the vertical axis and quantity on the horizontal axis. Each of the points a–e corresponds to a figure in Table 2.2. Thus, for example, a price rise from 60p per kilogram to 80p per kilogram will cause a movement along the supply curve from point c to point d: total market supply will rise from 350 000 tonnes per month to 530 000 tonnes per month.

1. How much would be supplied at a price of 70p per kilo?
2. Draw a supply curve for farmer X. Are the axes drawn to the same scale as in Figure 2.3?

Not all supply curves will be upward sloping (positively sloped). Sometimes they will be vertical, or horizontal or even downward sloping. This will depend largely on the time period over which firms' response to price changes is considered. This question is examined in the section on the elasticity of supply (see section 2.4 below) and in more detail in Chapters 6 and 7.

Other determinants of supply

Like demand, supply is not simply determined by price. The other determinants of supply are as follows.

The costs of production. The higher the costs of production, the less profit will be made at any price. As costs rise, firms will cut back on production, probably switching to alternative products whose costs have not risen so much.

The main reasons for a change in costs are as follows:

- Change in input prices: costs of production will rise if wages, raw material prices, rents, interest rates or any other input prices rise.
- Change in technology: technological advances can fundamentally alter the costs of production. Consider, for example, how the microchip revolution has changed production methods and information handling in virtually every industry in the world.
- Organisational changes: various cost savings can be made in many firms by reorganising production.
- Government policy: costs will be lowered by government subsidies and raised by various taxes. Government regulation may also increase costs; examples include minimum wages and obligations for employers to provide and contribute to employee pensions.

Definition

Supply curve A graph showing the relationship between the price of a good and the quantity of the good supplied over a given period of time.

Figure 2.3 Market supply curve of potatoes (monthly)

The profitability of alternative products (substitutes in supply). If a product which is a **substitute in supply** becomes more profitable to supply than before, producers are likely to switch from the first good to this alternative. Supply of the first good falls. Other goods are likely to become more profitable if their prices rise and/or their costs of production fall. For example, if the price of carrots goes up, or the cost of producing carrots comes down, farmers may decide to cut down potato production in order to produce more carrots.

The profitability of goods in joint supply. Sometimes when one good is produced, another good is also produced at the same time. These are said to be **goods in joint supply**. An example is the refining of crude oil to produce petrol. Other grade fuels will be produced as well, such as diesel and paraffin. If more petrol is produced due to a rise in demand and hence its price, then the supply of these other fuels will rise too.

Nature, 'random shocks' and other unpredictable events. In this category we would include the weather and diseases affecting farm output, wars affecting the supply of imported raw materials, the breakdown of machinery, industrial disputes, earthquakes, floods and fire, etc. For example, in April 2017 the grape harvest in both France and the UK was significantly affected by heavy frosts leading to a reduction in the supply of wine.

The aims of producers. A profit-maximising firm will supply a different quantity from a firm that has a different aim, such as maximising sales. For most of the time we shall assume that firms are profit maximisers. In Chapter 9, however, we consider alternative aims.

Expectations of future price changes. If price is expected to rise, producers may temporarily reduce the amount they sell. They may build up their stocks and only release them on to the market when the price does rise. At the same time they may install new machines or take on more labour, so that they can be ready to supply more when the price has risen.

The number of suppliers. If new firms enter the market, supply is likely to increase.

? By referring to each of the above determinants of supply, identify what would cause (a) the supply of potatoes to fall and (b) the supply of leather to rise.

Movements along and shifts in the supply curve

The principle here is the same as with demand curves. The effect of a change in price is illustrated by a movement along the supply curve: for example, from point *d* to point *e* in Figure 2.3 when price rises from 80p to 100p. Quantity supplied rises from 530 000 to 700 000 tonnes per month.

If any other determinant of supply changes, the whole supply curve will shift. A rightward shift illustrates an

increase in supply. A leftward shift illustrates a decrease in supply. Thus in Figure 2.4, if the original curve is S_0 , the curve S_1 represents an increase in supply (more is supplied at each price), whereas the curve S_2 represents a decrease in supply (less is supplied at each price).

A movement along a supply curve is often referred to as a **change in the quantity supplied**, whereas a shift in the supply curve is simply referred to as a **change in supply**.

? This question is concerned with the supply of oil for central heating. In each case consider whether there is a movement along the supply curve (and in which direction) or a shift in it (and whether left or right).

- New oil fields start up in production.
- The demand for central heating rises.
- The price of gas falls.
- Oil companies anticipate an upsurge in demand for central-heating oil.
- The demand for petrol rises.
- New technology decreases the costs of oil refining.
- All oil products become more expensive.

Definitions

Substitutes in supply These are two goods where an increased production of one means diverting resources away from producing the other.

Joint supply goods These are two goods where the production of more of one leads to the production of more of the other.

Change in the quantity supplied The term used for a movement along the supply curve to a new point. It occurs when there is a change in price.

Change in supply The term used for a shift in the supply curve. It occurs when a determinant other than price changes.

*** LOOKING AT THE MATHS**

Using survey data and regression analysis, equations can be estimated relating supply to some of its determinants. Note that not all determinants can be easily quantified (e.g. nature and the aims of firms), and they may thus be left out of the equation.

The simplest form of supply equation relates supply to just one determinant. Thus a function relating supply to price would be of the form

$$Q_s = c + dP \quad (1)$$

Using regression analysis, values can be estimated for c and d . Thus an actual supply equation might be something like

$$Q_s = 500 + 1000P \quad (2)$$

1. If P was originally measured in pounds, what would happen to the value of the d term in equation (2) if P were now measured in pence?
2. Draw the schedule (table) and graph for equation (2) for prices from £1 to £10. What is it in the equation that determines the slope of the supply 'curve'?

If any determinant other than price changed, a new equation would result. For example, if costs of production fell, the equation might then be

$$Q_s = 1000 + 1500P \quad (3)$$

More complex supply equations would relate supply to more than one determinant. For example:

$$Q_s = 200 + 80P - 20a_1 - 15a_2 + 30j \quad (4)$$

where P is the price of the good, a_1 and a_2 are the profitabilities of two alternative goods that could be supplied instead, and j is the profitability of a good in joint supply.

Explain why the P and j terms have a positive sign, whereas the a_1 and a_2 terms have a negative sign.

Section summary

1. When the price of a good rises, the quantity supplied per period of time will usually also rise. This applies both to individual producers' supply and to the whole market supply.
2. There are two reasons in the short run why a higher price encourages producers to supply more: (a) they are now willing to incur the higher costs per unit associated with producing more; (b) they will switch to producing this product and away from products that are now less profitable. In the long run, there is a third reason: new producers will be attracted into the market.
3. The relationship between price and quantity supplied per period of time can be shown in a table (or schedule) or as a graph. As with a demand curve, price is plotted on the vertical axis and quantity per period of time on the horizontal axis. The resulting supply curve is upward sloping (positively sloped).
4. Other determinants of supply include the costs of production, the profitability of alternative products, the profitability of goods in joint supply, random shocks and expectations of future price changes.
5. If price changes, the effect is shown by a movement along the supply curve. We call this effect 'a change in the quantity supplied'.
6. If any determinant *other* than price changes, the effect is shown by a shift in the whole supply curve. We call this effect 'a change in supply'. A rightward shift represents an increase in supply; a leftward shift represents a decrease in supply.
- *7. The relationship between the quantity supplied and the various determinants of supply can be expressed in the form of an equation.

2.3 PRICE AND OUTPUT DETERMINATION**Equilibrium price and output**

We can now combine our analysis of demand and supply. This will show how the actual price of a product and the actual quantity bought and sold are determined in a free and competitive market.

Let us return to the example of the market demand and market supply of potatoes, and use the data from Tables 2.1 and 2.2. These figures are given again in Table 2.3.

What will be the actual price and output? If the price started at 20p per kilogram, demand would exceed supply by

600 000 tonnes ($A - a$). Consumers would be unable to obtain all they wanted and would thus be willing to pay a higher price. Producers, unable or unwilling to supply enough to meet the demand, will be only too happy to accept a higher price. The effect of the shortage, then, will be to drive up the price. The same would happen at a price of 40p per kilogram. There would still be a shortage; price would still rise. But as the price rises, the quantity demanded falls and the quantity supplied rises. The shortage is progressively eliminated.

Table 2.3 The market demand and supply of potatoes (monthly)

Price of potatoes (pence per kg)	Total market demand (tonnes: 000s)	Total market supply (tonnes: 000s)
20	700 (A)	100 (a)
40	500 (B)	200 (b)
60	350 (C)	350 (c)
80	200 (D)	530 (d)
100	100 (E)	700 (e)

? Explain the process by which the price of houses would rise if there were a shortage.

What would happen if the price of potatoes started at a much higher level: say, at 100p per kilogram? In this case supply would exceed demand by 600 000 tonnes ($e - E$). The effect of this surplus would be to drive the price down as farmers competed against each other to sell their excess supplies. The same would happen at a price of 80p per kilogram. There would still be a surplus; price would still fall.

In fact, only one price is sustainable – the price where demand equals supply: namely, 60p per kilogram, where both demand and supply are 350 000 tonnes. When supply matches demand the market is said to *clear*. There is no shortage and no surplus.

As we have already seen in section 1.2, the price where demand equals supply is called the *equilibrium price* and we return to this in more detail in Threshold Concept 4 on page 47. In Table 2.3, if the price starts at anything other than 60p per kilogram, it will tend to move towards 60p. The equilibrium price is the only price at which producers' and consumers'

wishes are mutually reconciled: where the producers' plans to supply exactly match the consumers' plans to buy.

Equilibrium is the point where conflicting interests are balanced. Only at this point is the amount that demanders are willing to purchase the same as the amount that suppliers are willing to supply. It is a point that will be automatically reached in a free market through the operation of the price mechanism.

Demand and supply curves

The determination of equilibrium price and output can be shown using demand and supply curves. Equilibrium is where the two curves intersect.

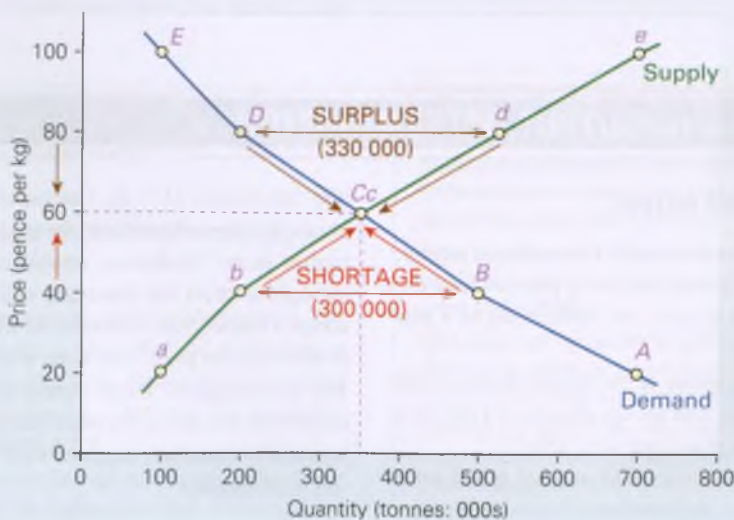

Figure 2.5 shows the demand and supply curves of potatoes corresponding to the data in Table 2.3. Equilibrium price is P_e (60p) and equilibrium quantity is Q_e (350 000 tonnes).

At any price above 60p, there would be a surplus. Thus at 80p there is a surplus of 330 000 tonnes ($d - D$). More is supplied than consumers are willing and able to purchase at that price. Thus a price of 80p fails to clear the market. Price will fall to the equilibrium price of 60p. As it does so, there will be a movement along the demand curve from point D to point C , and a movement along the supply curve from point d to point c .

At any price below 60p, there would be a shortage. Thus at 40p there is a shortage of 300 000 tonnes ($B - b$). Price will

Definition

Market clearing A market clears when supply matches demand, leaving no shortage or surplus.

Figure 2.5 The determination of market equilibrium (potatoes: monthly)

rise to 60p. This will cause a movement along the supply curve from point *b* to point *c* and along the demand curve from point *B* to point *C*.

Point *Cc* is the equilibrium: where demand equals supply.

Movement to a new equilibrium

The equilibrium price will remain unchanged only so long as the demand and supply curves remain unchanged. If either of the curves shifts, a new equilibrium will be formed.

A change in demand

If one of the determinants of demand changes (other than price), the whole demand curve will shift. This will lead to a movement *along* the supply curve to the new intersection point.

For example, in Figure 2.6, if a rise in consumer incomes led to the demand curve shifting to D_2 , there would be a

Figure 2.6 Effect of a shift in the demand curve

THRESHOLD CONCEPT 4

MARKETS EQUATE DEMAND AND SUPPLY

THINKING LIKE AN ECONOMIST

'Let the market decide.' 'Market forces will dictate.' 'You can't buck the market.'

These sayings about the market emphasise the power of market forces and how they affect our lives. Markets affect the prices of the things we buy and the incomes we earn. Even governments find it difficult to control many key markets. Governments might not like it when stock market prices plummet or when oil prices soar, but there is little they can do about it.

In many ways a market is like a democracy. People, by choosing to buy goods, are voting for them to be produced. Firms finding 'a market' for their products are happy to oblige and produce them. The way it works is simple. If people want more of a product, they buy more and thereby 'cast their votes' (i.e. their money) in favour of more being produced. The resulting shortage drives up the price, which gives firms the incentive to produce more of the product. In other words, firms are doing what consumers want – not because of any 'love' for consumers, or because they are being told to produce more by the government, but because it is in their own self-interest. They supply more because the higher price has made it profitable to do so.

This is a *threshold concept* because to understand market forces – the forces of demand and supply – is to go straight to the heart of a market economy. And in this process, prices are the key. It is changes in price that balance demand and supply. If demand exceeds supply, price will rise. This will choke off some of the demand and encourage more supply until demand equals supply – until an equilibrium has been reached. If supply exceeds demand, price will fall. This will discourage firms from supplying so much and encourage consumers to buy more, until, once more, an equilibrium has been reached.

In this process, markets act like an 'invisible hand' – a term coined by the famous economist Adam Smith (see Box 1.5 on page 25). Market prices guide both producers to respond to

consumer demand and consumers to respond to changes in producer supply.

In many circumstances, markets bring outcomes that people want. As we have seen, if consumers want more, then market forces will lead to more being produced. Sometimes, however, market forces can bring adverse effects. We explore these in various parts of the book. It is important, at this stage, however, to recognise that markets are rarely perfect. Market failures, from pollution to the domination of our lives by big business, are very real. Understanding this brings us to Threshold Concept 7 (see page 81).

Partial equilibrium

The type of equilibrium we will be examining for the next few chapters is known as 'partial equilibrium'. It is partial because what we are doing is examining just one tiny bit of the economy at a time: just one market (e.g. that for eggs). It is even partial within the market for eggs because we are assuming that price is the *only* thing that changes to balance demand and supply: that nothing else changes. In other words, when we refer to equilibrium price and quantity, we are assuming that all the other determinants of both demand and supply are held constant.

If another determinant of demand or supply *does* change, there would then be a new partial equilibrium as price adjusts and both demanders and suppliers respond. For example, if a health scare connected with egg consumption causes the demand for eggs to fall, the resulting surplus will lead to a fall in the equilibrium price and quantity.

1. If there is a shortage of certain skilled workers in the economy, how will market forces lead to an elimination of the skills shortage?
2. If consumers want more of a product, is it always desirable that market forces result in more being produced?

shortage of $h-g$ at the original price P_{e_1} . This would cause price to rise to the new equilibrium P_{e_2} . As it did so, there would be a movement along the supply curve from point g to point i , and along the new demand curve (D_2) from point h to point i . Equilibrium quantity would rise from Q_{e_1} to Q_{e_2} .

The effect of the shift in demand, therefore, has been a movement *along* the supply curve from the old equilibrium to the new: from point g to point i .

What would happen to price and quantity if the demand curve shifted to the left? Draw a diagram to illustrate your answer.

A change in supply

Likewise, if one of the determinants of supply changes (other than price), the whole supply curve will shift. This will lead to a movement *along* the demand curve to the new intersection point.

For example, in Figure 2.7, if costs of production rose, the supply curve would shift to the left: to S_2 . There would be a shortage of $g-j$ at the old price of P_{e_1} . Price would rise from P_{e_1} to P_{e_2} . Quantity would fall from Q_{e_1} to Q_{e_2} . In other words, there would be a movement along the demand curve from point g to point k , and along the new supply curve (S_2) from point j to point k .

To summarise: a shift in one curve leads to a movement along the other curve to the new intersection point.

Sometimes a number of determinants might change. This might lead to a shift in *both* curves. When this happens, equilibrium simply moves from the point where the old curves intersected to the point where the new ones intersect.

What will happen to the equilibrium price and quantity of butter in each of the following cases? You should state whether demand or supply (or both) have shifted and in which direction. (In each case assume *ceteris paribus*.)

- A rise in the price of non-dairy spread.
- A rise in the demand for cream.
- A rise in the price of bread.

Figure 2.7 Effect of a shift in the supply curve

(d) A rise in the demand for bread.

(e) An expected rise in the price of butter in the near future.

(f) A tax on butter production.

(g) The invention of a new, but expensive, process for removing all saturated fat from butter, alongside the passing of a law which states that all butter producers must use this process.

Incentives in markets

Throughout this chapter we have seen that people and firms respond to incentives. In all cases of changes in demand and supply, the resulting changes in price act as both signals and incentives. This is Threshold Concept 5.

* LOOKING AT THE MATHS

We saw on pages 39 and 45 how demand and supply curves can be represented by equations. Assume that the equations for the supply and demand curves in a particular market are as follows:

$$Q_D = a - bP \quad (1)$$

$$Q_S = c + dP \quad (2)$$

We can find the market equilibrium price by setting the two equations equal to each other, since, in equilibrium, the quantity supplied (Q_S) equals the quantity demanded (Q_D). Thus:

$$c + dP = a - bP$$

Subtracting c from and adding bP to both sides gives:

$$\begin{aligned} dP + bP &= a - c \\ \therefore (d + b)P &= a - c \\ \therefore P &= \frac{a - c}{d + b} \end{aligned} \quad (3)$$

We can then solve for equilibrium quantity (Q_e) by substituting equation (3) in either equation (1) or (2) (since $Q_D = Q_S$). Thus, from equation (1):

$$\begin{aligned} Q_e &= a - b \left(\frac{a - c}{d + b} \right) \\ &= \frac{a(d + b) - b(a - c)}{d + b} \\ &= \frac{ad + ab - ba + bc}{d + b} = \frac{ad + bc}{d + b} \end{aligned} \quad (4)$$

or, from equation (2):

$$\begin{aligned} Q_e &= c + d \left(\frac{a - c}{d + b} \right) \\ &= \frac{cd + cb + da - dc}{d + b} = \frac{cb + da}{d + b} \end{aligned} \quad (5)$$

Thus:

$$Q_e = \frac{ad + bc}{d + b} \text{ (equation (4))} = \frac{cb + da}{d + b} \text{ (equation (5))}$$

A worked example is given in Maths Case 2.1 on the student website.

*Identifying the position of demand and supply curves

Both demand and supply depend on price, and yet their interaction determines price. For this reason it is difficult to identify just what is going on when price and quantity change, and to identify just what the demand and supply curves look like.

Let us say that we want to identify the demand curve for good X. We observe that when the price was 20p, 1000 units were purchased. At a later date the price has risen to 30p and 800 units are now purchased. What can we conclude from this about the demand curve? The answer is that without further information we can conclude very little. Consider Figures 2.8 and 2.9. Both are consistent with the facts.

In Figure 2.8 the demand curve has not shifted. The rise in price and the fall in sales are due entirely to a shift in the supply curve. The movement from point *a* to point *b* is thus a movement along the demand curve. If we can be certain that the demand curve has not shifted, then the evidence allows us to identify its position (or, at least, two points on it).

In Figure 2.9, however, not only has the supply curve shifted, but so also has the demand curve. Let us assume that people's tastes for the product have increased. In this case a movement from *a* to *b* does *not* trace out the demand curve.

We cannot derive the demand curve(s) from the evidence of price and quantity alone.

The problem is that when the supply curve shifts, we often cannot know whether or not the demand curve has shifted, and if so by how much. How would we know, for example, just how much people's tastes have changed?

The problem works the other way round too. It is difficult to identify a supply curve when the demand curve shifts. Is the change in price and quantity entirely due to the shift in the demand curve, or has the supply curve shifted too?

This is known as the **identification problem**. It is difficult to identify just what is causing the change in price and quantity.

Definition

Identification problem The problem of identifying the relationship between two variables (e.g. price and quantity demanded) from the evidence when it is not known whether or how the variables have been affected by other determinants. For example, it is difficult to identify the shape of a demand curve simply by observing price and quantity when it is not known whether changes in other determinants have shifted the demand curve.

Figure 2.8 Problems in identifying the position and shape of the demand curve: shift in supply curve alone

Figure 2.9 Problems in identifying the position and shape of the demand curve: shift in supply and demand curves

THRESHOLD CONCEPT 5

PEOPLE RESPOND TO INCENTIVES

So it's important to get them right

What gets you out of bed and into an economics lecture on time? What helps decide whether you wear a cycle helmet when out for a bike ride? What motivates a firm to invest in extra training for its workforce? Incentives drive the way individuals and businesses behave – even when we don't see that the incentive exists.

Financial and non-financial incentives

When there is a shortage of a good, its market price will rise, the opportunity cost goes up and there is an incentive for us to consume less. Similarly there is an incentive for firms to produce more. After all, the good is now more profitable to produce. This is an example of a financial incentive, for both buyers and producers. Other financial incentives include wages (i.e. being paid to work), bursaries for students and tax relief on investment for businesses.

But when we look at what motivates people making decisions, we see that non-financial incentives also play an important role. When we give to charity, support a football team, buy presents for our family or decide to run across a busy road rather than use a crossing, we are reacting to non-financial incentives.

Do incentives lead to desirable outcomes?

Let us return to the example of a shortage of a good, leading to a price rise. The resulting incentives could be seen as desirable, the shortage is eliminated and consumers are able to buy more of a good where demand initially exceeds supply.

However, there are plenty of instances where incentives may be 'perverse'. In other words, they could have undesirable effects. For example, if a particular course or module on your degree is assessed by two pieces of coursework, this may act as an incentive for you to concentrate solely on these two pieces and do little work on the rest of the syllabus.

There are plenty of other examples where incentives can be perverse. Making cars safer may encourage people to drive faster. Increasing top rates of income tax may encourage high earners to work less or to evade paying taxes by not declaring income – tax revenues may end up falling.

If an economic system is to work well, it is important, therefore, that the incentives are appropriate and do not bring about undesirable

BOX 2.2

UK HOUSE PRICES

The ups and downs (and ups again) of the housing market

The housing market is very important to consumers, firms and government in the UK. Households spend more on housing as a proportion of their income than any other good or service. Higher house prices tend to increase consumer confidence, leading to higher levels of spending and economic growth. Banks may also feel more confident about lending money to both consumers and firms. If house prices fall, the opposite is true. It is therefore not surprising that so many people take such a keen interest in both house prices and the outlook for the market.

The chart shows what happened to house prices in the period 1984 to 2017. It clearly illustrates the volatility of the market. For example, in the late 1980s, there was a boom with prices doubling between 1984 and 1989. By the end of 1988, prices were rising at an astonishing annual rate of 34 per cent.

However, this boom came to an end in late 1989. Between 1990 and 1995, house prices fell by 12.2 per cent, causing many households to move into 'negative equity'. This is where the size of a household's mortgage is greater than the value of their house, meaning that if they sold their house, they would still owe money. Many people during this period, therefore, found that they were unable to move house.

In the latter part of the 1990s the housing market started to recover, with prices rising at around 5 per cent per annum. This steady increase turned into another boom, with house prices rising at an annual rate of 26 per cent at the peak (in the 12 months to January 2003). With the financial crisis of 2007–8, house prices started to decline rapidly once again and in 2009 they fell by 19 per cent. They remained flat for several years, mirroring the lack of growth in the economy.

Prices started to rise again in late 2013 and by July 2014 annual house price inflation had reached 11.7 per cent. However, there was significant regional variation across the UK. Similar trends continued into 2015 and early 2016. For example, in June 2016 house prices grew at an annual rate of 13.2 per cent in the East of England compared with 4.7 per cent in Yorkshire and the Humber. This growth began to slow after the EU referendum. Then in April 2017, house prices recorded their first quarterly fall since 2012.

The determinants of house prices

House prices are determined by demand and supply. If demand rises (i.e. shifts to the right) or if supply falls (i.e. shifts to the left), the equilibrium price of houses will rise. Similarly, if demand falls or supply rises, the equilibrium price will fall.

So why did house prices rise so rapidly in the 1980s, the late 1990s through to 2007 and once more from 2013 to 2016? Why did they also fall in the early 1990s and again from 2008 to 2013? The answer lies primarily in changes in the *demand* for housing. Let us examine the various factors that affected the demand for houses.

Incomes (actual and anticipated). The second half of the 1980s, 1996 to 2007 and 2013 to 2016 were periods of rising incomes. The economy was experiencing an economic 'boom', or recovery in the later period. Many people wanted to spend much of their extra income on housing: either buying a house for the first time, or moving to a better one. What is more,

side effects. This is a *threshold concept* because virtually every action taken by households or firms is influenced by incentives. We need to understand just what the incentives are, what their effects are likely to be, and how the incentives could be improved.

We can see the outcome of inappropriate incentives, when we look at what happened in the former Soviet Union in the days of central planning. The targets given to factory managers (see Box 1.4 on pages 22–3) were often inappropriate. For example, if targets were specified in tonnes, the incentive was to produce heavy products. Soviet furniture and cooking utensils tended to be very heavy! If targets were set in area (e.g. sheet glass), then the incentive was to produce thin products. If targets were set simply in terms of number of units, then the incentive was to produce shoddy products.

Despite the lessons that should have been learnt from the failures of Soviet planning, we still see a lack of real understanding of incentives and the role they can play. If banks are told to increase the amount of financial capital they hold, they may cut down on lending to small businesses. If a university's quality is measured by how many first and upper second-class degrees it awards, then

there is an incentive to make it easier for students to get high marks.

We will examine the role of incentives in more detail later in the book, particularly when we look at behavioural economics. One crucial incentive is that of profit. In a competitive environment, firms striving for increased profit may result in better products and a lower price for consumers as firms seek to undercut each other. In other cases, however, firms may be able to make bigger profits by controlling the market and keeping competitors out or by colluding with them. Here the profit incentive has a perverse effect: it leads to higher prices for consumers and less choice.

1. Give two other examples of perverse incentives. How could the incentives be improved?
2. Suppose that the kitchen is very untidy – what are the incentives for you to address this? What incentives could you use to get someone else to do it for you?
3. Many students undertake voluntary work while at university. What do think the incentives are for this? Identify any perverse incentives associated with volunteering and how they could be addressed.

UK house price inflation (annual %, adjusted quarterly)

Source: Based on Halifax House Price Index (Lloyds Banking Group).

many people were confident that their incomes would continue to grow and were prepared to stretch themselves financially in the short term by buying an expensive house, assuming that their mortgage payments would become more affordable over time.

The early 1990s and late 2000s, by contrast, were periods of recession or low growth, with rising unemployment and flat or falling incomes. For example, average real earnings (i.e. earnings after taking inflation into account) fell by 9 per cent between 2008 and 2013. People were less confident about their ability to afford large mortgages. In 2017, rising inflation caused real wages to fall once again. This, combined with uncertainty about the future of the economy following the UK's decision to leave the European Union, had a negative impact on demand.

The number of households. Social and demographic changes have resulted in a sharp increase in the number of households over the past 30 years. In 1981, there were 20.18 million households in Great Britain; by 2016 this had increased to 27.1 million. Reasons include more lone parents, increased life expectancy and flows of workers from abroad. Although average household size was lower, the overall impact was an increase in demand for housing.

The cost of mortgages. During the second half of the 1980s, mortgage interest rates were generally falling. Although they were still high compared with rates today, in real terms they were negative.

In 1989, however, this trend went into reverse. Mortgage interest rates started rising. Many people found it difficult to maintain their existing payments, let alone take on a larger mortgage. From 1996 to 2003 mortgage rates generally fell, once more fuelling the demand for houses. Even with gently rising interest rates from 2003 to 2007, mortgages were still relatively affordable. Between 2009 and 2017, interest rates remained at an all-time low, which reduced the cost of mortgage repayments. However, a combination of continued uncertainty following the financial crisis and cautious lenders meant that demand did not start to increase significantly until around 2013. The result of the EU referendum

introduced more uncertainty back into the market from the second half of 2016.

The availability of mortgages. In the late 1980s, mortgages were readily available. Banks and building societies were prepared to accept smaller deposits on houses and to grant mortgages of 3.5 times a person's annual income (compared with 2.5 times in the early 1980s). In the early 1990s, however, banks and building societies became much more cautious. They were aware that, with falling house prices, rising unemployment and the increasing problem of negative equity, there was a growing danger that borrowers would default on payments.

With the recovery of the economy in the mid-1990s and with increased competition between lenders, mortgages became more readily available and for greater amounts relative to people's incomes. This helped to push up prices. The belief that prices would continue to rise led lenders to relax their requirements even further. After all, if borrowers were to default, lenders would still have a good chance of getting their money back if house prices continued to rise. By the mid-2000s, many lenders were allowing borrowers to self-certify their income and were increasingly willing to lend to those with a poor credit history. This was the 'sub-prime' market. In 2001, the average house price was 3.4 times greater than average earnings. By 2007, this figure had risen to 5.74. Problems in the mortgage market were a key contributing factor to the financial crises of 2007–8.

From late 2007 to 2012 the willingness of lenders to issue mortgages changed dramatically. The credit crunch in 2008–9 meant that the banks had less money to lend. Falling house prices and rising unemployment also made them much more wary. Many mortgage lenders began asking for deposits of at least 25 per cent – over £40 000 for an average house in the UK.

This requirement was relaxed through 2013 and 2014 and the government-backed 'Help to buy' schemes were introduced to help borrowers get a mortgage with a 5 per cent deposit. This easing in the ability of people to obtain access to finance contributed to the increase in house prices once again.

Speculation. A belief that house prices will continue to move in a particular direction can exacerbate house price movements. In other words, speculation tends to increase house price movements. In the 1980s, 1997–2007 and 2013–16, people generally believed that house prices would continue rising. This encouraged them to buy, and to take out the biggest mortgage possible, before prices went up any further. There was also an effect on supply. Those with houses to sell held back until the last possible moment in the hope of getting a higher price. The net effect was a rightward shift in the demand curve for houses and a leftward shift in the supply curve. The effect of this speculation, therefore, was to help bring about the very effect that people were predicting (for more on the impact of speculation see section 2.5).

In the early 1990s and late 2000s, the opposite occurred. People thinking of buying houses held back, hoping to get a better deal when prices had fallen. People with houses to sell tried to sell as quickly as possible before prices fell any further. Again the effect of this speculation was to aggravate the change in prices – this time a fall in prices.

The impact of speculation has also been compounded by the growth in the ‘buy-to-let’ industry, with mortgage lenders entering this market in large numbers and a huge amount of media attention focused on the possibilities for individuals to make very high returns.

Supply. While speculation about changing house prices is perhaps the biggest determinant of housing supply in the short run, over the long term supply depends on house building. Governments’ housing policy is often focused on how to encourage the building industry by providing tax and other incentives and streamlining planning regulations. But house building may bring adverse environmental and social problems and people often oppose new developments in their area. Building on the ‘Green Belt’ has become a controversial issue.

What of the future?

The Institute of Fiscal Studies¹ forecast that average real wages will be lower in 2021 than they were in 2008. If this forecast is accurate, the decade from 2012 to 2021 will

represent the worst period of pay for workers in 70 years and will have a negative impact on the future demand for housing. Data from the Office of National Statistics² suggest that house prices are the least affordable they have ever been. Between 1997 and 2016 the cost of an average home increased by 259 per cent while average real earnings increased by 68 per cent. The average house cost 7.6 times more than average earnings in 2016. As we saw above, the corresponding figure in 2001 was 3.4.

Will these negative factors on the demand side of the market lead to falling house prices? Many observers believe that they will continue to rise because of a lack of supply. The number of new households has exceeded the number of new houses built in every year since 2008, with the gap growing in recent years. Estimates suggest that 250 000 to 300 000 new homes would have to be built every year to keep up with demand. The figure for the year to June 2016 was 139 030. It looks increasingly likely that the government will fail to meet its target of building a million new homes by May 2020.

1. Draw supply and demand diagrams to illustrate what was happening to house prices (a) in the second half of the 1980s and the period from 1997 to 2007; (b) in the early 1990s and 2008–12; (c) 2014–16 in London, and in a region outside SE England.
2. What determines the supply of housing? How will factors on the supply side influence house prices?
3. What is the role of the prices of ‘other goods’ in determining the demand for housing?
4. Find out what forecasters are predicting for house prices over the next year and attempt to explain their views.

BOX 2.3

STOCK MARKET PRICES

Demand and supply in action

Firms that are quoted on the stock market can raise money by issuing shares. These are sold on the 'primary stock market'. People who own the shares receive a 'dividend' on them, normally paid six-monthly. The amount varies with the profitability of the company.

People or institutions that buy these shares, however, may not wish to hold on to them for ever. This is where the 'secondary stock market' comes in. It is where existing shares are bought and sold. There are stock markets, primary and secondary, in all the major countries of the world.

There are 2226 companies (as of April 2017) whose shares and other securities are listed on the London Stock Exchange and trading in them takes place each weekday. The prices of shares depend on demand and supply. For example, if the demand for Tesco shares at any one time exceeds the supply on offer, the price will rise until demand and supply are equal. Share prices fluctuate throughout the trading day and sometimes price changes can be substantial.

To give an overall impression of share price movements, stock exchanges publish share price indices. The most famous one in the UK is the FTSE ('footsie') 100, which stands for the 'Financial Times Stock Exchange' index of the 100 largest companies' shares. The index represents an average price of these 100 shares. The chart shows movements in the FTSE 100 from 1995 to 2017. The index was first calculated on 3 January 1984 with a base level of 1000 points. It reached a peak of 6930 points on 30 December 1999 and fell to 3287 on 12 March 2003, before rising again to a high of 6730 on 12 October 2007. However, with the financial crisis, the index fell to a low of 3512 on 3 March 2009. During the latter part of

2009 and 2010, the index began to recover, briefly passing the 6000 mark at the end of 2010, but fluctuating around 5500 during 2011/12. The index then started on an upward trend in 2013, peaking at 7104 on 27 April 2015, before falling back to around 6000 in early 2016.

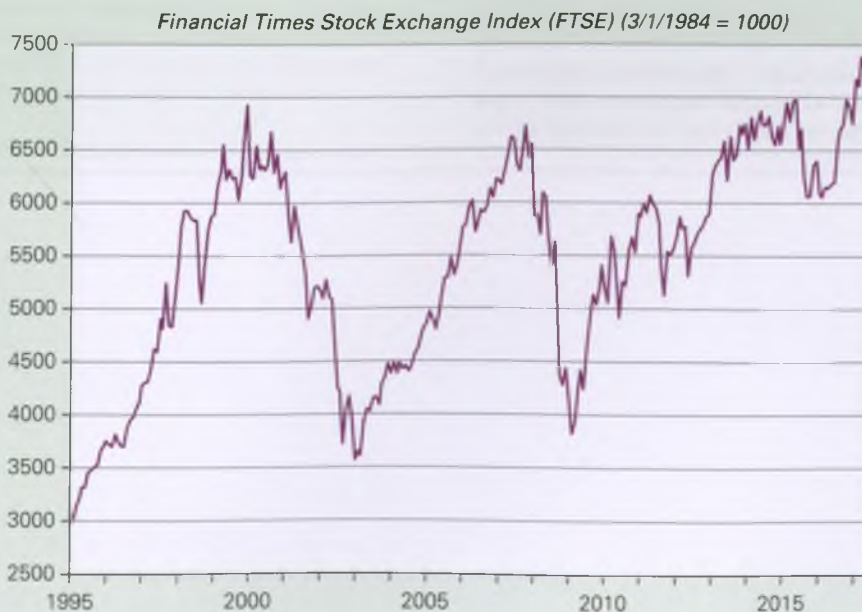

After the initial shock of the Brexit vote in June 2016, it rose again to over 7000 in June 2016. Part of the reason for this was the fall in the sterling exchange rate that occurred because of the uncertainty over the nature of the Brexit deal. With many of the FTSE 100 companies having assets denominated in dollars, a falling sterling exchange rate meant that these dollar assets were now worth more pounds.

What causes share prices to change? Why were they so high in 1999, but only just over half that value only three years later? Why did this trend occur again in the late 2000s and what is likely to happen as the time for the UK leaving the EU approaches. The answer lies in the determinants of the demand and supply of shares.

Demand

There are five main factors that affect the demand for shares.

The dividend yield. This is the dividend on a share as a percentage of its price. The higher the dividend yields on shares the more attractive they are as a form of saving. One of the main explanations of rising stock market prices from 2003 to 2007 was high profits and resulting high dividends. The financial crisis and slowdown in the world economy explains the falling profits and dividends of companies from

2007 and the subsequent recovery in the global economy caused them to increase once again.

The price of and/or return on substitutes. The main substitutes for shares in specific companies are other shares. Thus if, in comparison with other shares, Tesco shares are expected to pay high dividends relative to the share price, people will buy Tesco shares. As far as shares in general are concerned, the main substitutes are other forms of saving. Thus if the interest rate on savings accounts in banks and building societies fell, people with such accounts would be tempted to take their money out and buy shares instead.

Another major substitute is property. If house prices rise rapidly, as they did in 2002 and 2003, this will reduce the demand for shares as many people switch to buying property in anticipation of even higher prices. If house prices level off, as they did in 2005/6, this makes shares relatively more attractive as an investment and can boost the demand for them. With the global slowdown in 2008 pushing both house and share prices downwards, investors looked for other substitutes. Gold and government debt became more popular, as they were considered to be a safer investment.

Incomes. If the economy is growing rapidly and people's incomes are rising rapidly, they are likely to save some of their extra income and therefore buy more shares. Thus in the mid-to-late 1990s, when UK incomes were rising at an average annual rate of over 3 per cent, share prices rose rapidly (see chart). As growth rates fell in the early 2000s, so did share prices. The trend then repeated itself with growth rates picking up from 2003 to 2007 and then declining again with the onset of recession from 2007. With signs of a global economic recovery, share price rose again between 2012 and mid-2015.

Wealth. 'Wealth' is people's accumulated savings and property. Wealth rose in the 1990s and many people used their increased wealth to buy shares. It was a similar picture in the mid-2000s.

Expectations. From 2003 to 2007, people expected share prices to go on rising. They were optimistic about continued growth in the economy and that certain sectors, such as leisure and high-tech industries, would grow particularly strongly. As people bought shares, this put more upward pressure on prices, thereby fuelling further speculation that they would go on rising and encouraging further share buying.

With the financial crisis and fears of recession, there was a dramatic fall in share prices as confidence was shaken. As people anticipated further price falls, they held back from buying, thereby reducing demand and pushing prices lower. Prices remained volatile after the financial crisis, as uncertainty remained about the prospects for the global economy. Only when people

became increasingly confident about the chances of an economic recovery did share prices begin to rise consistently once more.

However, uncertainty has increased again with concerns about the slow recovery in Europe, falling growth in China and many other developing countries, and the consequences of the UK's exit from the EU. The impact of speculation is examined in more detail in section 2.5.

Supply

The factors affecting supply are largely the same as those affecting demand, but in the opposite direction.

If the return on alternative forms of saving falls, people with shares are likely to hold on to them, as they represent a better form of saving. The supply of shares to the market will fall. If incomes or wealth rise, people again are likely to want to hold on to their shares.

As far as expectations are concerned, if people believe that share prices will rise, they will hold on to the shares they have. Supply to the market will fall, thereby pushing up prices. If, however, they believe that prices will fall, as they did in 2008, they will sell their shares now before prices do fall. Supply will increase, driving down the price.

Share prices and business

Companies are crucially affected by their share price. If a company's share price falls, this is taken as a sign that 'the market' is losing confidence, as was the case with Tesco during the latter part of 2014. This will make it more difficult to raise finance, not only by issuing additional shares in the primary market, but also from banks. It will also make the company more vulnerable to a takeover bid. This is where one company seeks to buy out another by offering to buy all its shares. A takeover will succeed if the owners of more than half of the company's shares vote to accept the offered price. Shareholders are more likely to agree to the takeover if they have been disappointed by the recent performance of the company's shares.

1. If the rate of economic growth in the economy is 3 per cent in a particular year, why are share prices likely to rise by more than 3 per cent that year?
2. Find out what has happened to the FTSE 100 index over the past 12 months and explain why (see site B27 on the hotlinks part of the website).
3. Why would you expect the return on shares to be greater than that offered by a bank savings account?

Section summary

1. If the demand for a good exceeds the supply, there will be a shortage. This will lead to a rise in the price of the good.
2. If the supply of a good exceeds the demand, there will be a surplus. This will lead to a fall in the price.
3. Price will settle at the equilibrium. The equilibrium price is the one that clears the market: the price where demand equals supply.
4. If the demand or supply curve shifts, this will lead either to a shortage or to a surplus. Price will therefore either rise or fall until a new equilibrium is reached at the position where the supply and demand curves now intersect.
5. It is difficult to identify the position of a real-world supply (or demand) curve simply by looking at the relationship between price and quantity at different points in time. The problem is that the other curve may have shifted (by an unknown amount).

2.4 ELASTICITY

Price elasticity of demand

When the price of a good rises, the quantity demanded will fall. But in most cases we will want to know more than this. We will want to know by just *how much* the quantity demanded will fall. In other words, we will want to know how *responsive* demand is to a rise in price.

Take the case of two products: oil and cabbages. In the case of oil, a rise in price is likely to result in a relatively small fall in the quantity demanded. If people want to continue driving, they have to pay the higher prices for fuel. A few may turn to riding bicycles, and some people may make fewer journeys, but for most people, a rise in the price of petrol and diesel will make little difference in the short term to how much they use their cars.

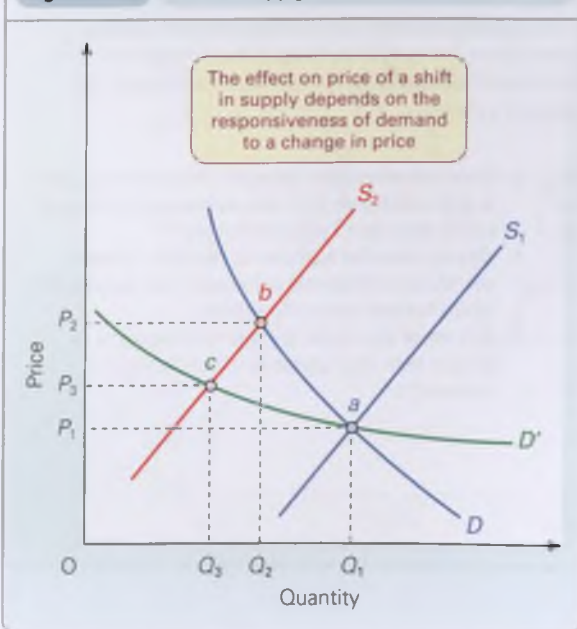

In the case of cabbages, however, a rise in price may lead to a substantial fall in the quantity demanded. The reason is that there are alternative vegetables that people can buy. Many people, when buying vegetables, will buy whatever is reasonably priced.

We call the responsiveness of demand to a change in price the **price elasticity of demand**, and it is one of the most important concepts in economics. For example, if we know the price elasticity of demand for a product, we can predict the effect on price and quantity of a shift in the *supply* curve for that product.

Figure 2.10 shows the effect of a shift in supply with two quite different demand curves (D and D'). Curve D' is more elastic than curve D over any given price range. In other words, for any given change in price, there will be a larger change in quantity demanded along curve D' than along curve D .

Assume that initially the supply curve is S_1 , and that it intersects with both demand curves at point a , at a price of P_1 and a quantity of Q_1 . Now supply shifts to S_2 . What will happen to price and quantity? In the case of the less elastic demand curve D , there is a relatively large rise in price (to P_2) and a relatively small fall in quantity (to Q_2): equilibrium is at point b . In the case of the more elastic demand curve D' , however, there is only a relatively small rise in price (to P_3), but a relatively large fall in quantity (to Q_3): equilibrium is at point c .

Figure 2.10 Market supply and demand

Measuring the price elasticity of demand

What we want to compare is the size of the change in quantity demanded with the size of the change in price. But since price and quantity are measured in different units, the only sensible way we can do this is to use percentage or

Definition

Price elasticity of demand The responsiveness of quantity demanded to a change in price.

proportionate changes. This gives us the following **formula for the price elasticity of demand** (P_{ϵ_D}) for a product: percentage (or proportionate) change in quantity demanded divided by the percentage (or proportionate) change in price. Putting this in symbols gives:

$$P_{\epsilon_D} = \frac{\% \Delta Q_D}{\% \Delta P}$$

where ϵ (the Greek epsilon) is the symbol we use for elasticity, and Δ (the capital Greek delta) is the symbol we use for a 'change in'.

Thus if a 40 per cent rise in the price of oil caused the quantity demanded to fall by a mere 10 per cent, the price elasticity of oil over this range will be

$$-10\%/40\% = -0.25$$

whereas if a 5 per cent fall in the price of cabbages caused a 15 per cent rise in the quantity demanded, the price elasticity of demand for cabbages over this range would be

$$15\%/-5\% = -3$$

Cabbages have a more elastic demand than oil, and this is shown by the figures. But just what do these two figures show? What is the significance of minus 0.25 and minus 3?

Interpreting the figure for elasticity

The use of proportionate or percentage measures

Elasticity is measured in proportionate or percentage terms for the following reasons:

- It allows comparison of changes in two qualitatively different things, which are thus measured in two different types of unit: i.e. it allows comparison of *quantity* changes with *monetary* changes.
- It is the only sensible way of deciding *how big* a change in price or quantity is. Take a simple example. An item goes up in price by £1. Is this a big increase or a small increase? We can answer this only if we know what the original price was. If a can of beans goes up in price by £1 that is a huge price increase. If, however, the price of a house goes up by £1 that is a tiny price increase. In other words, it is the percentage or proportionate increase in price that determines how big a price rise is.

The sign (positive or negative)

Demand curves are generally downward sloping. This means that price and quantity change in opposite directions. A *rise* in price (a positive figure) will cause a *fall* in the quantity demanded (a negative figure). Similarly a *fall* in price will cause a *rise* in the quantity demanded. Thus when working out price elasticity of demand, we either divide a negative figure by a positive figure, or a positive figure by a negative. Either way, we end up with a negative figure.

The value (greater or less than 1)

If we now ignore the negative sign and just concentrate on the value of the figure, this tells us whether demand is *elastic* or *inelastic*.

Elastic ($\epsilon > 1$). This is where a change in price causes a proportionately larger change in the quantity demanded. In this case, the value of elasticity will be greater than 1, since we are dividing a larger figure by a smaller figure. Hence, if the elasticity figure is -2.5 it tells us that if prices were increased by 1 per cent, demand would fall by 2.5 per cent. Customers are very sensitive to a change in the price.

Inelastic ($\epsilon < 1$). This is where a change in price causes a proportionately smaller change in the quantity demanded. In this case, elasticity will be less than 1, since we are dividing a smaller figure by a larger figure. Hence, if the elasticity figure is -0.3 it tells us that if prices were increased by 1 per cent, demand would fall by 0.3 per cent. Customers are relatively insensitive to a change in the price.

Unit elastic ($\epsilon = 1$). **Unit elasticity of demand** occurs where price and quantity demanded change by the same proportion. This will give an elasticity equal to 1, since we are dividing a figure by itself. An increase in price by 1 per cent leads to a fall in demand by 1 per cent.

Determinants of price elasticity of demand

The price elasticity of demand varies enormously from one product to another. For example, the demand for a holiday in any given resort typically has a price elasticity greater than 5, whereas the demand for electricity has a price elasticity less than 0.5 (ignoring the negative signs). But why do some products have a highly elastic demand, whereas others have a highly *inelastic* demand? What determines price elasticity of demand?

The number and closeness of substitute goods. This is the most important determinant. The more substitutes there are and the closer they are to the good, the more people will switch

Definitions

Formula for price elasticity of demand (P_{ϵ_D}) The percentage (or proportionate) change in quantity demanded divided by the percentage (or proportionate) change in price: $\% \Delta Q_D \div \% \Delta P$.

Elastic demand Where quantity demanded changes by a larger percentage than price. Ignoring the negative sign, it will have a value greater than 1.

Inelastic demand Where quantity demanded changes by a smaller percentage than price. Ignoring the negative sign, it will have a value less than 1.

Unit elasticity of demand Where quantity demanded changes by the same percentage as price. Ignoring the negative sign, it will have a value equal to 1.

to these alternatives when the price of the good rises: the greater, therefore, will be the price elasticity of demand. The number of substitutes is strongly influenced by how broadly a market is defined.

A broadly defined market, such as alcohol, has very few substitutes. Customers tend to be relatively insensitive to the price. Using data from the *General Household Survey* and the *Expenditure and Food Survey* (now the *Living Costs and Food Survey*), researchers from the University of Sheffield estimated an elasticity figure for alcohol of -0.40 in the UK.¹ A more narrowly defined market such as beer is likely to have more substitutes (i.e. wine, spirits and cider) so consumers will tend to be less price inelastic. A figure of between -0.98 and -1.27 has been estimated for off-trade beer: i.e. sold in supermarkets and licensed shops.² The elasticity of demand for a good produced by a single firm (i.e. a particular brand of whisky or beer) is likely to be even more price sensitive. Consumers can switch to another supplier of the same product.

? Why will the price elasticity of demand for holidays in Crete be greater than that for holidays in general? Is this difference the result of a difference in the size of the income effect or the substitution effect? Is there anything the suppliers of holidays in Crete can do to reduce this higher price elasticity?

The proportion of income spent on the good. The higher the proportion of our income we spend on a good, the more we will be forced to cut consumption when its price rises: the bigger will be the income effect and the more elastic will be the demand.

Thus salt has a very low price elasticity of demand. Part of the reason is that there is no close substitute. But part is that we spend such a tiny fraction of our income on salt that we would find little difficulty in paying a relatively large percentage increase in its price: the income effect of a price rise would be very small. By contrast, there will be a much bigger income effect when a major item of expenditure rises in price. For example, if mortgage interest rates rise (the 'price' of loans for house purchase), people may have to cut down substantially on their demand for housing – being forced to buy somewhere much smaller and cheaper, or to live in rented accommodation.

? Will a general item of expenditure such as food or clothing have a price-elastic or inelastic demand? (Consider both the determinants we have considered so far.)

1 Petra Meier et al., 'Modelling the potential impact of pricing and promotion policies for alcohol in England: results from the Sheffield Alcohol Policy Model Version 2008 (1-1)', *Independent Review of the Effects of Alcohol Pricing and Promotion* (University of Sheffield, 2008).

2 Y. Meng, A. Brennan, R. Purshouse et al., 'Estimation of own and cross price elasticities of alcohol demand in the UK: A pseudo-panel approach using the Living Costs and Food Survey 2001–2009', *Journal of Health Economics*, vol. 34 (White Rose Research Online, 2014).

The time period. When price rises, people may take time to adjust their consumption patterns and find alternatives. The longer the time period after a price change the more elastic the demand is likely to be.

To illustrate this, let us return to our example of oil. The Office for Budget Responsibility estimates that the price elasticity of demand for fuel is -0.07 in the short run and -0.13 in the medium term. Other studies have estimated a long-run figure of approximately -0.85 .³ Why is the figure for fuel so much more inelastic in the short run than the long run? If fuel prices rise, people will find it difficult to reduce their consumption by a significant amount in the short run. If public transport options are limited, they still have to drive their cars to work and for leisure purposes. Although the number of journeys they make may remain unchanged, some people may be able to reduce their fuel consumption slightly by driving more economically. Firms still have to use fuel to transport their goods and oil may be a major source of energy in a production process that cannot easily be changed.

Over time, people can find other ways to respond, such as purchasing new fuel-efficient vehicles, car sharing or moving closer to their work. Firms can also change their production methods and the way they transport their goods.

? Demand for oil might be relatively elastic over the longer term, and yet it could still be observed that over time people consume more oil (or only very slightly less) despite rising oil prices. How can this apparent contradiction be explained?

Price elasticity of demand and consumer expenditure

One of the most important applications of price elasticity of demand concerns its relationship with the total amount of money consumers spend on a product. **Total consumer expenditure (TE)** is simply price multiplied by quantity purchased.

$$TE = P \times Q$$

For example, if consumers buy 3 million units (Q) at a price of £2 per unit (P), they will spend a total of £6 million (TE).

Total consumer expenditure will be the same as the **total revenue (TR)** received by firms from the sale of the product (before any taxes or other deductions).

Definitions

Total consumer expenditure on a product (TE) (per period of time) The price of the product multiplied by the quantity purchased: $TE = P \times Q$.

Total revenue (TR) (per period of time) The total amount received by firms from the sale of a product, before the deduction of taxes or any other costs. The price multiplied by the quantity sold: $TR = P \times Q$.

3 *Analysis of the Dynamic Effects of Fuel Duty Reductions* (HM Treasury, April 2014).

What will happen to consumer expenditure (and hence firms' revenue) if there is a change in price? The answer depends on the price elasticity of demand.

Elastic demand

As price rises, so quantity demanded falls and vice versa. When demand is elastic, quantity demanded changes proportionately more than price. Thus the change in quantity has a bigger effect on total consumer expenditure than does the change in price. For example, when the price rises, there will be such a large fall in consumer demand that *less* will be spent than before. This can be summarised as follows:

- P rises; Q falls proportionately more; thus TE falls.
- P falls; Q rises proportionately more; thus TE rises.

In other words, total expenditure changes in the same direction as *quantity*.

This is illustrated in Figure 2.11. The areas of the rectangles in the diagram represent total expenditure. Why? The area of a rectangle is its height multiplied by its length. In this case, this is price multiplied by quantity bought, which is total expenditure. Demand is elastic between points a and b . A rise in price from £4 to £5 causes a proportionately larger fall in quantity demanded: from 20 million to 10 million. Total expenditure *falls* from £80 million (the striped area) to £50 million (the pink area).

When demand is elastic, then, a rise in price will cause a fall in total consumer expenditure and thus a fall in the total revenue that firms selling the product receive. A reduction in price, however, will result in consumers spending more, and hence firms earning more.

Inelastic demand

When demand is *inelastic*, it is the other way around. Price changes proportionately more than quantity. Thus the change in price has a bigger effect on total consumer

expenditure than does the change in quantity. To summarise the effects:

- P rises; Q falls proportionately less; TE rises.
- P falls; Q rises proportionately less; TE falls.

In other words, total consumer expenditure changes in the same direction as *price*.

This is illustrated in Figure 2.12. Demand is inelastic between points a and c . A rise in price from £4 to £8 causes a proportionately smaller fall in quantity demanded: from 20 million to 15 million. Total expenditure *rises* from £80 million (the striped area) to £120 million (the pink area).

In this case, firms' revenue will increase if there is a rise in price and fall if there is a fall in price.

Assume that demand for a product is inelastic. Will consumer expenditure go on increasing as price rises? Would there be any limit?

Special cases

Figure 2.13 shows three special cases: (a) a totally inelastic demand ($P_{\epsilon_D} = 0$), (b) an infinitely elastic demand ($P_{\epsilon_D} = \infty$) and (c) a unit elastic demand ($P_{\epsilon_D} = -1$).

Totally inelastic demand. This is shown by a vertical straight line. No matter what happens to price, quantity demanded remains the same. It is obvious that the more the price rises, the bigger will be the level of consumer expenditure. Thus in Figure 2.13(a), consumer expenditure will be higher at P_2 than at P_1 .

Can you think of any examples of goods which have a totally inelastic demand (a) at all prices; (b) over a particular price range?

Infinitely elastic demand. This is shown by a horizontal straight line. At any price above P_1 in Figure 2.13(b), demand is zero. But at P_1 (or any price below) demand is 'infinitely' large.

Figure 2.11 Price elasticity of demand and total expenditure: elastic demand between two points

Figure 2.12 Price elasticity of demand and total expenditure: inelastic demand between two points

Figure 2.13 Price elasticity of demand: special cases

This seemingly unlikely demand curve is in fact relatively common for an *individual producer*. In a perfect market, as we have seen, firms are small relative to the whole market (like the small-scale grain farmer). They have to accept the price as given by supply and demand in the *whole market*, but at that price they can sell as much as they produce. (Demand is not *literally* infinite, but as far as the firm is concerned it is.) In this case, the more the individual firm produces, the more revenue will be earned. In Figure 2.13(b), more revenue is earned at Q_2 than at Q_1 .

Unit elastic demand. This is where price and quantity change in exactly the same proportion. Any rise in price will be exactly offset by a fall in quantity, leaving total consumer expenditure unchanged. In Figure 2.13(c), the striped area is exactly equal to the pink area: in both cases, total expenditure is £800.

You might have thought that a demand curve with unit elasticity would be a straight line at 45° to the axes. Instead it is a curve called a *rectangular hyperbola*. The reason for its shape is that the proportionate *rise* in quantity must equal the proportionate *fall* in price (and vice versa). As we move down the demand curve, in order for the *proportionate* change in both price and quantity to remain constant there must be a bigger and bigger *absolute* rise in quantity and a smaller and smaller absolute fall in price. For example, a rise in quantity from 200 to 400 is the same proportionate change as a rise from 100 to 200, but its absolute size is double. A fall in price from £5 to £2.50 is the same percentage as a fall from £10 to £5, but its absolute size is only half.

To illustrate these figures, draw the demand curve corresponding to the following table.

P	Q	TE
£2.50	400	£1000
£5.00	200	£1000
£10.00	100	£1000
£20.00	50	£1000
£40.00	25	£1000

If the curve had an elasticity of -1 throughout its length, what would be the quantity demanded (a) at a price of £1; (b) at a price of $10p$; (c) if the good were free?

The measurement of elasticity: arc elasticity

We have defined price elasticity as the percentage or proportionate change in quantity demanded divided by the percentage or proportionate change in price. But how, in practice, do we measure these changes for a specific demand curve? We shall examine two methods. The first is called the *arc method*. The second (in an optional section) is called the *point method*.

A common mistake that students make is to think that you can talk about the elasticity of a *whole curve*. In fact in most cases the elasticity will vary along the length of the curve.

Take the case of the demand curve illustrated in Figure 2.14. Between points *a* and *b*, total expenditure rises ($P_2Q_2 > P_1Q_1$): demand is thus elastic between these two points. Between points *b* and *c*, however, total expenditure falls ($P_3Q_3 < P_2Q_2$). Demand here is inelastic.

Normally, then, we can only refer to the elasticity of a *portion* of the demand curve, not of the *whole* curve. There are, however, two exceptions to this rule.

Figure 2.14 Different elasticities along different portions of a demand curve

ADVERTISING AND ITS EFFECT ON DEMAND CURVES

CASE STUDIES AND APPLICATIONS

How to increase sales and price

When we are told that a product will make us more attractive, enrich our lives, make our clothes smell great or allow us to save the planet, just what are the advertisers up to? 'Trying to sell the product', you may reply.

In fact there is a bit more to it than this. Advertisers are trying to do two things:

- Shift the product's demand curve to the right.
- Make it less price elastic.

This is illustrated in the diagram.

Effect of advertising on the demand curve

D_1 shows the original demand curve with price at P_1 and sales at Q_1 . D_2 shows the curve after an advertising campaign. The rightward shift allows an increased quantity (Q_2) to be sold at the original price. If the demand is also made highly inelastic, the firm can raise its price and still have a substantial increase in sales. Thus, in the diagram,

price can be raised to P_2 and sales will be Q_3 – still substantially above Q_1 . The total gain in revenue is shown by the shaded area.

How can advertising bring about this new demand curve?

Shifting the demand curve to the right

This can occur in two ways. First, if advertising brings the product to more people's attention, then the market for the good grows and the demand curve shifts to the right. Second, if the advertising increases people's desire for the product, they will be prepared to pay a higher price for each unit purchased.

Making the demand curve less elastic

This will occur if the advertising creates greater brand loyalty. People must be led to believe (rightly or wrongly) that competitors' brands are inferior. This can be done directly by comparing the brand being advertised with a competitor's product. Alternatively, the adverts may concentrate on making the product seem so special that it implies that no other product can compete. These approaches will allow the firm to raise its price above that of its rivals with no significant fall in sales. The substitution effect will have been lessened because consumers have been led to believe that there are no close substitutes.

1. Think of some advertisements which deliberately seek to make demand less elastic.
2. Imagine that 'Sunshine' sunflower spread, a well-known brand, is advertised with the slogan 'It helps you live longer'. What do you think would happen to the demand curve for a supermarket's own brand of sunflower spread? Consider both the direction of shift and the effect on elasticity. Will the elasticity differ markedly at different prices? How will this affect the pricing policy and sales of the supermarket's own brand? What do you think might be the response of government to the slogan?

The first is when the elasticity just so happens to be the same all the way along a curve, as in the three special cases illustrated in Figure 2.13. The second is where two curves are drawn on the same diagram, as in Figure 2.10. Here we can say that demand curve D is less elastic than demand curve D' at any given price. Note, however, that each of these two curves will still have different elasticities along its length.

Although we cannot normally talk about the elasticity of a whole curve, we can nevertheless talk about the elasticity between any two points on it. This is known as **arc elasticity**. In fact, the formula for price elasticity of demand that we have used so far is the formula for arc elasticity. Let us examine it more closely. Remember the formula we used was:

$$\frac{\text{Proportionate } \Delta Q}{\text{Proportionate } \Delta P} \text{ (where } \Delta \text{ means 'change in')}$$

The way we measure a proportionate change in quantity is to divide that change by the level of Q : $\Delta Q/Q$. Similarly, we measure a proportionate change in price by dividing that change by the level of P : $\Delta P/P$. Price elasticity of demand can thus now be rewritten as

$$\frac{\Delta Q}{Q} \div \frac{\Delta P}{P}$$

But just what value do we give to P and Q ? Consider the demand curve in Figure 2.15. What is the elasticity of

Definition

Arc elasticity The measurement of elasticity between two points on a curve.

Figure 2.15 Measuring elasticity

Similarly, the proportionate change in quantity between points m and n is $10/15$, since 15 is midway between 10 and 20.

Thus using the **average (or 'midpoint') formula**, arc elasticity between m and n is given by:

$$\frac{\Delta Q}{\text{average } Q} \div \frac{\Delta P}{\text{average } P} = \frac{10}{15} \div \frac{-2}{7} = -2.33$$

Since, ignoring the negative sign, 2.33 is greater than 1, demand is elastic between m and n .

? Referring to Figure 2.15, use the midpoint formula to calculate the price elasticity of demand between (a) $P = 6$ and $P = 4$; (b) $P = 4$ and $P = 2$. What do you conclude about the elasticity of a straight-line demand curve as you move down it?

demand between points m and n ? Price has fallen by £2 (from £8 to £6), but what is the proportionate change? Is it $-2/8$ or $-2/6$? The convention is to express the change as a proportion of the average of the two prices, £8 and £6: in other words, to take the midpoint price, £7. Thus the proportionate change is $-2/7$.

Definition

Average (or 'midpoint') formula for price elasticity of demand $\Delta Q_D / \text{average } Q_D \div \Delta P / \text{average } P$.

BOX 2.5 ANY MORE FARES?

CASE STUDIES AND APPLICATIONS

Pricing on the buses

Imagine that a local bus company is faced with increased costs and fears that it will make a loss. What should it do?

The most likely response of the company will be to raise its fares. But this may be the wrong policy, especially if existing services are underutilised. To help it decide what to do, it commissions a survey to estimate passenger demand at three different fares: the current fare of 50p per mile, a higher fare of 60p and a lower fare of 40p. The results of the survey are shown in the first two columns of the table.

Demand turns out to be elastic. This is because of the existence of alternative means of transport. As a result of the elastic demand, total revenue can be increased by reducing the fare from the current 50p to 40p. Revenue would rise from £2m to £2.4m per annum.

But what will happen to the company's profits? Its profit is the difference between the total revenue from passengers and its total costs of operating the service. If buses are currently

underutilised, it is likely that the extra passengers can be carried without the need for extra buses, and hence at no extra cost.

At a fare of 50p, the old profit was £0.2m (£2.0m – £1.8m). After the increase in costs, a 50p fare now gives a loss of £0.2m (£2.0m – £2.2m).

By raising the fare to 60p, the loss is increased to £0.4m. But by lowering the fare to 40p, a profit of £0.2m can again be made.

1. Estimate the price elasticity of demand between 40p and 50p and between 50p and 60p.
2. Was the 50p fare the best fare originally?
3. The company considers lowering the fare to 30p, and estimates that demand will be 8.5 million passenger miles. It will have to put on extra buses, however. How should it decide?

Fare (£ per mile)	Estimated demand (passenger miles per year: millions)	Total revenue (£ millions per year)	Old total cost (£ millions per year)	New total cost (£ millions per year)
(1)	(2)	(3)	(4)	(5)
0.40	6	2.4	1.8	2.2
0.50	4	2.0	1.8	2.2
0.60	3	1.8	1.8	2.2

*The measurement of elasticity: point elasticity

Rather than measuring elasticity between two points on a demand curve, we may want to measure it at a single point: for example, point r in Figure 2.16. In order to measure **point elasticity** we must first rearrange the terms in the formula $\Delta Q/Q = \Delta P/P$. By doing so we can rewrite the formula for price elasticity of demand as:

$$\frac{\Delta Q}{\Delta P} \times \frac{P}{Q}$$

Since we want to measure price elasticity at a *point* on the demand curve, rather than between two points, it is necessary to know how quantity demanded would react to an *infinitesimally small* change in price. In the case of point r in Figure 2.16, we want to know how the quantity demanded would react to an infinitesimally small change from a price of 30.

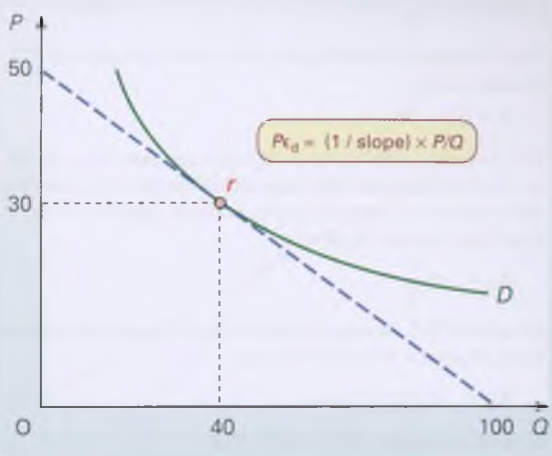

An infinitesimally small change is signified by the letter d . The formula for price elasticity of demand thus becomes

$$\frac{dQ}{dP} \times \frac{P}{Q}$$

where dQ/dP is the differential calculus term for the rate of change of quantity with respect to a change in price (see Appendix 1). And conversely, dP/dQ is the rate of change of price with respect to a change in quantity demanded. At any given point on the demand curve, dP/dQ is given by the *slope* of the curve (its rate of change). The slope is found by drawing a tangent to the curve at that point and finding the slope of the tangent.

The tangent to the demand curve at point r is shown in Figure 2.16. Its slope is $-50/100$. Thus, dP/dQ is $-50/100$ and dQ/dP is the inverse of this, $-100/50 = -2$.

Figure 2.16 Measuring elasticity at a point

Returning to the formula $dQ/dP \times P/Q$, elasticity at point r equals

$$-2 \times 30/40 = -1.5$$

Rather than having to draw the graph and measure the slope of the tangent, the technique of differentiation can be used to work out point elasticity as long as the equation for the demand curve is known. An example of the use of this technique is given in Box 2.6 (on page 64).

Definition

Point elasticity The measurement of elasticity at a point on a curve. The formula for price elasticity of demand using the point elasticity method is $dQ/dP \times P/Q$, where dQ/dP is the inverse of the slope of the tangent to the demand curve at the point in question.

* LOOKING AT THE MATHS

Elasticity of a straight-line demand curve

A straight-line demand curve has a different elasticity at each point on it. The only exceptions are a vertical demand curve ($P_{E_D} = 0$) and a horizontal demand curve ($P_{E_D} = \infty$). The reason for this differing elasticity can be demonstrated using the equation for a straight-line demand curve:

$$Q = a - bP$$

The term $-b$ would give the slope of the demand curve if we were to plot Q on the vertical axis and P on the horizontal. Since we plot them the other way around,¹ the term $'b'$ gives the inverse of the slope as plotted. The slope of the curve as plotted is given by dP/dQ ; the inverse of the slope is given by $dQ/dP = -b$.

The formula for price elasticity of demand (using the point elasticity method) is

$$P_{E_D} = \frac{dQ}{dP} \cdot \frac{P}{Q}$$

Different elasticities along a straight-line demand curve

This can thus be rewritten as

$$P\epsilon_D = -b \frac{P}{Q}$$

This is illustrated in the diagram, which plots the following demand curve:

$$Q = 50 - 5P$$

The slope of the demand curve (dP/dQ) is constant (i.e. $-10/50$ or -0.2). The inverse of the slope (dQ/dP) is thus -5 , where 5 is the 'b' term in the equation. In this example, therefore, price elasticity of demand is given by

$$P\epsilon_D = -5 \frac{P}{Q}$$

The value of P/Q , however, differs along the length of the demand curve. At point n , $P/Q = 8/10$. Thus

$$P\epsilon_D = -5(8/10) = -4$$

At point m , however, $P/Q = 6/20$. Thus

$$P\epsilon_D = -5(6/20) = -1.5$$

These questions refer to the diagram.

1. What is the price elasticity of demand at points l and k ?
2. What is the price elasticity of demand at the point (a) where the demand curve crosses the vertical axis; (b) where it crosses the horizontal axis?
3. As you move down a straight-line demand curve, what happens to elasticity? Why?
4. Calculate price elasticity of demand between points n and l using the arc method. Does this give the same answer as the point method? Would it if the demand curve were actually curved?

1 It is contrary to normal convention to plot the independent variable (P) on the vertical axis and the dependent variable (Q) on the horizontal axis. The reason why we do this is because there are many other diagrams in economics where Q is the *independent* variable. Such diagrams include cost curves and revenue curves, which we will consider in Chapter 6. As you will see, it is much easier if we *always* plot Q on the horizontal axis even when, as in the case of demand curves, Q is the dependent variable.

* BOX 2.6

USING CALCULUS TO CALCULATE THE PRICE ELASTICITY OF DEMAND

EXPLORING ECONOMICS

(A knowledge of the rules of differentiation is necessary to understand this box. See Appendix 1.)

The following is an example of an equation for a demand curve:

$$Q_d = 60 - 15P + P^2$$

(where Q_d is measured in thousands of units). From this the following table and the graph can be constructed.

P	60	$-15P$	$+P^2$	=	Q_d (000s)
0	60	-0	+0	=	60
1	60	-15	+1	=	46
2	60	-30	+4	=	34
3	60	-45	+9	=	24
4	60	-60	+16	=	16
5	60	-75	+25	=	10
6	60	-90	+36	=	6

Point elasticity can be easily calculated from such a demand equation using calculus. To do this you will need to know the rules of differentiation (see pages A: 9–12). Remember the formula for point elasticity:

$$P\epsilon_D = dQ/dP \times P/Q$$

The term dQ/dP can be calculated by differentiating the demand equation:

$$\begin{aligned} \text{Given } Q_d &= 60 - 15P + P^2 \\ \text{then } dQ/dP &= -15 + 2P \end{aligned}$$

Thus at a price of 3, for example,

$$\begin{aligned} dQ/dP &= -15 + (2 \times 3) \\ &= -9 \end{aligned}$$

Thus price elasticity of demand at a price of 3

$$\begin{aligned} &= -9 \times P/Q \\ &= -9 \times 3/24 \\ &= -9/8 \text{ (which is elastic)} \end{aligned}$$

Calculate the price elasticity of demand on this demand curve at a price of (a) 5; (b) 2; (c) 0.

Price elasticity of supply ($P\epsilon_s$)

When price changes, there will be not only a change in the quantity demanded, but also a change in the quantity supplied. Frequently we will want to know just how responsive quantity supplied is to a change in price. The measure we use is the *price elasticity of supply*.

Figure 2.17 shows two supply curves. Curve S_2 is more elastic between any two prices than curve S_1 . Thus, when price rises from P_1 to P_2 there is a larger increase in quantity supplied with S_2 (namely, Q_1 to Q_3) than there is with S_1 (namely, Q_1 to Q_2). For any shift in the demand curve there will be a larger change in quantity supplied and a smaller change in price with curve S_2 than with curve S_1 . Thus the effect on price and quantity of a shift in the demand curve will depend on the price elasticity of supply.

The *formula for the price elasticity of supply* ($P\epsilon_s$) is: the percentage (or proportionate) change in quantity supplied divided by the percentage (or proportionate) change in price. Putting this in symbols gives

$$P\epsilon_s = \frac{\% \Delta Q_s}{\% \Delta P}$$

In other words, the formula is identical to that for the price elasticity of demand, except that quantity in this case is quantity *supplied*. Thus if a 10 per cent rise in price caused a 25 per cent rise in the quantity supplied, the price elasticity of supply would be

$$25\%/10\% = 2.5$$

and if a 10 per cent rise in price caused only a 5 per cent rise in the quantity, the price elasticity of supply would be

$$5\%/10\% = 0.5$$

In the first case, supply is elastic ($P\epsilon_s > 1$); in the second it is inelastic ($P\epsilon_s < 1$). Notice that, unlike the price elasticity of demand, the figure is positive. This is because price and quantity supplied change in the *same* direction.

Determinants of price elasticity of supply

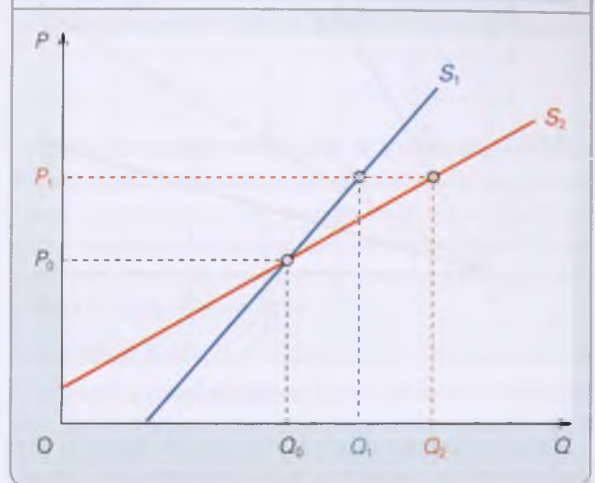

The amount that costs rise as output rises. The less the additional costs of producing additional output, the more firms will be encouraged to produce for a given price rise: the more elastic will supply be.

Supply is thus likely to be elastic if firms have plenty of spare capacity, if they can readily get extra supplies of raw materials, if they can easily switch away from producing alternative products and if they can avoid having to introduce overtime working, at higher rates of pay. The less these conditions apply, the less elastic will supply be.

Time period

- Immediate time period. Firms are unlikely to be able to increase supply by much immediately. Supply is virtually fixed, or can only vary according to available stocks. Supply is highly inelastic.

Figure 2.17 Supply curves with different price elasticity of supply

- Short run. If a slightly longer period of time is allowed to elapse, some inputs can be increased (e.g. raw materials) while others will remain fixed (e.g. heavy machinery). Supply can increase somewhat.
- Long run. In the long run, there will be sufficient time for all inputs to be increased and for new firms to enter the industry. Supply, therefore, is likely to be highly elastic in many cases. In some circumstances the long-run supply curve may even slope downwards. (See the section on economies of scale in Chapter 6, pages 162–3.)

The measurement of price elasticity of supply

A vertical supply has zero elasticity. It is totally unresponsive to a change in price. A horizontal supply curve has infinite elasticity. There is no limit to the amount supplied at the price where the curve crosses the vertical axis.

When two supply curves cross, the steeper one will have the lower price elasticity of supply (e.g. curve S_1 in Figure 2.17). Any straight-line supply curve starting at the origin, however, will have an elasticity equal to 1 throughout its length, *irrespective of its slope*. This perhaps rather surprising result is illustrated in Figure 2.18. This shows three supply curves, each with a different slope, but each starting from the origin. On each curve two points are marked. In each case there is the *same* proportionate rise in Q as in P . For example, with curve S_1 a doubling in price from £3 to £6 leads to a doubling of output from 1 unit to 2 units.

Definitions

Price elasticity of supply The responsiveness of quantity supplied to a change in price.

Formula for price elasticity of supply ($P\epsilon_s$) The percentage (or proportionate) change in quantity supplied divided by the percentage (or proportionate) change in price: $\% \Delta Q_s \div \% \Delta P$. Using the arc formula, this is calculated as $\Delta Q_s / \text{average } Q_s \div \Delta P / \text{average } P$

Figure 2.18 Unit elastic supply curves

This demonstrates nicely that it is not the *slope* of a curve that determines its elasticity, but its proportionate change.

Other supply curves' elasticities will vary along their length. In such cases we have to refer to the elasticity either between two points on the curve, or at a specific point. Calculating elasticity between two points will involve the *arc method*. Calculating elasticity at a point will involve the point method. These two methods are just the same for supply curves as for demand curves: the formulae are the same, only the term Q now refers to quantity supplied rather than quantity demanded.

Income elasticity of demand

So far we have looked at the responsiveness of demand and supply to a change in price. But price is just one of the determinants of demand and supply. In theory, we could look at the responsiveness of demand or supply to a change in *any* one of their determinants. We could have a whole range of different types of elasticity of demand and supply.

Elasticity. The responsiveness of one variable (e.g. demand) to a change in another (e.g. price). This concept is fundamental to understanding how markets work. The more elastic variables are, the more responsive is the market to changing circumstances.

In practice, there are just two other elasticities that are particularly useful to us, and both are demand elasticities.

The first is the *income elasticity of demand* (Y_{ϵ_D}). This measures the responsiveness of demand to a change in consumer incomes (Y). It enables us to predict how much the demand curve will shift for a given change in income. The *formula for the income elasticity of demand* is: the percentage (or proportionate) change in demand divided by the percentage (or proportionate) change in income. Putting this in symbols gives

$$Y_{\epsilon_D} = \frac{\% \Delta Q_D}{\% \Delta Y}$$

*LOOKING AT THE MATHS

We can use a supply equation to demonstrate why a straight-line supply curve through the origin has an elasticity equal to 1. Assume that the supply equation is

$$Q_s = a + bP \quad (1)$$

If the supply curve passes through the origin, the value of $a = 0$. Thus:

$$Q_s = bP \quad (2)$$

The point elasticity formula for price elasticity of supply is similar to that for price elasticity of demand (see page 63) and is given by

$$P\epsilon_s = \frac{dQ_s}{dP} \cdot \frac{P}{Q_s} \quad (3)$$

But

$$b = \frac{dQ_s}{dP} \quad (4)$$

since this is the slope of the equation (the inverse of the slope of the curve). Substituting equation (4) in equation (3) gives

$$P\epsilon_s = b \cdot \frac{P}{Q_s} \quad (5)$$

Substituting equation (2) in equation (5) gives:

$$\begin{aligned} P\epsilon_s &= b \cdot \frac{P}{bP} \\ &= \frac{bP}{bP} \\ &= 1 \end{aligned}$$

Given the following supply schedule:

P	2	4	6	8	10
Q	0	10	20	30	40

- Draw the supply curve.
- Using the arc method, calculate price elasticity of supply (i) between $P = 2$ and $P = 4$; (ii) between $P = 8$ and $P = 10$
- *Using the point method, calculate price elasticity of supply at $P = 6$
- Does the elasticity of the supply curve increase or decrease as P and Q increase? Why?
- What would be the answer to (d) if the supply curve were a straight line but intersecting the horizontal axis to the right of the origin?

Definitions

Formula for price elasticity of supply (arc method)
 $\Delta Q_s / \text{average } Q_s \div \Delta P / \text{average } P$.

Income elasticity of demand The responsiveness of demand to a change in consumer incomes.

Formula for income elasticity of demand (Y_{ϵ_D}) The percentage (or proportionate) change in demand divided by the percentage (or proportionate) change in income:
 $\% \Delta Q_D \div \% \Delta Y$.

In other words, the formula is identical to that for the price elasticity of demand, except that we are dividing the change in demand by the change in income that caused it rather than by a change in price. Thus if a 2 per cent rise in income caused an 8 per cent rise in a product's demand, then its income elasticity of demand would be:

$$8\%/2\% = 4$$

The major determinant of income elasticity of demand is the degree of 'necessity' of the good. In a developed country, the demand for luxury goods expands rapidly as people's incomes rise, whereas the demand for basic goods rises only a little. Thus items such as designer handbags and foreign holidays have a high income elasticity of demand, whereas items such as vegetables and socks have a low income elasticity of demand.

If income elasticity of demand is positive and greater than 1 then this tells us that the share of consumers' income spent on the good increases as their income rises. If the figure is positive but less than 1 then this tells us that the share of consumers' income spent on the good falls as income rises. In both of these cases people demand more of the good as incomes rise. However, the demand for some goods actually *decreases* as people's incomes rise beyond a certain level. These are inferior goods such as supermarkets' 'value lines' and bus journeys. As people earn more, so they switch to better quality products. Unlike **normal goods**, which have a positive income elasticity of demand, **inferior goods** have a negative income elasticity of demand.

Look ahead to Table 3.1 (page 96). It shows the income elasticity of demand for various foodstuffs. Explain the difference in the figures for milk, bread and fresh fish.

Income elasticity of demand is an important concept to firms considering the future size of the market for their product. If the product has a high income elasticity of demand, sales are likely to expand rapidly as national income rises, but may also fall significantly if the economy moves into recession. (See Case Study 2.5, *Income elasticity of demand and the balance of payments*, on the student website. This shows how the concept of income elasticity of demand can help us understand why so many developing countries have chronic balance of payments problems.)

Cross-price elasticity of demand ($C\epsilon_{D_{AB}}$)

This is often known by its less cumbersome title of **cross elasticity of demand**. It is a measure of the responsiveness of demand for one product to a change in the price of another (either a substitute or a complement). It enables us to predict how much the demand curve for the first product will shift when the price of the second product changes.

The **formula for the cross-price elasticity of demand** ($C\epsilon_{D_{AB}}$) is: the percentage (or proportionate) change in demand for good A divided by the percentage (or proportionate) change in price of good B. Putting this in symbols gives

$$C\epsilon_{D_{AB}} = \frac{\% \Delta Q_{D_A}}{\% \Delta P_B}$$

If good B is a **substitute** for good A, A's demand will *rise* as B's price rises. In this case, cross elasticity will be a positive figure. For example, if the demand for butter rose by 2 per cent when the price of margarine (a substitute) rose by 8 per cent, then the cross elasticity of demand for butter with respect to margarine would be

$$2\%/8\% = 0.25$$

If good B is **complementary** to good A, however, A's demand will *fall* as B's price rises and thus as the quantity of B demanded falls. In this case, cross elasticity of demand will be a negative figure. For example, if a 4 per cent rise in the price of bread led to a 3 per cent fall in demand for butter, the cross elasticity of demand for butter with respect to bread would be

$$-3\%/4\% = -0.75$$

The major determinant of cross elasticity of demand is the closeness of the substitute or complement. The closer it is, the bigger will be the effect on the first good of a change in the price of the substitute or complement, and hence the greater the cross elasticity – either positive or negative. For example, a figure of 1.169 has been estimated for the cross-price elasticity of demand for on-trade spirits (i.e. whisky, vodka, etc.) with respect to the price of on-trade beer. This suggests they are moderately close substitutes in consumption.

Firms need to know the cross elasticity of demand for their product when considering the effect on the demand for their product of a change in the price of a rival's product or of a complementary product. These are vital pieces of information for firms when making their production plans.

Definitions

Normal goods Goods whose demand increases as consumer incomes increase. They have a positive income elasticity of demand. Luxury goods will have a higher income elasticity of demand than more basic goods.

Inferior goods Goods whose demand decreases as consumer incomes increase. Such goods have a negative income elasticity of demand.

Cross-price elasticity of demand The responsiveness of demand for one good to a change in the price of another.

Formula for cross-price elasticity of demand ($C\epsilon_{D_{AB}}$) The percentage (or proportionate) change in demand for good A divided by the percentage (or proportionate) change in price of good B: $\% \Delta Q_{D_A} \div \% \Delta P_B$.

THRESHOLD CONCEPT 6

ELASTICITY: OF A VARIABLE TO A CHANGE IN A DETERMINANT

THINKING LIKE AN ECONOMIST

As we have seen in the case of price elasticity of demand, elasticity measures the responsiveness of one variable (e.g. quantity demanded) to change in another (e.g. price). This concept is fundamental to understanding how markets work. The more elastic variables are, the more responsive is the market to changing circumstances.

Elasticity is more than just a technical term. It's not difficult to learn the formula

$$P\epsilon_D = \frac{\% \Delta Q_D}{\% \Delta P}$$

in the case of price elasticity of demand, and then to interpret this as

$$P\epsilon_D = \frac{\Delta Q_D}{\text{average } Q_D} \div \frac{\Delta P}{\text{average } P}$$

using the arc elasticity method, or as

$$P\epsilon_D = \frac{dQ_D}{dP} \times \frac{P}{Q}$$

using the point elasticity method.

We can also very simply state the general formula for any elasticity as

$$\epsilon_{XY} = \frac{\% \Delta X}{\% \Delta Y}$$

where the formula refers to the responsiveness of variable X to a change in variable Y (where X could be quantity supplied or demanded, and Y could be price, income, the price of substitutes, or any other determinant of demand or supply). Again, we could use the arc or point elasticity methods. Although students often find it hard at first to use the formulae, it's largely a question of practice in mastering them.

What makes elasticity a *threshold concept* is that it lies at the heart of how economic systems operate. In a market economy, prices act as signals that demand or supply has changed. They also act as an incentive for people to respond to the new circumstances. The greater the elasticity of demand, the bigger will be the response to a change in supply; the greater the elasticity of supply, the bigger will be the response to a change in demand.

Understanding elasticity and what determines its magnitude helps us understand how an economy is likely to respond to the ever-changing circumstances of the real world.

In a perfect market economy, firms face an infinitely elastic (horizontal) demand curve: they are price takers (see pages 59–60 and Figure 2.13(b)). What this means is that they have no power to affect prices: they are highly dependent on market forces.

By contrast, big businesses (and some small ones too) are in a very different position. If there are only one or two firms in a market, each is likely to face a relatively inelastic demand. This gives them the power to raise prices and make more profit. As we have seen, if demand is price inelastic, then raising price will increase the firm's revenue (see Figure 2.13(b)). Even if demand is elastic (but still downward sloping) the firm could still increase profit by raising prices, provided that the fall in revenue was less than the reduction in costs from producing less. The general point here is that the less elastic is the firm's demand curve, the greater will be its power to raise prices and make a bigger profit.

It's not just price elasticity of demand that helps us understand how market economies operate. In a perfect market, market supply is likely to be highly elastic, especially in the long run after firms have had time to enter the industry. Thus, if a new lower-cost technique is discovered, which increases profits in an industry, new firms will enter the market, attracted by the higher profits. This increased supply will then have the effect of driving prices down and hence profit rates will fall back. What this means is that in highly competitive industries firms are very responsive to changing economic circumstances. If they are not, they are likely to be forced out of business; it's a question of survival of the fittest. We explore this process in more detail in section 7.2.

If there is less competition, firms have an easier life. But what is good for them may be bad for us as consumers. We may end up paying higher prices and having poorer quality goods – although not necessarily. We explore this in sections 7.3 and 7.4 and in Chapter 8.

So, getting to grips with elasticity is not just about doing calculations. It's about understanding the very essence of how economies operate.

1. What would you understand by the 'wage elasticity of demand for labour'? How would the magnitude of this elasticity affect the working of the market for (a) plumbers and (b) footballers?
2. How can income elasticity of demand help explain how the structure of economies changes over the years?

Another application of the concept of cross elasticity of demand is in the field of international trade and the balance of payments. How does a change in the price of domestic goods affect the demand for imports? If there is a high cross elasticity of demand for imports (because they are close substitutes for home-produced goods), and if

prices at home rise due to inflation, the demand for imports will rise substantially, thus worsening the balance of trade.

Which are likely to have the highest cross elasticity of demand: two brands of coffee, or coffee and tea?

* LOOKING AT THE MATHS

Calculating income and cross-price elasticities from a demand equation

The following demand equation relates quantity demanded (Q_A) for good A to its own price (P_A), consumer income (Y) and the price of a substitute good B (P_B).

$$Q_A = a - bP_A + cY + eP_B$$

Note that this is a 'linear' equation because it has no power terms, such as P^2 or Y^2 . The formula¹ for income elasticity of demand for good A will be

$$Y\epsilon_D = \frac{\partial Q_A}{\partial Y} \cdot \frac{Y}{Q_A}$$

But since the term $\partial Q_A / \partial Y$ represents the amount that Q_A will change for a given change in Y (i.e. the value of c), then

$$Y\epsilon_D = c \frac{Y}{Q_A}$$

Similarly, the formula for cross-price elasticity of demand for good A with respect to good B will be

$$\epsilon_{D_{AB}} = \frac{\partial Q_A}{\partial P_B} \cdot \frac{P_B}{Q_A} = e \frac{P_B}{Q_A}$$

A worked example of these two formulae is given in Maths Case 2.2 on the student website. We can also use calculus to work out the two elasticities for both linear and non-linear demand equations. A worked example of this is given in Maths Case 2.3 on the student website.

1 Note that in this case we use the symbol '∂' rather than 'd' to represent an infinitesimally small change. This is the convention when the equation contains more than one independent variable (in this case P_A , Y and P_B). The term $\partial Q_A / \partial Y$ is the 'partial derivative' (see page A:13) and refers to the rate of change of Q_A to just one of the three variables (in this case Y).

Section summary

- Elasticity is a measure of the responsiveness of demand (or supply) to a change in one of the determinants.
- It is defined as the proportionate change in quantity demanded (or supplied) divided by the proportionate change in the determinant.
- If quantity changes proportionately more than the determinant, the figure for elasticity will be greater than 1 (ignoring the sign): it is elastic. If the quantity changes proportionately less than the determinant, the figure for elasticity will be less than 1: it is inelastic. If they change by the same proportion, the elasticity has a value of 1: it is unit elastic.
- Price elasticity of demand measures the responsiveness of demand to a change in price. Given that demand curves are downward sloping, price elasticity of demand will have a negative value. Demand will be more elastic the greater the number and closeness of substitute goods, the higher the proportion of income spent on the good and the longer the time period that elapses after the change in price.
- When demand is price elastic, a rise in price will lead to a reduction in total expenditure on the good and hence a reduction in the total revenue of producers.
- Demand curves normally have different elasticities along their length. We can thus normally refer only to the specific value for elasticity between two points on the curve or at a single point.
- Elasticity measured between two points is known as arc elasticity. When applied to price elasticity of demand the formula is

$$\frac{\Delta Q_d}{\text{average } Q_d} \div \frac{\Delta P}{\text{average } P}$$
- Elasticity measured at a point is known as *point elasticity*. When applied to price elasticity of demand the formula is

$$\frac{dQ}{dP} \times \frac{P}{Q}$$
 where dQ/dP is the inverse of the slope of the tangent to the demand curve at the point in question.
- Price elasticity of supply measures the responsiveness of supply to a change in price. It has a positive value. Supply will be more elastic the less costs per unit rise as output rises and the longer the time period.
- Income elasticity of demand measures the responsiveness of demand to a change in income. For normal goods it has a positive value. Demand will be more income elastic the more luxurious the good and the less rapidly demand is satisfied as consumption increases. For inferior goods, income elasticity has a negative value.
- Cross-price elasticity of demand measures the responsiveness of demand for one good to a change in the price of another. For substitute goods the value will be positive; for complements it will be negative. The cross-price elasticity will be higher the closer the two goods are as substitutes or complements.

2.5 THE TIME DIMENSION

The full adjustment of price, demand and supply to a situation of disequilibrium will not be instantaneous. It is necessary, therefore, to analyse the time path which supply takes in responding to changes in demand, and which demand takes in responding to changes in supply.

Short-run and long-run adjustment

As we saw in the previous section, elasticity varies with the time period under consideration. The reason is that producers and consumers take time to respond to a change in price. The longer the time period, the bigger the response, and thus the greater the elasticity of supply and demand.

This is illustrated in Figures 2.19 and 2.20. In both cases, as equilibrium moves from points *a* to *b* to *c*, there is a large short-run price change (P_1 to P_2) and a small short-run quantity change (Q_1 to Q_2), but a small long-run price change (P_1 to P_3) and a large long-run quantity change (Q_1 to Q_3).

Price expectations and speculation

In a world of shifting demand and supply curves, prices do not stay the same. Sometimes they go up; sometimes they come down.

If people think prices are likely to change in the foreseeable future, this will affect the behaviour of buyers and sellers *now*. If, for example, it is now December and you are thinking of buying a new television, you might decide to wait until the January sales, and in the meantime make do with your

set. If, on the other hand, in December you see a summer holiday advertised that you like, you might well book it then and not wait until nearer the summer for fear that the price will have gone up by then. Thus a belief that prices will go up will cause people to buy now; a belief that prices will come down will cause them to wait.

The reverse applies to sellers. If you are thinking of selling your house and prices are falling, you will want to sell it as quickly as possible. If, on the other hand, prices are rising sharply, you will wait as long as possible so as to get the highest price. Thus a belief that prices will come down will cause people to sell now; a belief that prices will go up will cause them to wait.

KEY
IDEA
10

People's actions are influenced by their expectations.

People respond not just to what is happening now (such as a change in price), but to what they anticipate will happen in the future.

This behaviour of looking into the future and making buying and selling decisions based on your predictions is called *speculation*. Speculation is often based on current

Definition

Speculation Where people make buying or selling decisions based on their anticipations of future prices.

Figure 2.19 Response of supply to an increase in demand

Figure 2.20 Response of demand to an increase in supply

trends in prices. If prices are currently rising, people may try to decide whether they are about to peak and go back down again, or whether they are likely to go on rising. Having made their prediction, they will then act on it. Their actions will then affect demand and supply, which in turn will affect price. Speculation is commonplace in many markets: the stock exchange, the foreign exchange market and the housing market are three examples.

Sometimes people will take advantage of expected price rises purely to make money and have no intention of keeping the item they have bought. For example, if shares in a particular company are expected to rise in price, people may buy them now while they are cheap and sell them later when the price has risen, thereby making a profit from the difference in price.

Similarly, people will sometimes take advantage of expected price reductions by selling something now only to buy it back later. For example, if you own shares and expect their price to fall, you may sell them now and buy them back later when their price has fallen. Again, you make a profit from the difference in price.

Sometimes the term *speculation* is used in this narrower sense of buying (or selling) commodities or financial assets simply to make money from later selling them (or buying them back) again at a higher (or lower) price. The term *speculators* usually refers to people engaged in such activities.

In the extreme case, speculators need not part with any money. If they buy an item and sell it back fairly soon at a higher price, they may be able to use the money from the sale to pay the original seller: just pocketing the difference. Alternatively, speculators may sell an item they do not even possess, as long as they can buy it back in time (at a lower price) to hand it over to the original purchaser. Again, they simply pocket the difference in price.

It may sound as if speculators are on to a good thing, and often they are, but speculation does carry risks: the predictions of individual speculators may turn out to be wrong, and then they could make losses rather than profits.

Nevertheless, speculators on average tend to gain rather than lose. The reason is that speculation tends to be *self-fulfilling*. In other words, the actions of speculators tend to bring about the very effect on prices that they had anticipated. For example, if speculators believe that the price of Barclays shares is about to rise, they will buy some. But by doing this they will contribute to an increase in demand and ensure that the price *will* rise; the prophecy has become self-fulfilling.

Speculation can either help to reduce price fluctuations or aggravate them: it can be stabilising or destabilising.

Stabilising speculation

Speculation will tend to have a *stabilising* effect on price fluctuations when suppliers and/or demanders believe that a change in price is only *temporary*.

An initial fall in price. In Figure 2.21 demand has shifted from D_1 to D_2 ; equilibrium has moved from point a to point b , and price has fallen to P_2 . How do people react to this fall in price?

Given that they believe this fall in price to be only temporary, suppliers *hold back*, expecting prices to rise again: supply shifts from S_1 to S_2 . After all, why supply now when, by waiting, they could get a higher price?

Definitions

Speculators People who buy (or sell) commodities or financial assets with the intention of profiting by selling them (or buying them back) at a later date at a higher (lower) price.

Self-fulfilling speculation The actions of speculators tend to cause the very effect that they had anticipated.

Stabilising speculation Where the actions of speculators tend to reduce price fluctuations.

Figure 2.21 Stabilising speculation: initial price fall

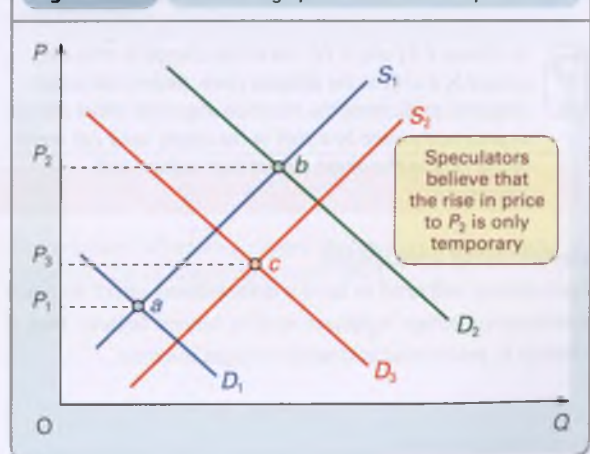

Figure 2.22 Stabilising speculation: initial price rise

Buyers *increase* their purchases, to take advantage of the temporary fall in price. Demand shifts from D_2 to D_3 .

The equilibrium moves to point c , with price rising back towards P_1 .

An initial rise in price. In Figure 2.22 demand has shifted from D_1 to D_2 . Price has risen from P_1 to P_2 .

Suppliers bring their goods to market now, before price falls again. Supply shifts from S_1 to S_2 . Demanders, however, hold back until price falls. Demand shifts from D_2 to D_3 . The equilibrium moves to point c , with price falling back towards P_1 .

An example. A good example of stabilising speculation is that which occurs in agricultural commodity markets. Take the case of wheat. When it is harvested in the autumn, there will be a plentiful supply. If all this wheat were to be put on the market, the price would fall to a very low level. Later in the year, when most of the wheat would have been sold, the price would then rise to a very high level. This is all easily predictable.

So what do farmers do? The answer is that they speculate. When the wheat is harvested, they know price will tend to fall, and so instead of bringing it all to market they put some into store. The more the price falls, the more they will put into store *anticipating that the price will later rise*. But this holding back of supplies prevents prices from falling. In other words, it stabilises prices.

Later in the year, when the price begins to rise, they will gradually release grain onto the market from the stores. The more the price rises, the more they will release on to the market *anticipating that the price will fall again by the time of the next harvest*. But this releasing of supplies will again stabilise prices by preventing them from rising so much.

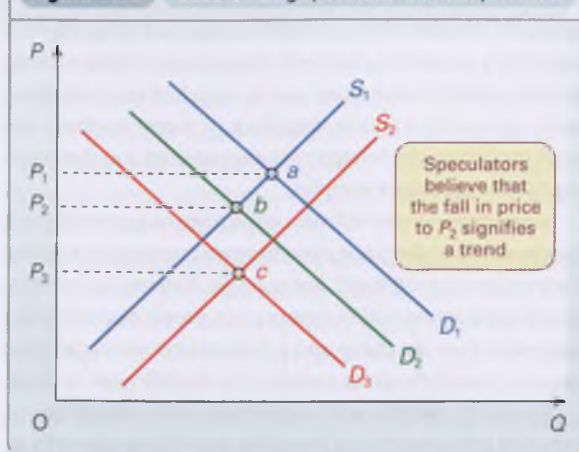

Rather than the farmers doing the speculation, it could be done by grain merchants. When there is a glut of wheat in the autumn, and prices are relatively low, they buy wheat on the grain market and put it into store. When there is a shortage in the spring and summer they sell wheat from their stores. In this way they stabilise prices just as the farmers did when they were the ones who operated the stores.

? In Figures 2.21 and 2.22, the initial change in price was caused by a shift in the demand curve. Redraw these two diagrams to illustrate the situation where the initial change in price was caused by a shift in the supply curve (as would be the case in the wheat market that we have just considered).

Destabilising speculation

Speculation will tend to have a *destabilising* effect on price fluctuations when suppliers and/or buyers believe that a change in price heralds similar changes to come.

Figure 2.23 Destabilising speculation: initial price fall

An initial fall in price. In Figure 2.23 demand has shifted from D_1 to D_2 and price has fallen from P_1 to P_2 . This time, believing that the fall in price heralds further falls in price to come, suppliers sell now before the price does fall. Supply shifts from S_1 to S_2 . And demanders wait: they wait until price does fall further. Demand shifts from D_2 to D_3 .

Their actions ensure that price does fall further: to P_3 .

An initial rise in price. In Figure 2.24 a price rise from P_1 to P_2 is caused by a rise in demand from D_1 to D_2 . Suppliers wait until price rises further. Supply shifts from S_1 to S_2 . Demanders buy now before any further rise in price. Demand shifts from D_2 to D_3 . As a result, price continues to rise: to P_3 .

In section 2.3 we examined the housing market (see Box 2.2). In this market, speculation is frequently destabilising. Assume that people see house prices beginning to move upwards. This might be the result of increased demand brought about by a cut in mortgage interest rates or by growth in the economy. People may well believe that the rise in house prices signals a boom in the housing market: that prices will go on rising. Potential buyers will thus try to buy as soon as possible before prices rise any further. This will increase demand (as in Figure 2.24) and will thus lead to even bigger price rises. This is precisely what happened in the UK housing market in 1999–2007 and from mid-2013 (see chart in Box 2.2 on page 50). Conversely, in early 2008 prices started to fall; potential buyers believed that they would fall

Definition

Destabilising speculation Where the actions of speculators tend to make price movements larger.

Figure 2.24 Destabilising speculation: initial price rise

further and thus held off entering the market, leading to even bigger price falls.

? Estate agents consistently 'talk up' the housing market, often predicting price rises when other commentators are more cautious. Explain why they might have a vested interest in doing so.

Conclusion

In some circumstances, then, the action of speculators can help to keep price fluctuations to a minimum (stabilising speculation). This is most likely when markets are relatively stable in the first place, with only moderate underlying shifts in demand and supply.

In other circumstances, however, speculation can make price fluctuations much worse. This is most likely in times of uncertainty, when there are significant changes in the determinants of demand and supply. Given this uncertainty, people may see price changes as signifying some trend. They then 'jump on the bandwagon' and do what the rest are doing, further fuelling the rise or fall in price.

? Redraw Figures 2.23 and 2.24 assuming, as in the previous question, that the initial change in price was caused by a shift in the supply curve.

Dealing with uncertainty and risk

When price changes are likely to occur, buyers and sellers will try to anticipate them. Unfortunately, on many occasions no one can be certain just what these price changes will be. Take the case of stocks and shares. If you anticipate that the price of, say, Marks & Spencer shares is likely to go up substantially in the near future, you may well decide to buy some now and then sell them later after the price has risen. But you cannot be certain that they will go up in price: they may fall instead. If you buy the shares, therefore, you will be taking a gamble.

Now, gambles can be of two types. The first is where you know the odds. Let us take the simplest case of a gamble on the toss of a coin. Heads you win; tails you lose. You know that the odds of winning are precisely 50 per cent. If you bet on the toss of a coin, you are said to be operating under conditions of **risk**. Risk is when the probability of an outcome is known. Risk itself is a measure of the variability of an outcome. For example, if you bet £1 on the toss of a coin, such that heads you win £1 and tails you lose £1, then the variability is $-\text{£}1$ to $+\text{£}1$.

The second form of gamble is the more usual. This is where the odds are not known or are known only roughly. Gambling on the stock exchange is like this. You may have a good idea that a share will go up in price, but is it a 90 per cent chance, an 80 per cent chance or what? You are not certain. Gambling under this sort of condition is known as operating under **uncertainty**. This is when the probability of an outcome is not known.

You may well disapprove of gambling and want to dismiss people who engage in it as foolish or morally wrong. But 'gambling' is not just confined to horses, cards, roulette and the like. Risk and uncertainty pervade the whole of economic life, and decisions are constantly having to be made whose outcome cannot be known for certain. Even the most morally upright person will still have to decide which career to go into, whether and when to buy a house, or even something as trivial as whether or not to take an umbrella when going out. Each of these decisions and thousands of others are made under conditions of uncertainty (or occasionally risk).

Definitions

Risk When a (desirable) outcome of an action may or may not occur, but the probability of its occurring is known. The lower the probability, the greater the risk involved in taking the action.

Uncertainty When an outcome may or may not occur and its probability of occurring is not known.

BOX 2.7

SHORT SELLING

EXPLORING ECONOMICS

Gambling on a fall in share prices

A form of speculation that can be very damaging to stock markets is the practice of **short selling**. This is where people take advantage of anticipated falls in share prices by selling shares they do not possess. How does this work?

Assume that a share price is currently £10 per share and traders on the stock market believe that the price is about to fall. They want to take advantage of this but don't possess any. What they do is borrow shares from dealers who do own some and agree to return them on a specified date. They pay a fee for doing this. In the meantime they sell the shares on the market at the current price of £10 and wait for it to fall. They are now 'short' of the shares (i.e. they don't possess them but still owe them).

Assume that just before the agreed time comes for returning the shares the price has fallen to £8. The trader then buys the shares, returns them to the dealer who had lent them and pockets the difference of £2 (minus the fee).

Although anyone can short sell shares, it is largely traders from various financial institutions who engage in this practice. Huge bonuses can be earned from their employers if the short selling is profitable. This encourages an atmosphere of risk-taking and looking to short-term gains rather than providing long-term capital to firms.

Short selling in the banking crisis of 2008

The practice of short selling had become rife and added to the instability of markets, driving share prices down that were anticipated to fall. This was a particular problem in 2008, when worries about bad debts and losses in the banking sector led many traders to short sell the shares of banks and other financial institutions felt to be most at risk.

The short selling of Halifax Bank of Scotland (HBOS) shares in September 2008 was a major contributing factor to the collapse in its share price. HBOS, the UK's largest mortgage lender, had been suffering losses as a result of falling house prices and difficulties of many house owners in keeping up with their monthly mortgage payments. The share price plummeted by over 70 per cent in the space of a few days. The fall was driven on by speculation, much of it short selling. On 17 September it was announced that HBOS would be taken over by Lloyds TSB.

Concerns about the practice of short selling driving instability in financial markets led a number of governments – or agencies acting on their behalf – to introduce temporary bans on the practice. In September 2008, the Financial Services Authority, the UK industry's regulator at the time, announced a four-month ban on the practice. At the same time, the US financial regulator, the Securities and Exchange Commission, announced a similar move. Both these bans were imposed for a matter of months, whereas Denmark held a similar policy for more than two years.

In May 2012, the EU passed a law giving the European Securities and Markets Authority (ESMA) the power to ban short selling in emergency situations: i.e. where it threatens the stability of the EU financial system. The UK government opposed the legislation but the EU Court of Justice rejected the challenge in 2014.

Is short selling always profitable?

Short selling, as with other forms of speculation, is a type of gambling. If you gamble on a price fall and the price does fall, your gamble pays off and you make a profit. If you get it wrong, however, and the price rises, you will make a loss. In the case of short selling, you would have to buy the shares (to give back to the lender) at a higher price than you sold them for.

This is just what happened in September 2008. With central banks around the world supporting markets, with the US government announcing that it would take over the bad debts of banks and with future short selling temporarily banned, share prices rapidly increased. The FTSE rose by a record 8.8 per cent on 19 September. Those with 'short positions' – i.e. those who had sold shares they had borrowed – then had to buy them back at a much higher price. Losses of hundreds of millions of pounds were made by short sellers. But they gained little sympathy from the general public, who blamed their 'greed' for much of the falls in share prices of the previous weeks.

1. Why would owners of shares, such as pension funds, lend them to short sellers rather than selling the shares themselves and then buying them back later?
2. What are the potential benefits of short selling for the economy?
3. 'Naked' short selling has been banned in many countries. What exactly is naked short selling?

Definition

Short selling (or shorting) Where investors borrow an asset, such as shares, oil contracts or foreign currency; sell the asset, hoping the price will soon fall; then buy it back later and return it to the lender. Assuming the price has

fallen, the short seller will make a profit of the difference (minus any fees). There is always the danger, however, that the price may have risen, in which case the short seller will make a loss.

BOX 2.8

DEALING IN FUTURES MARKETS

EXPLORING ECONOMICS

A way of reducing uncertainty

One way of reducing or even eliminating uncertainty is by dealing in **futures** or **forward markets**. Let us examine first the activities of sellers and then those of buyers.

Sellers

Suppose you are a farmer and want to store grain to sell at some time in the future, expecting to get a better price than now. The trouble is that there is a chance that the price will go down. Given this uncertainty, you may be unwilling to take a gamble.

An answer to your problem is provided by the **commodity futures market**. This is a market where prices are agreed between sellers and buyers today for delivery at some specified date in the future.

For example, if it is 20 October today, you could be quoted a price today for delivery in six months' time (i.e. on 20 April). This is known as the six-month **future price**. Assume that the six-month future price is £160 per tonne. If you agree to this price and make a six-month forward contract, you are agreeing to sell a specified amount of wheat at £160 on 20 April. No matter what happens to the **spot price** (i.e. the current market price) in the meantime, your selling price has been agreed. The spot price could have fallen to £140 (or risen to £180) by April, but your selling price when 20 April arrives is fixed at £160. There is thus *no risk to you whatsoever of the price going down*. You will, of course, have lost out if the spot price is *more* than £160 in April.

Buyers

Now suppose that you are a flour miller. In order to plan your expenditures, you would like to know the price you will have to pay for wheat, not just today, but also at various future dates. In other words, if you want to take delivery of wheat at some time in the future, you would like a price quoted *now*. You would like the risks removed of prices going up.

Let us assume that today (20 October) you want to *buy* the same amount of wheat on 20 April that a farmer wishes to sell on that same date. If you agree to the £160 future price, a future contract can be made with the farmer. You are then guaranteed that purchase price, no matter what happens to the spot price in the meantime. There is thus *no risk to you whatsoever of the price going up*. You will, of course, have lost out if the spot price is *less* than £160 in April.

The determination of the future price

Prices in the futures market are determined in the same way as in other markets: by demand and supply. For example, the six-month wheat price or the three-month coffee price will be that which equates the demand for

those futures with the supply. If the five-month sugar price is currently £220 per tonne and people expect by then, because of an anticipated good beet harvest, that the spot price for sugar will be £170 per tonne, there will be few who want to buy the futures at £220 (and many who want to sell). This excess of supply of futures over demand will push the price down.

Speculators

Many people operate in the futures market who never actually handle the commodities themselves. They are neither producers nor users of the commodities. They merely speculate. Such speculators may be individuals, but they are more likely to be financial institutions.

Let us take a simple example. Suppose that the six-month (April) coffee price is £1300 per tonne and that you, as a speculator, believe that the spot price of coffee is likely to rise above that level between now (October) and six months' time. You thus decide to buy 20 tonnes of April coffee futures now.

But you have no intention of taking delivery. After four months, let us say, true to your prediction, the spot price (February) has risen and as a result the April price (and other future prices) have risen too. You thus decide to *sell* 20 tonnes of April (two-month) coffee futures, whose price, let us say, is £1500. You are now 'covered'.

When April comes, what happens? You have agreed to buy 20 tonnes of coffee at £1300 per tonne and to sell 20 tonnes of coffee at £1500 per tonne. All you do is to hand the futures contract to buy to the person to whom you agreed to sell. They sort out delivery between them and you make £200 per tonne profit.

If, however, your prediction had been wrong and the price had *fallen*, you would have made a loss. You would have been forced to sell coffee contracts at a lower price than you bought them.

Speculators in the futures market thus incur risks, unlike the sellers and buyers of the commodities, for whom the futures market eliminates risk. Financial institutions offering futures contracts will charge for the service: for taking on the risks.

If speculators believed that the price of cocoa in six months was going to be below the six-month future price quoted today, how would they act?

Definitions

Futures or forward market A market in which contracts are made to buy or sell at some future date at a price agreed today.

Future price A price agreed today at which an item (e.g. commodities) will be exchanged at some set date in the future.

Spot price The current market price.

People's actions are influenced by their attitudes towards risk. Many decisions are taken under conditions of risk or uncertainty. Generally, the lower the probability of (or the more uncertain) the desired outcome of an action, the less likely people will be to undertake the action.

Give some examples of decisions you have taken recently that were made under conditions of uncertainty. With hindsight do you think you made the right decisions?

We shall be examining how risk and uncertainty affect economic decisions on several occasions throughout the book. For example, in Chapter 5 we will see how it affects people's attitudes and actions as consumers and how taking out insurance can help to reduce their uncertainty. At this

point, however, let us focus on firms' attitudes when supplying goods.

Stock holding as a way of reducing the problem of uncertainty

A simple way that suppliers can reduce the problem of uncertainty is by holding stocks. Take the case of the wheat farmers we saw in the previous section. At the time when they are planting the wheat in the spring, they are uncertain as to what the price of wheat will be when they bring it to market. If they keep no stores of wheat, they will just have to accept whatever the market price happens to be at harvest time. If, however, they have storage facilities, they can put the wheat into store if the price is low and then wait until the price goes up. Alternatively, if the price of wheat is high at harvest time, they can sell the wheat straight away. In other words, they can choose the time to sell.

Section summary

1. A complete understanding of markets must take into account the time dimension.
2. Given that producers and consumers take a time to respond fully to price changes, we can identify different equilibria after the lapse of different lengths of time. Generally, short-run supply and demand tend to be less price elastic than long-run supply and demand. As a result, any shifts in D or S curves tend to have a relatively bigger effect on price in the short run and a relatively bigger effect on quantity in the long run.
3. People often anticipate price changes and this will affect the amount they demand or supply. This speculation will tend to stabilise price fluctuations if people believe that the price changes are only temporary. However, speculation will tend to destabilise these fluctuations (i.e. make them more severe) if people believe that prices are likely to continue to move in the same direction as at present (at least for some time).
4. Many economic decisions are taken under conditions of risk or uncertainty. Uncertainty over future prices can be tackled by holding stocks. When prices are low, the stocks can be built up. When they are high, stocks can be sold.

END OF CHAPTER QUESTIONS

1. The weekly demand and supply schedules for T-shirts (in millions) in a free market are as follows:

Price (£)	8	7	6	5	4	3	2	1
Quantity demanded	6	8	10	12	14	16	18	20
Quantity supplied	18	16	14	12	10	8	6	4

- (a) What are the equilibrium price and quantity?
- (b) Assume that changes in fashion cause the demand for T-shirts to rise by 4 million at each price. What

will be the new equilibrium price and quantity? Has equilibrium quantity risen as much as the rise in demand? Explain why or why not.

- (c) Now plot the data in the table and mark the equilibrium. Also plot the new data corresponding to (b).
2. On separate demand and supply diagrams for bread, sketch the effects of the following: (a) a rise in the price of wheat; (b) a rise in the price of butter and margarine; (c) a rise in the price of rice, pasta and potatoes. In each case, state your assumptions.

3. For what reasons might the price of overseas holidays rise? In each case, identify whether these are reasons affecting demand, supply, or both.
4. If both demand and supply change, and if we know which direction they have shifted but not how much, why is it that we will be able to predict the direction in which *either* price or quantity will change, but not both? (Clue: consider the four possible combinations and sketch them if necessary: (a) *D* left, *S* left; (b) *D* right, *S* right; (c) *D* left, *S* right; (d) *D* right, *S* left.)
5. If you were the owner of a clothes shop, how would you set about deciding what prices to charge for each garment at the end-of-season sale?
6. Is there any truth in the saying that the price of a good is a reflection of its quality?
7. Assume that oil begins to run out and that extraction becomes more expensive. Trace through the effects of this on the market for oil and the market for other fuels.
8. Why are both the price elasticity of demand and the price elasticity of supply likely to be greater in the long run?
9. Which of the following will have positive signs and which will have negative ones: (a) price elasticity of demand; (b) income elasticity of demand (normal good); (c) income elasticity of demand (inferior good); (d) cross elasticity of demand (with respect to changes in price of a substitute good); (e) cross elasticity of demand (with respect to changes in price of a complementary good); (f) price elasticity of supply?
10. What are the advantages and disadvantages of speculation from the point of view of (a) the consumer; (b) firms?

Government and the Market

CHAPTER MAP

3.1 The control of prices	80
Setting a minimum (high) price	81
Setting a maximum (low) price	82
3.2 Indirect taxes and subsidies	88
The effect of imposing taxes on goods	88
Elasticity and the incidence of taxation	90
The effect of subsidising products	92
3.3 Government rejection of market allocation	93
Providing goods and services free at the point of delivery: the case of hospital treatment	93
Prohibiting the sale of certain goods and services: the case of illegal drugs	94
3.4 Agriculture and agricultural policy	95
Why intervene?	95
Government intervention	98

In the previous chapter we looked at free markets: markets where there is no government intervention. However, as we saw in Chapter 1 the real world is one of mixed economies. Indeed, the government intervenes in many markets, even highly competitive ones. This intervention can take a number of forms:

- Fixing prices, either above or below the free-market equilibrium.
- Taxing the production or sale of various goods, such as petrol.

- Subsidising the production or sale of various goods, such as public transport.
- Producing goods or services directly (e.g. defence and health care).
- Regulation. Various laws could be passed to regulate the behaviour of firms. For example, some activities, such as the dumping of toxic waste, could be made illegal; or licences or official permission might have to be obtained to produce certain goods; or a regulatory body could supervise the activities of various firms and prevent any that it felt to be against the public interest (e.g. the production of unsafe toys).

Supply and demand analysis is a useful tool for examining the effects of government intervention. First, in section 3.1, we examine what could happen if a government fixes prices, either above or below the equilibrium. Then, in the following section, we look at the effects of government taxes on products. We see the impact on prices and output and how this depends on the price elasticity of demand and supply.

In section 3.3 we examine what happens if the government seeks to do away with a market system of allocation altogether, either by providing things free to consumers, or by banning certain harmful activities.

Finally, we look at the impact of government intervention in agriculture – a sector that has received massive government support in many countries of the world. We look at the economic arguments for such intervention and then examine some specific measures that governments have taken.

The role of government in the economy is examined further in Chapters 11 to 14.

3.1 THE CONTROL OF PRICES

At the equilibrium price, there will be no shortage or surplus. The equilibrium price, however, may not be the most desirable price. The government, therefore, may prefer to keep prices above or below the market clearing level.

If the government sets a **minimum price** above the equilibrium (a price floor), there will be a surplus. This is illustrated in Figure 3.1. With curves S and D , the surplus is $Q_s - Q_d$ ($b - a$). Legislation prevents the price from falling to eliminate this surplus.

The size of the surplus at any given minimum price will depend on the price elasticity of demand and supply. For example, if supply and demand are less elastic (S_1 and D_1 instead of S and D) the same minimum price will create a smaller surplus: $Q_{s_1} - Q_{d_1}$ ($d - c$). Given the impact of

time on elasticity, the surplus will tend to be larger in the long run.

If the government sets a **maximum price** below the equilibrium (a price ceiling), there will be a shortage. This is illustrated in Figure 3.2. With curves S and D the shortage is

Definitions

Minimum price A price floor set by the government or some other agency. The price is not allowed to fall below this level (although it is allowed to rise above it).

Maximum price A price ceiling set by the government or some other agency. The price is not allowed to rise above this level (although it is allowed to fall below it).

Figure 3.1 Minimum price: price floor

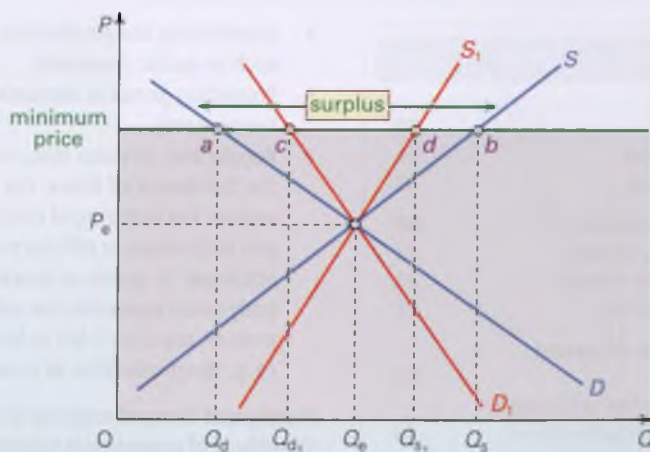

Figure 3.2 Maximum price: price ceiling

THRESHOLD CONCEPT 7

GOVERNMENTS CAN SOMETIMES IMPROVE MARKET OUTCOMES

THINKING LIKE AN ECONOMIST

Threshold Concept 3 was that markets may fail to meet social objectives; this implies that there may be a need for government intervention. Governments have a number of policy instruments that they can use, either to influence markets or to replace them altogether. These policy instruments include taxation, benefits and subsidies, laws and regulations, licences and permits, and direct provision by government departments or agencies (such as the National Health Service in the UK).

The threshold concept here is not merely that governments intervene, but that they can correct, or at least lessen, market failures. Once we have understood the nature of a market failure, we can then set about designing a policy to correct it. For example, if we could identify that the cost to society of producing a product in a way which created pollution was £20 per unit more than the benefit that society gained from the product, then the government could tax the producer £20 per unit.

In Chapters 11 to 14 we consider a number of these policy instruments and seek to identify the *optimum* level of

government intervention to meet social objectives. In this chapter we have a preliminary look at some of these instruments.

Governments themselves, however, are imperfect organisations with a number of different motivations. For an economic adviser to recommend a particular policy as the best means of correcting a market failure does not mean that the government will carry it out efficiently or, indeed, carry it out at all. In fact sometimes intervention can make things worse rather than better.

1. What market failures could be corrected by the use of welfare benefits? Does the payment of such benefits create any problems for society?
2. Assume that the government sees litter as a market failure that requires government action. Give some examples of policies it could adopt to reduce litter.

$Q_d - Q_s(b - a)$. Legislation prevents the price from rising to eliminate this shortage.

The size of the shortage at any given maximum price will again depend on the price elasticity of demand and supply. For example, if demand is less elastic (D_1 instead of D) the same maximum price will create a smaller shortage: $Q_{d_1} - Q_{s_1}(d - c)$.

Setting a minimum (high) price

The government sets minimum prices to prevent them from falling below a certain level. It may do this for various reasons:

- To protect producers' incomes. If the industry is subject to supply fluctuations (e.g. fluctuations in weather affecting crops), prices are likely to fluctuate severely. Minimum prices will prevent the fall in producers' incomes that would accompany periods of low prices. (This is examined further in section 3.4 in the context of agricultural intervention.)
- To create a surplus (e.g. of grains) – particularly in times of plenty – which can be stored in preparation for possible future shortages.
- To deter the consumption of particular goods. Some people may consume more of a good than is in their own self-interest because they do not fully appreciate the future costs to their health. They may also act irrationally because of self-control and addiction issues. See chapter 5 for more detail.
- In the case of wages (the price of labour), minimum wage legislation can be used to prevent workers' wage rates from falling below a certain level. This may form part of a government policy on poverty and inequality (see Box 11.2).

Draw a supply and demand diagram with the price of labour (the wage rate) on the vertical axis and the quantity of labour (the number of workers) on the horizontal axis. What will happen to employment if the government raises wages from the equilibrium to some minimum wage above the equilibrium?

The government can use various methods to deal with the surpluses associated with minimum prices.

- The government could buy the surplus and store it, destroy it or sell it abroad in other markets. This is illustrated in Figure 3.3, where the government purchases the unsold surplus of $b - a$ (i.e. $Q_s - Q_d$). The cost to the government of buying this surplus is the shaded area (abQ_sQ_d). This is what happened in the EU's Common Agricultural Policy where 'Intervention Boards' bought up surpluses and in most cases (e.g. grains, milk, powder and beef) put them in storage. The expense of storage would have to be added to the shaded area in Figure 3.3 to obtain the full cost to the government of the policy. These costs would be lower if the government could sell surpluses on the world market.
- Supply could be artificially lowered by restricting producers to particular quotas. For example, in Figure 3.1, supply could be reduced to Q_d (or Q_{d_1} in the case of D_1). This would reduce the costs to the government of having to purchase the surplus, but it might be a difficult policy to enforce.
- Demand could be raised by advertising, by finding alternative uses for the good, or by reducing consumption of substitute goods (e.g. by imposing taxes or quotas on substitutes, such as imports).

Figure 3.3 The cost to the government of a minimum price

One of the problems with minimum prices is that firms with surpluses on their hands may try to evade the price control and cut their prices.

Another problem is that high prices may cushion inefficiency. Firms may feel less need to find more efficient methods of production and to cut their costs if their profits are being protected by the high price. Also, the high price may discourage firms from producing alternative goods which they could produce more efficiently or which are in higher demand, but which nevertheless have a lower (free-market) price.

Setting a maximum (low) price

The government may set maximum prices to prevent them from rising above a certain level. The rationale for this type of policy is usually one of fairness, with the government setting maximum prices for basic goods so that people on lower incomes can afford to buy them. This may be a particular issue in times of famine or war.

The resulting shortages, however, create further problems. If the government merely sets prices and does not intervene further, the shortages will lead to sellers having to allocate the good amongst its potential customers in one or more of the following ways:

- *'First-come, first-served' basis.* This is likely to lead to queues developing outside shops, or websites crashing if people try to purchase the good on line. To try to deal with these issues firms may have to adopt waiting lists. Queues have been a common feature of life in Venezuela and Argentina where the governments have kept the prices of many basic goods below the level necessary to equate demand and supply.
- *Random ballot.* The seller puts the name of every customer willing to pay the maximum price into a random draw.

Only those who are lucky enough to have their name drawn receive the good.

- *Favoured customers.* This could be the seller's friends, family and/or regular customers.
- *A measure of merit.* For example, the number of students who want a place on a particular course at a university and are willing to pay the tuition fee may exceed the number of places available. In this instance, the university may allocate places to those who achieve the highest grades.
- *A rule or regulation.* State schools facing excess demand often allocate places based on the distance children live from the school (in the case the maximum price is zero). Preference is also given to applicants who have an older sibling already at the school.

None of the above may be considered fair since some people in need may be forced to go without. Therefore, the government may adopt a system of **rationing**. People could be issued with a set number of coupons for each item rationed.

A major problem with maximum prices is likely to be the emergence of **illegal markets** (sometimes called **underground** or **shadow markets**), where customers, unable to buy enough in legal markets, may well be prepared to pay very high prices: prices above P_e in Figure 3.2 (see Box 3.2).

Definitions

Rationing Where the government restricts the amount of a good that people are allowed to buy.

Illegal or underground or shadow markets Where people ignore the government's price and/or quantity controls and sell illegally at whatever price equates illegal demand and supply.

BOX 3.1

A MINIMUM UNIT PRICE FOR ALCOHOL

CASE STUDIES AND APPLICATIONS

A way of reducing alcohol consumption?

A market where the use of minimum pricing has been extensively discussed is that of alcohol. In early 2010, the UK House of Commons Health Select Committee¹ proposed the introduction of a form of minimum pricing. Known as a 'minimum unit price' (MUP), the price floor is set according to the alcoholic content of the drink rather than the volume of liquid. The Select Committee report suggested that a MUP of 50p would save more than 3000 lives per year.

In March 2012, the UK government announced its intention to introduce MUP following a period of consultation with industry stakeholders. The Scottish government passed legislation for the introduction of a 50p MUP in June 2012.

What impact would a 50p MUP have on the price of alcoholic drinks in the UK? The table provides some examples across a range of products.

Effect of a 50p MUP on the price of various alcoholic drinks

Product	Volume	Strength (% abv)	Units of alcohol	Minimum price
Vodka	70cl	37.5	26.25	£13.13
Whisky	70cl	40.0	28.00	£14.00
Alcopop	70ml	4.0	2.80	£1.40
Lager (4 pack)	440 ml × 4	5.0	2.20	£4.40
Wine (white)	750ml	12.0	9.00	£4.50

Minimum unit pricing versus higher taxes

What are the advantages of introducing a MUP rather than simply increasing tax and duties on alcohol?

Evidence from researchers at Sheffield University² indicates that it is a more effective way of targeting heavy drinkers. Economic simulations undertaken to forecast the impact of a 50p MUP found that the policy would have a very small impact on people who consume moderate amounts of alcohol: i.e. men who drink fewer than 22 units per week and women who drink fewer than 15 units. On average, this group responds by drinking only 3 fewer units per year, equivalent to one pint of strong beer.

The simulations suggest that the impact of the policy on heavy drinkers would be much stronger. Men who drink over 50 units per week and women who drink over 35 units respond on average by consuming 134 fewer units per year. The impact on heavy drinkers in the poorest 20 per cent of households is even greater still. They respond by consuming 372 fewer units per year.

One disadvantage of an MUP is that any extra revenue goes to the retailers rather than to the government. Research by the Institute of Fiscal Studies,³ suggests it would reduce

competition and lead to windfall profits for the alcohol and retail industry. They argue that reforming taxes on alcohol is a more effective way of targeting heavy drinkers.

In July 2013, the UK government announced that it was not going ahead with its proposed MUP policy. The then Home Secretary, Theresa May, stated:

Consultation has been extremely useful. But it has not provided evidence that conclusively demonstrates that Minimum Unit Pricing will actually do what it is meant to do: reduce problem drinking without penalising all those who drink responsibly.⁴

The government instead introduced a minimum price at a much lower level. In May 2014, it became illegal for firms to sell alcoholic drinks at prices below the amount of duty and VAT levied on them. In 2016, this was £1.56 for four cans of average strength lager and £8.72 for a standard bottle of vodka.

At the time of writing, the MUP of 50p is yet to be introduced in Scotland because of a series of legal cases. After the legislation was passed, alcohol trade associations argued that the policy contravened European Union law by impeding trade between member states. They took their case to the Scottish Court of Session (SCS). The SCS initially concluded that the MUP did not infringe EU law but referred the case to the European Court of Justice (ECJ) for more guidance.

In December 2015, the ECJ ruled that the MUP was a restraint on trade but could be justified on the grounds that it protects human life. It referred the case back to the SCS. In October 2016, the SCS ruled that an MUP was consistent with EU law. However, the Scottish Whisky Association has submitted another appeal to the UK Supreme Court. The case is expected to be heard at some point in 2017.

1. Draw a diagram to illustrate the likely impact of setting a minimum price based on duty and VAT levels.
2. Explain how price elasticity of demand determines the impact of a 50p MUP on the consumption of alcohol.
3. In the 2017 Budget, the Chancellor introduced plans to introduce a minimum excise tax on cigarettes. Explain how this effectively imposes a price floor.

1 Alcohol: First Report of Session 2009–10 (House of Commons Health Committee, April 2010).

2 'Minimum pricing for alcohol effectively targets high risk drinkers, with negligible effects on moderate drinkers with low incomes', *The University of Sheffield News*, February 2014.

3 'Reforms to alcohol taxes would be more effective than minimum unit pricing', Institute for Fiscal Studies, March 2013.

4 Home Office, 'Next steps following the consultation on delivering the government's alcohol strategy', July 2013, p. 3.

BOX 3.2 THE RISE IN ILLEGAL LENDING**The consequence of a maximum price in the payday loan market**

Governments in countries such as Venezuela and Argentina have imposed maximum prices on a large number of different goods. However, there are far fewer instances of this type of policy in the UK.

One historical case is the use of rent controls in the housing market. First introduced in 1915 as a response to wartime housing shortages, they were finally abolished as part of the 1988 Housing Act. Since January 1989, no new private sector lettings in the UK have been subject to rent controls. Jeremy Corbyn, the leader of the Labour Party, has, however, argued in favour of their re-introduction.

The introduction of maximum pricing in the payday loan market

A recent example of maximum pricing in the UK is in the market for high-cost short-term credit (HCSTC). Otherwise known as the 'payday loan market', this is where customers typically borrow a few hundred pounds for a short time period, usually two to four weeks. One common reason given for this type of borrowing is the need to pay an unexpected

bill. The expectation is that the loan will be repaid when the borrower receives the next pay cheque.

What is the price of borrowing (i.e. buying money) in the credit market? It is the interest rate plus any other fees charged by the lender. If the market is competitive and unregulated then this price is determined by the interaction of the demand and supply. This is illustrated at point *a* in the diagram at the equilibrium price P_e .

The payday loan market grew dramatically after the financial crisis of 2007–8 and reached its peak in 2013 when the Financial Conduct Authority (FCA) estimated that approximately 400 firms made 10 million loans with a market value of £2.5 billion. However, as the market grew, politicians and even the Archbishop of Canterbury began to express concerns about the level of interest rates. For example, a borrower would typically have to pay around £38 for a 30-day loan of £100. This was an interest rate of 1.26 per cent per day or 4670 per cent per annum! Similar concerns were also expressed about the size of penalty charges imposed on borrowers when they failed to meet repayment deadlines.

The impact of a maximum price on the payday loan market

In an attempt to deal with these issues, the FCA announced a series of regulations in July 2014.¹ They came into effect in January 2015 and were as follows:

- The interest rate was capped at 0.8 per cent per day: i.e. a maximum price was introduced. This means that the maximum amount a lender can charge for a 30-day loan of £100 is £24 (assuming it is repaid on time).
- Charges for late repayments of loans were limited to a maximum amount of £15. The interest rate on outstanding debts was also capped at 0.8 per cent per day.
- The total amount borrowers could be charged, even if they defaulted, was limited to double the amount they borrowed.

The impact of maximum prices in the payday loan market

What is the impact of the maximum price on a competitive market if it is set below its equilibrium level? This is also illustrated in the diagram. With a price cap of P_c , the simple demand and supply model predicts that the quantity of the loans supplied falls from Q_e to Q_1 while the quantity demanded increases from Q_e to Q_2 . The supply side of the market dominates and so the amount of loans issued falls to Q_1 . There is a shortage of loans of $Q_2 - Q_1$ ($c - b$).

The FCA anticipated that the number of loans would fall, causing many lenders to go out of business. It forecast that, out of the 400 businesses registered as official payday lenders prior to the regulation, only four (one high street and three online) would survive. In reality, the reduction has been far smaller. In December 2016, the FCA announced that the number had fallen from 400 to 144.

The demand and supply model also predicts that the imposition of a maximum price gives an opportunity for the development of an illegal market. If supply is restricted to Q_1 , the market clearing price would now be P_2 (point d), where demand also equals Q_1 . If the legal price, therefore, is only P_c , there will be many people who would be willing to pay far more.

Let us say that an individual borrower is prepared to pay P_2 . Individual payday lenders may be willing to break the law and charge a price above P_c , but below P_2 , depending on their position on the supply curve. Thus both the borrower and the lender would be better off if they made a loan agreement at any

price between the price the borrower is willing to pay and the price the lender is willing to accept.

However, the maximum price legislation prevents this mutually beneficial transaction from taking place legally. If potential borrowers are willing to go to the unofficial market they may find illegal lenders (loan sharks) willing to lend them money at an interest rate above the capped level of 0.8 per cent per day but below the maximum rate they are willing to pay.

When discussing the impact of an interest-rate cap, Steve Davies of the Institute of Economic Affairs argued that:

the demand for these types of loans would remain but would now be met by truly unsavoury characters. If you want to help loan sharks and low life money lenders then restricting legitimate firms is the way to go.²

In November 2016, the FCA announced that it was launching a review of its payday market regulations and, in particular, it was:

keen to see if there is any evidence of consumers turning to illegal money lenders directly as a result of being excluded from high-cost credit because of the price cap.³

It will be interesting to see, once more evidence is available, if the benefits of the regulations on the payday loan industry outweigh the costs. The FCA is also considering whether to introduce a similar cap on interest rates and charges for bank overdrafts.

1. Using the concept of elasticity, explain why the impact of a maximum price, such as the one introduced by the FCA, may be different in the economic long run as opposed to the short run.
2. Discuss the economic rationale for introducing a maximum price into the market for payday lending.

¹ 'FCA proposes price cap for payday lenders', Financial Conduct Authority press release, 15 July 2014.

² 'Cracking down on payday lenders will hurt the poor', Institute for Economic Affairs, July 2013.

³ 'FCA launches call for input on high-cost credit and overdrafts', press release, 29 November 2016.

BOX 3.3 HOW CAN TICKET TOUTS MAKE SO MUCH MONEY?

Some pricing issues in the market for tickets

Some organisations set prices below market clearing levels. Take the example of the ticketing industry.

Tickets for live music, theatre, comedy and sporting events are sold by event organisers or authorised ticketing websites such as Ticketmaster®. This is the 'primary market' where the organiser or promoter sets the prices. There is evidence that ticket prices in the primary market are consistently below market clearing levels. For example, research by Media Insight Consulting found that, on average, fans were willing to pay £181 to see Adele in concert in the spring 2016 tour, whereas the tickets cost £65.

Organisers often set ticket prices below the market clearing level because of uncertainty over demand and the desire to avoid half-empty venues. They may also want to make the tickets available at reasonable prices to fans. However, by setting prices below market clearing levels in the primary market, it creates the opportunity for people to make large amounts of money in the secondary market.

The 'secondary market' is where someone resells a ticket they previously purchased in the primary market. The event organiser has no control over prices in this sector. One type of seller in the secondary market is someone who, because of changes in their circumstances, is no longer able to attend the event. Such people are simply trying to get their money back. However, another type of seller purchases tickets deliberately to resell them at a mark-up in the secondary market. This type of seller is sometimes called a 'ticket tout' or 'scalper' and the potential returns are considerable. The worldwide value of the secondary ticketing market has been estimated at around \$8 billion.

The scope for profit by ticket touts

Why can ticket touts sell for such large profits? The diagram helps to explain how it is possible. The supply curve is perfectly inelastic in the short run as the capacity of the venue holding the event (stadium, concert hall, theatre, etc.) is fixed at Q_c . The market-clearing price is P_e where the quantity of tickets demanded is equal to the quantity supplied. The price in the primary market is P_p . So there is a shortage of tickets: i.e. $Q_d > Q_c$.

Suppose that ticket touts are able to purchase half of the tickets on sale in the primary market (Q_t) using computer programs called bots. These automated pieces of software enable the user to make multiple transactions at the same time.

Assuming that none of the people with the highest willingness to pay (represented by points a to b on the demand curve) purchase the tickets in the primary market, the ticket touts will be able to resell all of their tickets for a price of P_s . The shaded area represents the potential profit.

The secondary ticketing market

Media reports have highlighted cases where tickets for sale in the primary market have sold out in less than an hour, with ticket touts suspected of purchasing large numbers using bots. These same tickets quickly start reappearing for prices far in excess of their face value on one of the four websites that dominate the secondary ticket market: Viagogo (based in Switzerland), Stubhub (owned by eBay), Seatwave and GetMeIn (both owned by Ticketmaster). In one extreme case

How ticket touts make money

an £85 ticket for an Adele concert at the O2 arena in 2016 was advertised by a seller on GetMeIn for a price of £24 840!

The resale of tickets for football matches in England and Wales without the clubs' permission was made illegal in 1994. Ticket touting was also prohibited for events at the London Olympic Games in 2012. Some pressure groups have argued that the existing legislation should be extended so that either the secondary ticket market for all music, cultural and sporting events is banned or limits placed on resale prices.

Attempts to control the secondary ticketing market in the UK

Consumer Rights Act

In response to these concerns the government introduced the Consumer Rights Act (CRA) in 2015. This came into force in May 2015 and placed the following requirements on people offering tickets for resale in the secondary market:

- The face value of the ticket, the seat location (i.e. its block, row and seat number) and any usage restrictions must be prominently displayed.
- Any relationship between the seller and the event organiser or official website must be clearly shown.
- Tickets purchased in the secondary market cannot be cancelled by the event organiser unless this condition has been made very clear in the original terms of sale.

The Waterson Review

The Act also stipulated that a review of the secondary ticketing market should take place within 12 months of the new legislation coming into force. In October 2015, the government commissioned the review and announced that its chair would be an economist, Professor Michael Waterson. Final recommendations were published in May 2016¹ and included the following:

- Increased responsibility should be placed on secondary ticketing websites to make sure that sellers using their sites adhere to the conditions stipulated in the CRA 2015.
- The sale of tickets in the primary market should be made much more transparent. For example, event organisers should clearly indicate the proportion of tickets already sold before they go on general sale.
- More actions should be taken to make sure that consumers understand the difference between the primary and secondary market.

Professor Waterson opposed an outright ban of the secondary market as he thought it would (a) drive sellers into the illegal sector so increasing the chances of fraud; (b) reduce consumer welfare, as evidence for the review indicated that prices were often below their face value. He also opposed a cap on resale

prices as he argued that sellers respond to this type of regulation by finding innovative ways of circumventing the rules. He also questioned whether the cost of the resources required to enforce a price cap would exceed the benefits the regulation would provide.

The government stated in March 2017 that it fully accepted all of the report's recommendations. It also announced that a new clause would be added to the Digital Economy Bill 2016 which would make the use of bots to purchase large numbers of tickets illegal and subject to unlimited fines.

CMA review. In June 2016, the Competition and Markets Authority (CMA) began a completely separate review of secondary ticketing websites. In December 2016, it announced an enforcement investigation of the sector as potential violations of consumer protection law had been identified in its initial findings.

Culture Media and Sport Select Committee hearings. The House of Commons Culture Media and Sports Select Committee also held sessions on 15 November 2016 and 21 March 2017 where its members listened to evidence from a number of interested parties. After the hearings it concluded that there were 'far-ranging and disturbing factors in the market'.

Changes in the primary market. The management of a number of bands and solo artists have taken measures in an attempt to reduce ticket touting. In particular, they have switched to paperless tickets where the person attending the event has to present the debit/credit card used to purchase the ticket in the primary market and some form of photo ID in order to gain entry. Some websites such as Twickets, Swap My Ticket only allow resale at the face value of the ticket.

The secondary ticketing market is a controversial area and its workings continue to be scrutinised by both the media and the government.

1. Are there any potential conflicts of interest when a primary market seller such as Ticketmaster owns secondary market websites such as Seatwave and GetMeIn?
2. To what extent is it in the interests of society to allow people to resell tickets at a price far in excess of their face value? What is the impact on allocative efficiency?

2 'Secondary ticket platforms compliance review', CMA, July 2016.

Another problem is that the maximum prices reduce the quantity produced of an already scarce commodity. For example, artificially low prices in a famine are likely to reduce food supplies: if not immediately, then at the next harvest, because of less being sown. In many developing countries, governments control the price of basic foodstuffs in order to help the urban poor. The effect, however, is to reduce incomes for farmers, who are then encouraged to leave the land and flock into the ever-growing towns and cities.

To minimise these types of problem the government may attempt to reduce the shortage by encouraging supply: by drawing on stores, by direct government production, or by giving subsidies or tax relief to firms. Alternatively, it may attempt to reduce demand: by the production of more alternative goods (e.g. home-grown vegetables in times of war) or by controlling people's incomes.

Another example of maximum prices is where the government imposes rent controls in an attempt to make rented accommodation more affordable. Here the 'price' is the rent people are charged. The danger of this policy is that it will create a shortage of rental property. The policy is examined in Case Study 3.3 on the student website.

Every year the number of people who want to run the London Marathon far exceeds the number of places available. For example, 253 000 applicants were willing to pay £35 to enter the 2017 event. Unfortunately, there were only 17 500 places for these applicants and so the majority ended up very disappointed. Find out the different methods used by the organisers to allocate all 40 000 places and consider their advantages and disadvantages.

Section summary

1. There are several ways in which the government intervenes in the operation of markets. It can fix prices, tax or subsidise products, regulate production, or produce goods directly itself.
2. The government may fix minimum or maximum prices. If a minimum price is set above the equilibrium, a surplus will result. If a maximum price is set below the equilibrium price, a shortage will result. The size of the surplus or shortage will depend on the price elasticity of demand and supply.
3. Minimum prices are set as a means of protecting the incomes of suppliers or creating a surplus for storage in case of future reductions in supply. If the government is not deliberately trying to create a surplus, it must decide what to do with it.
4. Maximum prices are set as a means of keeping prices down for the consumer. The resulting shortages will lead to sellers of the good having to allocate the good among its potential customers in a number of ways including: first-come, first-served; random ballot; favoured customers; measures of merit; rules/regulations. Alternatively, the government could introduce a system of rationing. With maximum prices, underground markets are likely to arise. This is where goods are sold illegally above the maximum price.

3.2 INDIRECT TAXES AND SUBSIDIES

The effect of imposing taxes on goods

We now turn to another example of government intervention – the imposition of taxes on goods. These *indirect taxes*, as they are called, include taxes such as value added tax (VAT) and excise duties on cigarettes, petrol and alcoholic drinks.

These taxes can be a fixed amount per unit sold – a *specific tax*. An example is the tax per litre of petrol. Alternatively,

they can be a percentage of the price or value added at each stage of production – an *ad valorem tax*. An example is VAT.

When a tax is levied on a good, this has the effect of shifting the supply curve upwards by the amount of the tax (see Figure 3.4). In the case of a specific tax, it will be a parallel shift, since the amount of the tax is the same at all prices. In the case of an *ad valorem tax*, the curve will *swing* upwards. At a zero price there would be no tax and hence no shift in the supply curve. As price rises, so the gap between the original

Definitions

Indirect tax A tax on the expenditure on goods. Indirect taxes include value added tax (VAT) and duties on tobacco, alcoholic drinks and petrol. These taxes are not paid directly by the consumer, but indirectly via the sellers of the good. Indirect taxes contrast with direct taxes (such as

income tax) which are paid directly out of people's incomes.

Specific tax An indirect tax of a fixed sum per unit sold.

Ad valorem tax An indirect tax of a certain percentage of the price of the good.

Figure 3.4 Effect of a tax on the supply curve

and new supply curves will widen, since a given *percentage* tax will be a larger *absolute* amount the higher the price.

But why does the supply curve shift upwards by the amount of the tax? This is illustrated in Figure 3.5. To be persuaded to produce the same quantity as before the imposition of the tax (i.e. Q_1), firms must now receive a price which allows them fully to recoup the tax they have to pay (i.e. $P_1 + \text{tax}$).

The effect of the tax is to raise price and reduce quantity. Price will not rise by the full amount of the tax, however, because the demand curve is downward sloping. In Figure 3.5, price rises only to P_2 . Thus the burden or

incidence of such taxes is distributed between consumers and producers. Consumers pay to the extent that price rises. Producers pay to the extent that this rise in price is not sufficient to cover the tax.

K1.5
p22**Definition**

Incidence of tax The distribution of the burden of tax between sellers and buyers.

Figure 3.5 Effect of a tax on price and quantity***LOOKING AT THE MATHS**

Assume that a specific tax per unit of t is imposed on producers of a good. This is then added to the pre-tax price of P_1 . The price paid by consumers is thus $P_1 + t$.

Assuming linear demand and supply equations (see page 48), these can be written as:

$$Q_D = a - b(P_1 + t) \quad (1)$$

$$Q_S = c + dP_1 \quad (2)$$

In equilibrium, $Q_D = Q_S$. Thus:

$$a - b(P_1 + t) + c + dP_1$$

We can rearrange this equation to give:

$$bP_1 + dP_1 = a - c - bt$$

Thus:

$$P_1 = \frac{a - c - bt}{b + d}$$

Take the following example. If the demand and supply equations were

$$Q_D = 120 - 10(P_1 + t) \quad (4)$$

and

$$Q_S = 10 + 5P_1 \quad (5)$$

and $t = 2$, then from equation (3):

$$P_1 = \frac{120 - 10 - (10 \times 2)}{10 + 5} = 6$$

and from equations (4) and (5):

$$Q_D = 120 - 80 = Q_S = 10 + 30 = 40$$

The market price will be

$$P_1 + t = 6 + 2 = 8$$

Assuming that the pre-tax equations were

$$Q_D = 120 + 10P$$

and

$$Q_S = 10 - 5P$$

what is (a) the consumer share of the tax and (b) the producer share?

Elasticity and the incidence of taxation

The incidence of indirect taxes depends on the elasticity of demand and supply of the commodity in question.

Consider cases (1)–(4) in Figure 3.6. In each of the diagrams (which are all drawn to the same scale), the size of the tax is the same: the supply curve shifts upwards by the same amount. Price rises to P_2 in each case and quantity falls to Q_2 ; but, as you can see, the size of this increase in price and decrease in quantity differs in each case, depending on the price elasticity of demand and supply.

The total tax revenue is given by the amount of tax per unit (the vertical difference between the two supply curves)

multiplied by the new amount sold (Q_2). This is shown as the total shaded area in each case in Figure 3.6.

The rise in price from P_1 to P_2 multiplied by the number of goods sold (Q_2) (the pink area) is the amount of the tax passed on to consumers and thus represents the *consumers' share* of

Definitions

Consumers' share of a tax on a good The proportion of the revenue from a tax on a good that arises from an increase in the price of the good.

BOX 3.4

ASHES TO ASHES?

A moral dilemma of tobacco taxes

Revenue from tobacco taxes

The price elasticity of demand for cigarettes is relatively inelastic at current prices (approximately -0.6 in the short run: see below), and so taxing tobacco is an effective means for the government to generate revenue. Tobacco duties in the UK are forecast to raise £9.2 billion in 2016/17 or 1.3 per cent of total tax revenue. This compares with 3.9 per cent for fuel duties and 1.5 per cent for alcohol duties. (Note that these figures exclude the additional revenue raised through VAT.) Over 60 per cent of the price of 20 cigarettes is tobacco duty. Once VAT is included, this figure rises to over 80 per cent.

Clearly, then, tobacco duties are a major source of revenue for the government. The fewer people who respond to higher taxes by either quitting or smoking less, the greater the increase in revenue. In fact, if the government encouraged people to smoke, it would raise more money. However, this creates an interesting dilemma as a strong pressure exists on governments around the world to discourage people from smoking: the more they succeed, the lower will be their tax revenue.

This is not a new problem. Cabinet papers released in May 2008 revealed that in 1956 the then Chancellor, Harold Macmillan, argued against issuing a government health warning about cigarettes, despite being presented with statistical evidence that it was harmful. He was concerned that an official warning would lead to reduced tax revenue from tobacco.

The costs of smoking

What is the impact of fewer people smoking on government finances? Tax revenues would clearly fall, but there would also be less spending on smoking-related health care. Estimates of the amount spent on smoking-related illness by the National Health Service vary between £3 billion and £6 billion per annum. One study by the Department of Public Health at Oxford University,¹ put the figure at £5.2 billion in 2005/6. This, however, is less than the £9.2 billion revenue raised from tobacco taxes. Clearly smokers more than pay for their own treatment. Indeed, the state and the NHS may acquire further financial benefit from smokers. The benefits

stem from the fact that smokers die younger. The NHS gains from avoiding many of the high-cost treatments required by elderly patients and the state gains from having to pay out less in pensions and other benefits.

There are other potential costs of people smoking. The think tank Policy Exchange estimated some figures for the following different categories.

■ Loss in output from premature death of smokers	£4.1 billion
■ Increased absenteeism from work	£2.5 billion
■ Loss in productivity from smoking breaks	£2.9 billion
■ Cost of smoking-related house fires	£507 million
■ Cost of cleaning up cigarette butts	£342 million

Although some people have questioned the accuracy of these data, they do help to illustrate the wide range of potential costs.

There is also the human cost from suffering and deaths. Data from the Office of National Statistics indicated that 78 000 deaths in 2014 were attributable to smoking – 17 per cent of all deaths. In 2014/15, there was an average of 4700 admissions to hospital every day for conditions that could have been caused by smoking.

The effects of raising tobacco taxes

So perhaps raising tobacco taxes would be doubly beneficial. Not only would it raise revenue, but also it would help to support other anti-smoking measures. The UK government is currently using a tobacco duty escalator – a policy of raising tobacco duty by 2 per cent above the rate of inflation each year. There are, however, three problems with this policy.

The first concerns smuggling and tobacco-related crime. Smuggled cigarettes accounted for around 13 per cent of the UK market in 2015/16. Not only is the high price differential between tobacco prices in the UK and abroad encouraging criminality, but estimates for 2015/16 suggest that smuggled tobacco products meant the government lost around £2.4 billion in tax revenue.

the tax. The remainder (the green area) is the **producers' share**. This is the amount by which the producers' net price ($P_2 - t$) is below the original price (P_1) multiplied by Q_2 .

The following conclusions can be drawn:

- Quantity will fall less, and hence tax revenue for the government will be greater, the less elastic are demand and supply (cases (1) and (3)).

Definitions

Producers' share of a tax on a good The proportion of the revenue from a tax on a good that arises from a reduction in the price to the producer (after the payment of the tax).

- Price will rise more, and hence the consumers' share of the tax will be larger, the less elastic is demand and the more elastic is supply (cases (1) and (4)).
- Price will rise less, and hence the producers' share will be larger, the more elastic is demand and the less elastic is supply (cases (2) and (3)).

Cigarettes, petrol and alcohol have been major targets for indirect taxes. Demand for each of them is high and fairly inelastic. Thus the tax will not curb demand greatly. They are good sources, therefore, of tax revenue to the government (see Box 3.4).

CASE STUDIES AND APPLICATIONS

Another issue concerns the disproportionate impact on those with low incomes. The proportion of people smoking in the poorest 40 per cent of households is approximately double the proportion smoking in the richest 40 per cent of households. In 2015/16, 1.2 per cent of total household expenditure by the poorest 20 per cent of the population was on cigarettes. The figure for the richest 10 per cent was just 0.2 per cent. Therefore, the higher the tax on tobacco, the more it redistributes incomes from the poor to the rich.

The third problem is that raising tobacco taxes does *not* have a very marked effect on the consumption of cigarettes; taxes are an ineffective way of discouraging smoking. Why is this? Think back to the discussion on elasticity in section 2.4; demand for cigarettes is inelastic because there are few substitutes and cigarette smokers are often addicted to their habit. A study by HM Revenue and Customs in December 2010² estimated the short-run elasticity of demand at approximately -0.57 , with long-run elasticity of -1.05 . In 2015, the long-run figure was updated to -1.19 . The work suggests that a 1 per cent increase in specific duty will raise an extra £25 million each year.

The use of alternative policies

This dilemma helps explain the move away from using taxes as a method of reducing smoking and towards policies that more directly affect smokers' behaviour. In 2006 and 2007, legislation came into force in the UK banning smoking in workplaces and public places such as shops, bars and restaurants. This followed similar moves in other countries and was supported by an earlier report by the Chief Medical Officer,³ which suggested that the policy would save up to £2.7 billion from a healthier workforce. In October 2015, it also became illegal in England and Wales to smoke in a vehicle carrying children.

Other measures are targeted at the promotion and advertising of tobacco. For example, large shops selling cigarettes have to keep them hidden from public view. A law on the plain packaging of cigarettes came into full effect in May 2017. This includes the following restrictions:

- Picture and text health warnings must cover at least 65 per cent of the front and back of the packet.

- The only advertising allowed on the packet are the product name and brand variant in a standard font size and colour.
- Packets must be cuboid in shape and contain a minimum of 20 cigarettes.

These measures appear to have had some impact, although a substantial minority continues to smoke. In 2014, 19 per cent of all adults in Great Britain were smokers, down from a peak of 46 per cent in 1974.

If smokers continue to give up in substantial numbers then the government will find itself having to look elsewhere for a source of replacement tax revenue. A number of countries are investigating the possibility of introducing new duties on e-cigarettes to make up for some of the shortfall. In 2015, 4 per cent of adults in the UK were e-cigarette users – more than triple the number in 2012.

- You are a government minister. What arguments might you put forward in favour of maximising the revenue from cigarette taxation?*
- What has been the likely impact on businesses and individuals of the ban on smoking in public places?*
- As we saw in the box, an HMRC study on smoking estimates the long-term price elasticity of demand as -1.19 , with a short-term elasticity of -0.57 . Explain these figures.*
- Many people think that if tobacco were to be discovered today it would be an illegal substance, as is the case with cannabis. What problems would a government face if it tried to ban smoking completely (see section 3.3)?*

Figure 3.6 The incidence of an indirect tax

? Supply tends to be more elastic in the long run than in the short run. Assume that a tax is imposed on a good that was previously untaxed. How will the incidence of this tax change as time passes? How will the incidence be affected if demand too becomes more elastic over time?

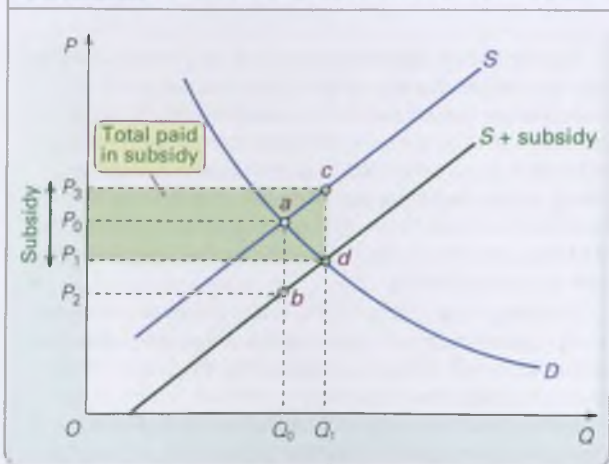

The effect of subsidising products

A subsidy is a payment by the government to a producer or consumer and so is the opposite of a tax. For example, in 2015/16 the train operating company Northern received 10.7p from the government per passenger kilometre travelled. This provided a total subsidy of £249 million. Investment in renewable energy such as wind farms has also received considerable government support.

When a government pays a subsidy per unit of a product to the producer it has the effect of shifting the market supply curve downwards by the amount of the subsidy. Why is this? Take the example of a fixed subsidy per unit sold (a specific subsidy) illustrated in Figure 3.7.

The market is initially in equilibrium at point *a* where the quantity demanded equals the quantity supplied. Price and quantity are P_0 and Q_0 respectively. Now assume the government introduces a subsidy per unit of an amount $a - b$. Firms are now willing to supply the same quantity (Q_0) for a lower market price (P_2) because the government is paying the difference ($P_0 - P_2$) via the subsidy. This willingness to supply at lower market prices is true for all quantities of output and so the whole market supply curve shifts downwards by the amount of the subsidy to $S + \text{subsidy}$. As the amount of the subsidy paid by the government is the same at all prices the shift is a parallel one.

The subsidy reduces the equilibrium price from P_0 to P_1 and increases the equilibrium quantity from Q_0 to Q_1 . However, as you can see, the price does not fall by the full amount

Figure 3.7 Effect of a subsidy on price and quantity

of the subsidy. As with the analysis of tax, the extent to which the subsidy is passed on to the consumer depends on the price elasticity of demand and supply. The consumer's share of the subsidy will be greater (i.e. the price fall will be greater), the less elastic the demand and the more elastic the supply.

? Demonstrate with a supply and demand diagram the incidence of a subsidy when demand is price elastic and supply is price inelastic.

How much does the subsidy cost the taxpayer? This will depend on two things – the size of the per-unit subsidy and the quantity sold after it has been introduced. This is illustrated by the shaded area in Figure 3.7: i.e. the per-unit subsidy ($P_3 - P_1$) multiplied by the quantity produced (Q_1).

Section summary

1. If the government imposes a tax on a good, this will cause its price to rise to the consumers, but it will also cause the revenue to producers (after the tax has been paid) to fall.
2. The 'incidence of tax' will depend on the price elasticity of demand and supply of the good.
3. The consumers' burden will be higher and the producers' burden correspondingly lower, the less elastic the demand and the more elastic the supply of the good. The total tax revenue for the government will be higher the less elastic are both demand and supply.
4. A subsidy is a payment by the government to a producer or consumer. It will cause the equilibrium price to fall and quantity to increase.
5. The cost of a specific subsidy for the government will depend on the size of the per unit payment and the equilibrium quantity after it has been introduced.

3.3 GOVERNMENT REJECTION OF MARKET ALLOCATION

Sometimes the government may consider that certain products or services are best not allocated through the market at all.

TC 7
p81

This section examines two extreme cases. The first is goods or services that are provided free at the point of delivery, such as treatment in National Health Service hospitals and education in state schools. The second is goods and services whose sale is banned, such as certain drugs, weapons and pornography.

Providing goods and services free at the point of delivery: the case of hospital treatment

When the government provides goods and services free to consumers, this often reflects the public's view that they have a *right* to such things. Most people believe that it would be wrong to charge parents for their children's schooling or for having treatment in a hospital, certainly emergency treatment. However, there are also economic reasons that lie behind the provision: for example, educating children brings a benefit to *all* society.

K14
P1A

But what are the consequences of not charging for a service such as health? The analysis is similar to that of a maximum price, only here the maximum price is zero. Figure 3.8 illustrates the situation. It shows a demand and a supply curve for a specific type of treatment in a given hospital.

The demand curve is assumed to be downward sloping. If people had to pay, the amount of treatment demanded would fall as the price went up – partly because some people would feel that they could not afford it (the income effect), and partly because people would turn to alternative treatments, such as prescription drugs. The fewer the alternatives,

and the less close they are to hospital treatment, the less elastic would be the demand curve.

The supply curve is assumed to be totally inelastic, at least in the short run, given current space and equipment. In the longer run, the supply curve may be upward sloping, but only if any charges made could be used to employ extra staff and buy more equipment, and even build extra wards and theatres, rather than the money simply going to the government.

At a price of zero, there is a shortage of $Q_d - Q_s$. Only at the equilibrium price of P_e will demand equal supply.

Figure 3.8 The demand for and supply of hospital treatment

The shortage will have to be dealt with and some form of rationing will be required. One way to ration health care is to have a waiting list system. Most hospitals in the UK have waiting lists for non-emergency treatments. The trouble with this 'solution', however, is that waiting lists will continue to lengthen unless the shortage is reduced. There is also the problem that some people on the waiting list may require urgent treatment; these cases will get faster treatment than non-urgent cases. A consequence is that people waiting for non-urgent treatments, such as hip replacements or the treatment of varicose veins, may have to wait a very long time. Public health care systems that do not make any charges for treatment are sometimes criticised for being unresponsive to the needs of patients.

Changes in demand and supply

One of the problems for the provision of health care is that the demand has grown more rapidly than people's incomes. Unless an increasing proportion of a nation's income is devoted to health care, shortages are likely to get worse. The demand curve in Figure 3.8 will shift to the right faster than the supply curve.

But why has demand grown so rapidly? There are two main reasons. The first has to do with demography. People in developed countries are living longer and the average age of the population is rising. But elderly people require a larger amount of medical treatment than younger people. The second has to do with advances in medical science and technology. More and more medical conditions are now treatable, so there is now a demand for such treatment where none existed before.

What is the solution? The answer for most people would be to increase supply, while keeping treatment free. Partly this can be done by increases in efficiency, and, indeed, various initiatives have been taken by government and health managers to try to reduce costs and increase the amount of treatment offered. Often, however, such measures are highly controversial; examples include reducing the length of time people are allowed to stay in hospital after an operation, or moving patients to hospitals, often at a distance, where operations can be done more cheaply.

The only other way of increasing supply is to allocate more funds to health care, and this means either increasing taxes or diverting resources from other forms of public expenditure, such as education or social security. But then, as we know, scarcity involves choices! Between 2000 and 2012, spending on the National Health Service in the UK increased from 5.5 per cent of GDP to 8.2 per cent, but fell back to 7.8 per cent by 2015. It is projected to fall further to 6.6 per cent by 2020/21, despite an ageing population and rapidly rising treatment costs. However, attention has increasingly been focused on improving outcomes and reducing administrative costs.

Schooling is free in state schools in most countries. If parents are given a choice of schools for their children, there will be a shortage of places at popular schools (the

analysis will be the same as in Figure 3.8, with the number of places in a given school measured on the horizontal axis). What methods could be used for dealing with this shortage? What are their relative merits?

Prohibiting the sale of certain goods and services: the case of illegal drugs

It is illegal to sell certain goods and services, and yet many of these goods have flourishing markets. Billions of pounds change hands worldwide in the illegal drugs, arms and pornography trades. What, then, is the impact of making certain products illegal? How would the effect compare with other policies, such as taxing these products?

Note that as economists we can examine the effects of such policies and hence help to inform public debate: we cannot, however, as economists make judgements as to whether such policies are *morally* right or wrong (see pages 29–30 on the distinction between positive and normative statements).

The market for illegal products

Figure 3.9 illustrates the market for a product such as a drug. If it were not illegal, the demand and supply curves would look something like D_{legal} and S_{legal} . The equilibrium price and quantity would be P_{legal} and Q_{legal} .

Now assume that the drug is made illegal. The effect will be to reduce supply and demand (i.e. shift both curves to the left), as both suppliers and users of the drug fear being caught and paying the penalty (fines or imprisonment). Also, some people will stop supplying or using the drug simply because it is illegal and irrespective of any penalty. The harsher the penalties for supplier or user, and the more likely they are to get caught, and also the more law-abiding people are, the bigger will be the leftward shift in the respective supply or demand curve.

In Figure 3.9, the supply curve shifts to S_{illegal} and the demand curve shifts to D_{illegal} . The quantity sold will fall to

Q_{illegal} and the price will rise to P_{illegal} . It is assumed that there will be a bigger shift in the supply curve (and hence a rise in price) as the penalties for supplying drugs are usually higher than those for merely possessing them.

Under what circumstances would making a product illegal (a) cause a fall in its price; (b) cause the quantity sold to fall to zero?

A comparison of prohibition with taxing the product

Cocaine is illegal. Other drugs, such as tobacco and alcohol, are taxed. But the effect in both cases is to reduce consumption. So are there any differences in the results of using taxation and prohibition?

A tax on a product, like making a product illegal, will have the effect of shifting the supply curve upwards to the left (as we saw in Figure 3.5 on page 89). Unlike making the product illegal, however, a tax will not shift the demand curve. A bigger shift in the supply curve would therefore be needed than in Figure 3.9 for a tax to have the same effect as prohibition

on the level of consumption. It would also result in a higher price for any given level of consumption.

So why not simply use taxes rather than making goods illegal? Those in favour of legalising various drugs argue that this would avoid the associated criminal activity that goes with illegal products (such as drugs gangs, violence and money laundering) and the resulting costs of law enforcement. It would also bring in tax revenue for the government.

The reason given by governments for keeping drugs illegal is that it sends out important messages to society and reflects what the majority wants. Taxing something, by contrast, implies that the product is acceptable. Also, if taxes were to be set high enough to reduce legal consumption to a politically acceptable level, there would then develop a large illegal market in the drugs as people sought to evade the tax.

What are the arguments for and against making the sale of alcoholic drinks illegal? To what extent can an economist help to resolve the issue?

Section summary

1. Sometimes the government will want to avoid allocation by the market for a particular good or service. Examples include things provided free at the point of use and products that are prohibited by the government.
2. If products are provided free to consumers, demand is likely to exceed supply. This is a particular problem in the case of health care, where demand is growing rapidly.
3. If products such as drugs are prohibited, an illegal market is likely to develop. Demand and supply would be less than in a free market. The price could be either higher or lower, depending on who faces the harshest penalties and the greatest likelihood of being caught – suppliers or users.
4. A similar reduction in consumption could be achieved by using taxation. Other effects, however, such as on the price, on allied crime and on public perceptions of the acceptability of the product, will be different.

3.4 AGRICULTURE AND AGRICULTURAL POLICY

If markets for agricultural products were free from government intervention, they would be about as close as one could get to perfect competition in the real world. There are thousands of farmers, each insignificantly small relative to the total market. As a result, farmers are price takers.

Yet despite this high degree of competition, there is more government intervention in agriculture throughout the world than in virtually any other industry. For example, nearly half of the EU budget is spent on agricultural support. Agricultural markets therefore pose something of a paradox. If they are so perfect, why is there so much government intervention?

Why intervene?

The following are the most commonly cited problems of a free market in agricultural products.

Agricultural prices are subject to considerable fluctuations. This has a number of effects:

- Fluctuating prices cause fluctuating farm incomes. In some years, farm incomes may be very low.
- In other years, the consumer will suffer by having to pay very high prices.
- Fluctuating prices make the prediction of future prices very difficult. This in turn makes rational economic decision making very difficult. How is a farmer to choose which of two or more crops to plant if their prices cannot be predicted?
- This uncertainty may discourage farmers from making long-term investment plans. A farmer may be reluctant to invest in, say, a new milking parlour if in a couple of years it might be more profitable to switch to arable farming. A lack of investment by farmers will reduce the growth of efficiency in agriculture.

Low incomes for those in farming. Over the years, farm incomes have tended to decline relative to those in other sectors of the economy. What is more, farmers have very little market power. A particular complaint of farmers is that they have to buy their inputs (tractors, fertilisers, etc.) from non-competitive suppliers who charge high prices. Then they often have to sell their produce at very low prices to food processors, packers, distributors and supermarkets. Farmers thus feel squeezed from both directions.

Traditional rural ways of life may be destroyed. The pressure on farm incomes may cause unemployment and bankruptcies; smaller farms may be taken over by larger ones; village life may be threatened – with the break-up of communities and the closure of schools, shops and other amenities.

Competition from abroad. Farming may well be threatened by cheap food imports from abroad. This may drive farmers out of business.

Against all these arguments must be set the argument that intervention involves economic costs. These may be costs to the taxpayer in providing financial support to farmers, or costs to the consumer in higher prices of foodstuffs, or costs to the economy as a whole by keeping resources locked into agriculture that could have been more efficiently used elsewhere.

Then there is the question of recent trends in food prices. With the rise in demand for food from rapidly growing countries, such as China and India, and with the increased use of land for growing biofuels rather than food crops, world food prices have risen. Farming in many parts of the world is becoming more profitable.

Causes of short-term price fluctuations

Supply problems. A field is not like a machine. It cannot produce a precisely predictable amount of output according to the inputs fed in. The harvest is affected by a number of unpredictable factors such as the weather, pests and diseases. Fluctuating harvests mean that farmers' incomes will fluctuate.

Demand problems. Food, being a basic necessity of life, has no substitute. If the price of food in general goes up, people cannot switch to an alternative: they have either to pay the higher price or to consume less food. They might consume a bit less, but not much. The price elasticity for food in general, therefore, is very low, as Table 3.1 shows.

It is not quite so low for individual foodstuffs because if the price of one goes up, people can always switch to an alternative. If beef goes up in price, people can buy pork or lamb instead. Nevertheless, certain foodstuffs still have a low price elasticity, especially if they are considered to be basic foods rather than luxuries, there are no close substitutes, or they account for a relatively small portion of consumers' income.

With an inelastic demand curve, any fluctuations in supply will cause large fluctuations in price. This is illustrated in Figure 3.10.

Table 3.1 Price and income elasticities of demand in the UK for various foodstuffs

Foodstuff	Price elasticity of demand (average 2001–9)	Income elasticity of demand (1998–2000)
Milk	-0.70	-0.17
Cheese	-0.60	0.23
Poultry	-0.94	0.16
Lamb	-0.59	0.15
Pork	-0.77	0.13
Fish	-0.36	0.27
Eggs	-0.57	-0.01
Fresh vegetables	-1.00	0.22
Potatoes	-0.51	0.09
Fresh fruit	-0.99	0.30
Bananas	-0.62	0.12
Canned and dried fruit	-0.78	0.37
Fruit juice	-0.79	0.45
All foods	-0.07	0.20

Sources: Price elasticity data: based on and averaged from multiple tables by JS in Richard Tiffin, Kelvin Balcombe, Matthew Salois and Ariane Kehlbacher *Estimating Food and Drink Elasticities* (University of Reading, 2011); Income elasticity data: *National Food Survey 2000* (National Statistics, 2001), extracted by JS from Tables 6.3 and 6.5.

Figure 3.10 Inelastic demand for food

? Why is the supply curve drawn as a vertical straight line in Figure 3.10?

Causes of declining farm incomes

Demand problems. There is a limit to the amount people wish to eat. As people get richer, they might buy better cuts of meat, or more convenience foods, but they will spend very little extra on basic foodstuffs. Their income elasticity of demand for basic foods is very low (see Table 3.1).

BOX 3.5 THE FALLACY OF COMPOSITION

EXPLORING ECONOMICS

Or when good is bad

Ask farmers whether they would like a good crop of potatoes this year, or whether they would rather their fields be ravaged by pests and disease, and the answer is obvious. After all, who would wish disaster upon themselves!

And yet what applies to an individual farmer does not apply to farmers as a whole. Disaster for all may turn out not to be disaster at all.

Why should this be? The answer has to do with price elasticity. The demand for food is highly price inelastic. A fall in supply, due to a poor harvest, will therefore cause a proportionately larger rise in price. Farmers' incomes will thus rise, not fall.

Look at diagram (a). Farmer Giles is a price taker. If he alone has a bad harvest, price will not change. He simply sells less (Q_2) and thus earns less. His revenue falls by the amount of the shaded area. But if all farmers have a bad harvest the picture is quite different, as shown in diagram (b). Supply falls from Q_1 to Q_2 , and consequently price rises from P_1 to P_2 . Revenue thus rises from areas (1 + 2) to areas (1 + 3).

(a) Farmer Giles

(b) All farmers

And so what applies to a single farmer in isolation (a fall in revenue) does not apply to farmers in general. This is known as the 'fallacy of composition'.

The fallacy of composition. What applies in one case will not necessarily apply when repeated in all cases.

1. Can you think of any other (non-farming) examples of the fallacy of composition?
2. Would the above arguments apply in the case of foodstuffs that can be imported as well as being produced at home?

Why don't farmers benefit from a high income elasticity of demand for convenience foods?

This very low income elasticity of demand has a crucial effect on farm incomes. It means that a rise in national income of 1 per cent leads to a rise in food consumption of considerably less than 1 per cent. As a result, total farm incomes will grow much more slowly than the incomes of other sectors, farmers' incomes will grow less rapidly than those of the owners of other businesses, and farm workers' wages will grow less rapidly than those of other workers.

Supply problems. Farming productivity has grown dramatically over the years as farmers have invested in new

technology and improved farming methods. But, given the price-inelastic demand for food, increased supply will have the effect of driving down agricultural prices, thus largely offsetting any reduction in costs. And given the income-inelastic demand for food, the long-term rise in demand will be less than the long-term rise in supply.

Figure 3.11 shows a basic foodstuff like potatoes or other vegetables. Rising productivity leads to an increase in supply from S_1 to S_2 . But given that demand is price inelastic and shifts only slightly to the right over time, from D_1 to D_2 , price falls from P_1 to P_2 .

As we saw above, this national effect of low price and income elasticities of demand and rising supply has been offset in recent years by growing world demand for food and

Figure 3.11 Decline in food prices over time

problems with world supply, such as poor harvests, rising input costs (such as diesel and fertilisers) and the diversion of land to growing biofuels – in 2013, some 35 per cent of the US maize (corn) crop was being used for ethanol production. The effect of all this is a substantial increase in the prices of many foodstuffs, and in particular wheat, rice, maize and soya.

Government intervention

There are five main types of government intervention that can be used to ease the problems for farmers.

Buffer stocks

Buffer stocks involve the government buying food and placing it in store when harvests are good, and then releasing the food back on to the market when harvests are bad. They can thus only be used with food that can be stored: i.e. non-perishable foods, such as grain; or food that can be put into frozen storage, such as butter. The idea of buffer stocks is a very ancient one, as Case Study 3.4 on the student website demonstrates.

What the government does is to fix a price. Assume that this is P_g in Figure 3.12. At this price demand is Q_{d1} . If there is a good harvest (S_{a1}), the government buys up the surplus, $Q_{s1} - Q_{d1}$, and puts it into store. If there is a bad harvest (S_{b1}), it releases $Q_d - Q_{s2}$ from the store on to the market.

This system clearly stabilises price, at P_g . At this price, though, farm incomes will still fluctuate with the size of the harvest. It is possible, however, to have a buffer stock system that stabilises *incomes*. Such a system is examined in Case Study 3.5 on the student website.

To prevent stores mounting over time, the government price will have to be the one that balances demand and supply over the years. Surpluses in good years will have to match shortages in bad years. Buffer stocks, therefore, can only

Figure 3.12 Buffer stocks to stabilise prices

stabilise prices or incomes; they do not *increase* farm incomes over the long term.

Subsidies

The government can pay subsidies or grant tax relief to farmers to compensate for low market prices. Subsidies can be used to increase farm incomes as well as to stabilise them. The simplest form of subsidy is one known as **direct income support** or **direct aid**. Here farmers are paid a fixed sum of money irrespective of output. Given that such subsidies are unrelated to output, they do not provide an incentive to produce more.

An alternative system is to pay a subsidy *per unit of output*, which we examined in section 3.2. Figure 3.7 on page 92 illustrates the impact of a specific subsidy on an agricultural product in which the country is self-sufficient – farmers have an incentive to produce more, and the market price falls.

When some of the product is imported, the effect is slightly different. Let us assume, for simplicity, that a country is a price taker in world markets. It will face a horizontal world supply curve of the product at the world price. In other words, consumers can buy all they want at the world price. In Figure 3.13 the world price is P_w . Without a subsidy, domestic supply is Q_{s1} . Domestic demand is Q_d . Imports are therefore the difference: $Q_d - Q_{s1}$.

Assume now that the government wants farmers to receive a price of P_g . At that price, domestic supply increases

Definitions

Buffer stocks Stocks of a product used to stabilise its price. In years of abundance, the stocks are built up. In years of low supply, stocks are released on to the market.

Direct income support or direct aid A fixed grant to farmers that does not vary with current output. It may be based on acreage, number of livestock or past output.

Figure 3.13 Effect of subsidies on agricultural products which are partly imported

to Q_{s2} , but the price paid by the consumer does not fall. It remains at P_w . The subsidy paid per unit is $P_g - P_w$. The cost to the taxpayer is again shown by the shaded area.

A problem with subsidies of a fixed amount per unit is that the price the farmer receives will fluctuate along with the market price. An alternative, therefore, would be to let the size of the subsidy vary with the market price. The lower the price, the bigger the subsidy.

An advantage of subsidies is that they result in lower prices for the consumer. On the other hand, they have to be paid from tax revenues and therefore result in higher taxes.

High minimum prices

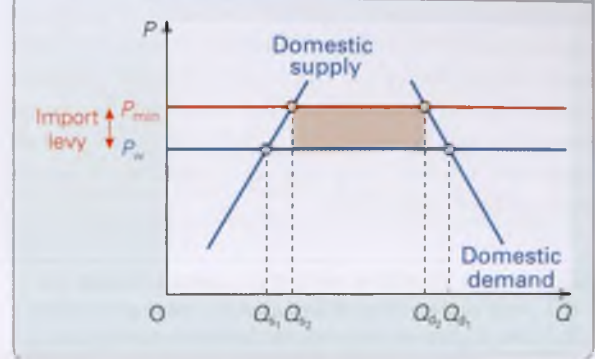

If the government considers agricultural prices to be too low, it can set a minimum price for each product above the free-market level as we discussed in section 3.1. This was the traditional approach adopted in the EU. In recent years, however, forms of intervention in the EU have become more diverse.

Once again, the effect of high minimum prices will vary between products, depending on whether the country is a net importer or self-sufficient. If the country is self-sufficient, Figure 3.3 on page 82 would illustrate its impact.

? How would Figure 3.3 change if the government were able to sell the surplus food on the world market.

Agricultural products where the country is a net importer. Assuming that the minimum price is above the world price, the government will need to impose customs duties (known alternatively as **tariffs** or **import levies**) on imported products to bring them up to the required price. Given that the world price will fluctuate, these import levies would need to be variable.

Figure 3.14 Minimum price where some of the product is imported

The effects of this system are illustrated in Figure 3.14. If trade took place freely at the world price P_w , Q_{d1} would be demanded and Q_{s1} supplied domestically. The difference ($Q_{d1} - Q_{s1}$) would be imported.

If a minimum price P_{min} is now set and a levy imposed on imports to raise their price to P_{min} , domestic prices will also rise to this level. Demand will fall to Q_{d2} . Domestic supply will rise to Q_{s2} . Imports will fall to $Q_{d2} - Q_{s2}$. The amount paid in import levies is shown by the shaded area.

? What would be the amount paid in Figure 3.14 if instead of the government buying the surpluses, export subsidies were given to farmers so as to guarantee them a price (plus subsidy) of P_{min} ?

Reductions in supply

An alternative approach would be to find some way of reducing supply. This would lead to a higher market price and could avoid the cost to the taxpayer of buying surpluses or paying subsidies.

In open markets, however, a reduction in domestic supply could simply lead to an increase in imports, with the result that the price would not rise to the desired level. In such a case, a combination of a reduction in domestic supply and import levies (or other import restrictions) would be required.

But how could supply be reduced? The simplest way would be to give farmers a quota specifying how much each was allowed to produce. Milk quotas, which have been in force in the EU since 1984, are an example of this system.

Definition

Tariffs or import levies Taxes on imported products: i.e. customs duties.

Alternatively, farmers could be required to limit the amount of *land* they use for a particular product. The problem with this is that supply, and hence price, would still vary according to the yield. Another alternative would be to require farmers to withdraw a certain percentage of their land from agricultural use. This would shift supply curves for food to the left generally, but they would still be upward sloping because farmers could still switch from one product to another on their remaining land, according to which products gave the best price.

Compare the relative merits of (a) quotas on output, (b) limits to the amount of land used for a particular product and (c) farmers being required to take land out of food production.

Structural policies

The government could provide retraining or financial help for people to leave agriculture. It could provide grants or other incentives for farmers to diversify into forestry, tourism, rural industry or different types of food, such as organically grown crops, or other foods with a high income elasticity of demand.

The EU has made major interventions in agriculture over the years under its Common Agricultural Policy or 'CAP' using a mixture of high minimum prices, import levies, subsidies and supply restrictions. It has made major reforms to the system over the years in response to various criticisms and the changing agricultural environment. The CAP is examined in Case Study 3.8 on the student website.

Section summary

- Despite the fact that a free market in agricultural produce would be highly competitive, there is large-scale government intervention in agriculture throughout the world. The aims of intervention include preventing or reducing price fluctuations, encouraging greater national self-sufficiency, increasing farm incomes, encouraging farm investment, and protecting traditional rural ways of life and the rural environment generally.
- Price fluctuations are the result of fluctuating supply combined with a price-inelastic demand. The supply fluctuations are due to fluctuations in the harvest.
- The demand for food is generally income inelastic and thus grows only slowly over time. Supply, on the other hand, has generally grown rapidly as a result of new technology and new farm methods. This puts downward pressure on prices – a problem made worse for farmers by the price inelasticity of demand for food.
- Government intervention can be in the form of buffer stocks, subsidies, price support, quotas and other ways of reducing supply, and structural policies.
- Buffer stocks can be used to stabilise prices. They cannot be used to increase farm incomes over time.
- Subsidies will increase farm incomes but will lower consumer prices to the world price level (or to the point where the market clears).
- Minimum (high) prices will create surpluses, which must be bought by the government and possibly resold on international markets. In the case of partly imported foodstuffs, the high price is achieved by imposing variable import levies.
- Supply can be reduced by the imposition of quotas on output or restricting the amount of land that can be used.

END OF CHAPTER QUESTIONS

1. Assume that the (weekly) market demand and supply of tomatoes are given by the following figures:

Price (£ per kilo)	4.00	3.50	3.00	2.50	2.00	1.50	1.00
Q_d (000 kilos)	30	35	40	45	50	55	60
Q_s (000 kilos)	80	68	62	55	50	45	38

- What are the equilibrium price and quantity?
- What will be the effect of the government fixing a *minimum* price of (i) £3 per kilo; (ii) £1.50 per kilo?
- Suppose that the government paid tomato producers a subsidy of £1 per kilo.
 - Give the new supply schedule.
 - What will be the new equilibrium price?
 - How much will this cost the government?
- Alternatively, suppose that the government guaranteed tomato producers a price of £2.50 per kilo.
 - How many tomatoes would it have to buy in order to ensure that all the tomatoes produced were sold?
 - How much would this cost the government?
- Alternatively, suppose it bought *all* the tomatoes produced at £2.50.
 - At what single price would it have to sell them in order to dispose of the lot?
 - What would be the net cost of this action?

2. Think of two things that are provided free of charge. In each case, identify whether and in what form a shortage might occur. In what ways are/could these shortages be dealt with? Are they the best solution to the shortages?
3. Discuss the relative merits of the different methods used by the All England Tennis Club to allocate tickets for Wimbledon each year.
4. If the government increases the tax on a litre of petrol by 5p, what will determine the amount by which the price of petrol will go up as a result of this tax increase?
5. Illustrate on four separate diagrams (as in Figure 3.6) the effect of different elasticities of demand and supply on the incidence of a subsidy.
6. The Soft Drinks Industry Levy will take effect in the UK from April 2018. Explain how this tax will work and discuss its potential impact on consumer behaviour.
7. Why are agricultural prices subject to greater fluctuations than those of manufactured products?
8. Compare the relative benefits of subsidies and high minimum prices to (a) the consumer; (b) the producer.

7	Profit Maximising under Perfect Competition and Monopoly	189
8	Profit Maximising under Imperfect Competition	217
9	The Behaviour of Firms	250
10	The Theory of Distribution of Income	277

We now examine in more detail how economies function at a micro level. In doing so, we look at some of the big questions of our time. How do consumers choose between different goods? Why do some firms make such large profits? Why is there such a gap between the rich and the poor?

Chapters 4 to 6 examine demand and supply in more detail. Then in Chapters 7 to 9 we look at how the degree of competition a firm faces affects its prices and profits. Finally, in Chapter 10 we look at the distribution of income: why some people are rich while others are poor.

The income and substitution effects of a price change	122
The usefulness of indifference analysis	124

In this chapter we take a more detailed look at consumer demand. If we had unlimited income and time we would not have to be careful with our money. In the real world, however, given limited incomes and the problem of scarcity, we have to make choices about what to buy. You may have to choose between buying textbooks and going to a festival, between a new pair of jeans and a meal out, between saving for a car and having more money to spend on everyday items.

We start by assuming in this chapter that consumers behave 'rationally'. Remember in Chapter 1 we defined rational choices, those that involve weighing up the costs and benefits of our actions. As far as consumption is concerned, rational action involves considering the relative costs and benefits to us of the alternatives we could spend our money on. We do this in order to gain the maximum satisfaction possible from our limited incomes.

Of course, this does not mean that you look at every item on the supermarket shelf and weigh up the satisfaction you think you would get from it against the price on the label. Nevertheless, you have probably learned over time the sort of things you like and what they cost and can make out a 'rational' shopping list quite quickly.

There are two main approaches to analysing consumer behaviour: the marginal utility approach and the indifference approach. We examine both of them in this chapter.

We also look at the problem of making rational choices when benefits occur over a period of time, as is the case with durable goods, or later, as is the case with goods where there is a waiting list or where orders take some time to deliver.

As we start by examining the *rational consumer*, it is important to understand what we mean by the term. Economists use it to refer to a person who attempts to get the best value for money from their purchases, given a limited income. Thus the rational consumer tries to ensure that the benefits of a purchase are worth the expense.

Sometimes we may act 'irrationally'. We may buy goods impetuously or out of habit. In general, however, economists believe it is reasonable to assume that people behave rationally.

 Do you ever purchase things irrationally? If so, what are they and why is your behaviour irrational?

Two words of warning before we go on. First, don't confuse irrationality and ignorance. In this chapter we assume that consumers behave rationally, (something we query in the next chapter) but that does not mean they have perfect information. Have you ever been disappointed after buying

something? Perhaps it was not as good as you had expected from an advert? Or perhaps you found later that you could have bought an alternative more cheaply? Perhaps a holiday may not turn out to be as good as the website led you to believe. This is a problem of ignorance rather than irrationality.

Second, the term 'rational' does not imply any approval of the decision involved. It is simply referring to behaviour that is consistent with your own particular goals: behaviour directed to getting the most out of your limited income. People may disapprove of the things that others buy – their clothes, junk food, lottery tickets – but as economists we should not make judgements about people's goals. We can, however, look at the implications of people behaving rationally in pursuit of those goals. This is what we are doing when we examine rational consumer behaviour: we are looking at its implications for consumer demand.

4.1 MARGINAL UTILITY THEORY

Total and marginal utility

People buy goods and services because they get satisfaction from them. Economists call this satisfaction 'utility'.

An important distinction must be made between *total utility* and *marginal utility*.

Total utility (TU) is the total satisfaction a person gains from all those units of a commodity consumed within a given time period. If Lucy drinks 10 cups of tea a day, her daily total utility from tea is the satisfaction derived from those 10 cups.

Marginal utility (MU) is the additional satisfaction gained from consuming one *extra* unit within a given period of time. Thus we might refer to the marginal utility that Lucy gains from her third cup of tea of the day or her eleventh cup.

A difficulty arises with the utility approach to explaining demand: how do you measure utility? Utility is subjective. There is no way of knowing what another person's experiences are really like. How satisfying does Nick find his first cup of tea in the morning? How does his utility compare with Lucy's?

For the moment, we will assume that a person's utility *can be measured*. We use an imaginary measure called *utils*, where a *util* is one unit of satisfaction.

Diminishing marginal utility

Up to a point, the more of a commodity you consume, the greater will be your total utility. However, as you become more satisfied, each extra unit that you consume will probably give you less additional utility than previous units. In other words, your marginal utility falls, the more you consume. This is known as the *principle of diminishing marginal utility*.

The principle of diminishing marginal utility. The more of a product a person consumes, the less will be the additional utility gained from one more unit.

For example, the second cup of tea in the morning gives you less additional satisfaction than the first cup. The third cup gives less satisfaction still.

At some level of consumption, your total utility will be at a maximum. No extra satisfaction can be gained by the consumption of further units within that period of time. Thus marginal utility will be zero. Your desire for tea may be fully satisfied at seven cups per day. An eighth cup will yield no extra utility. It may even give you displeasure (i.e. negative marginal utility).

Definitions

Rational consumer A person who weighs up the costs and benefits to them of each additional unit of a good purchased.

Total utility The total satisfaction a consumer gets from the consumption of all the units of a good consumed within a given time period.

Marginal utility The extra satisfaction gained from consuming one extra unit of a good within a given time period.

Util An imaginary unit of satisfaction from the consumption of a good.

Principle of diminishing marginal utility As more units of a good are consumed, additional units will provide less additional satisfaction than previous units.

Are there any goods or services where consumers do not experience diminishing marginal utility?

Total and marginal utility curves

If we could measure utility, we could construct a table showing how much total and marginal utility a person would gain at different levels of consumption of a particular commodity. This information could then be transferred to a graph. Table 4.1 and Figure 4.1 do just this. They show the imaginary utility that Ollie gets from consuming packets of crisps.

Referring first to the table, if Ollie consumes no crisps, he obviously gets no satisfaction from crisps: his total utility is zero. If he now consumes one packet a day, he gets 7 utils of satisfaction. (Sorry if this sounds silly, but we will tackle this question of measurement later.) His total utility is 7, and his marginal utility is also 7. They must be equal if only one unit is consumed.

If he now consumes a second packet, he gains an extra 4 utils (*MU*), giving him a total utility of 11 utils (i.e. 7 + 4). His marginal utility has fallen because, having already eaten one packet, he has less craving for a second. A third packet gives him less extra utility still: marginal utility has fallen to 2 utils, giving a total utility of 13 utils (i.e. 11 + 2).

By the time he has eaten five packets, he would rather not eat any more. A sixth actually reduces his utility (from 14 utils to 13): its marginal utility is negative.

The information in Table 4.1 is plotted in Figure 4.1. Notice the following points about the two curves:

- The *MU* curve slopes downwards. This is simply illustrating the principle of diminishing marginal utility.
- The *TU* curve starts at the origin. Zero consumption yields zero utility.
- The *TU* curve reaches a peak when marginal utility is zero. When marginal utility is zero (at five packets of crisps), there is no addition to total utility. Total utility must be at the maximum – the peak of the curve.
- Marginal utility can be derived from the *TU* curve. It is the slope of the line joining two adjacent quantities on the curve. For example, the marginal utility of the third packet of crisps is the slope of the line joining points *a* and *b*. The slope of such a line is given by the formula

$$\frac{\Delta TU}{\Delta Q} (= MU)$$

In our example $\Delta TU = 2$ (total utility has risen from 11 to 13 utils), and $\Delta Q = 1$ (one more packet of crisps has been consumed). Thus $MU = 2$.

Table 4.1 Ollie's utility from consuming crisps (daily)

Packets of crisps consumed	TU in utils	MU in utils
0	0	-
1	7	7
2	11	4
3	13	2
4	14	1
5	14	0
6	13	-1

*BOX 4.1

USING CALCULUS TO DERIVE A MARGINAL UTILITY FUNCTION

EXPLORING
ECONOMICS

The relationship between total utility and marginal utility can be shown using calculus. If you are not familiar with the rules of calculus, ignore this box (or see Appendix 1, pages A:9–13).

A consumer's typical utility function for a good might be of the form

$$TU = 60Q - 4Q^2$$

where Q is the quantity of the good consumed. This would give the figures shown in the following table.

Q	$60Q$	$-4Q^2$	=	TU
1	60	-4	=	56
2	120	-16	=	104
3	180	-36	=	144
4	240	-64	=	176

- ?** 1. Complete this table to the level of consumption at which TU is at a maximum.

Marginal utility is the first derivative of total utility. In other words, it is the rate of change of total utility. Differentiating the TU function gives

$$MU = \frac{dTU}{dQ} = 60 - 8Q$$

This gives the figures shown in the following table.

Q	$60Q$	$-8Q$	=	MU
1	60	-8	=	52
2	60	-16	=	44
3	60	-24	=	36
4	60	-32	=	28

Note that the marginal utility diminishes.

The MU function we have derived is a straight-line function. If, however, the TU function contained a cubed term (Q^3), the MU function would be a curve.

- ?** 2. Derive the MU function from the following TU function:

$$TU = 200Q - 25Q^2 + Q^3$$

From this MU function, draw a table (like the one above) up to the level of Q where MU becomes negative. Graph these figures.

- ?** If Ollie were to consume more and more crisps, would his total utility ever (a) fall to zero; (b) become negative? Explain.

The ceteris paribus assumption

The table and graph we have drawn are based on the assumption that other things do not change.

In practice, other things *do* change – and frequently. The utility that Ollie gets from crisps depends on what else he eats. If on Saturday he has a lot to eat he will get little satisfaction from crisps. If on Monday, however, he is too busy to eat proper meals, he would probably welcome one or more packets of crisps.

Each time the consumption of *other* goods changed – whether substitutes or complements – a new utility schedule would have to be drawn up. The curves would shift. Remember, utility is not a property of the goods themselves. Utility is in the mind of the consumer, and consumers change their minds. Their tastes change; their circumstances change; their consumption patterns change.

The optimum level of consumption: the simplest case – one commodity

Just how much of a good should people consume if they are to make the best use of their limited income? To answer this question we must tackle the problem of how to measure utility, given that in practice we cannot measure 'utils'.

One solution to the problem is to measure utility with money. In this case, utility becomes the value that people place on their consumption. Marginal utility thus becomes the amount of money a person would be prepared to pay to obtain one more unit: in other words, what that extra unit is worth to that person. If Ollie is prepared to pay 60p to obtain an extra packet of crisps, then we can say that packet yields him 60p worth of utility: $MU = 60p$.

So how many packets should he consume if he is to act rationally? To answer this we need to introduce the concept of **consumer surplus**.

Marginal consumer surplus

Marginal consumer surplus (MCS) is the difference between what you are willing to pay for one more unit of a good and what you are actually charged. If Ollie were willing to pay 45p for another packet of crisps which in fact only cost him 40p, he would be getting a marginal consumer surplus of 5p.

$$MCS = MU - P$$

Definitions

Consumer surplus The excess of what a person would have been prepared to pay for a good (i.e. the utility) over what that person actually pays.

Marginal consumer surplus The excess of utility from the consumption of one more unit of a good (MU) over the price paid: $MCS = MU - P$.

Total consumer surplus

Total consumer surplus (TCS) is the sum of all the marginal consumer surpluses that you have obtained from all the units of a good you have consumed. It is the difference between the total utility from all the units and your expenditure on them. If Ollie consumes four packets of crisps, and if he would have been prepared to spend £2.60 on them and only had to spend £2.20, then his total consumer surplus is 40p.

$$TCS = TU - TE$$

where TE is the total expenditure on a good: i.e. $P \times Q$.

Let us define **rational consumer behaviour** as the attempt to maximise consumer surplus. How do people set about doing this?

People will go on purchasing additional units as long as they gain additional consumer surplus: in other words, as long as the price they are prepared to pay exceeds the price they are charged ($MU > P$). But as more is purchased, so they will experience diminishing marginal utility. They will be prepared to pay less for each additional unit.

Their marginal utility will go on falling until $MU = P$: i.e. until no further consumer surplus can be gained. At that point, they will stop purchasing additional units. Their optimum level of consumption has been reached: consumer surplus has been maximised. If they continue to purchase beyond this point, MU would be less than P , and thus they would be paying more for the last units than they were worth to them.

The process of maximising consumer surplus can be shown graphically. Let us take the case of Tanya's annual purchases of petrol. Tanya has her own car, but as an alternative she can use public transport or walk. To keep the analysis simple, let us assume that Tanya's parents bought her the car and pay the licence duty, and that Tanya does not have the option of selling the car. She does, however, have to buy the petrol. The current price is £1.30 per litre. Figure 4.2 shows her consumer surplus.

If she were to use just a few litres per year, she would use them for very important journeys for which no convenient alternative exists. For such trips she may be prepared to pay up to £1.60 per litre. For the first few litres, then, she is getting a marginal utility of around £1.60 per litre, and hence a marginal consumer surplus of around 30p (i.e. £1.60 – £1.30).

By the time her annual purchase is around 200 litres, she would be prepared to pay only around £1.50 for additional litres. The additional journeys, although still important, would be less vital. Perhaps these are journeys where she could have taken public transport, albeit at some inconvenience. Her marginal consumer surplus at 200 litres is 20p (i.e. £1.50 – £1.30).

Gradually, additional litres give less and less additional utility as less important journeys are undertaken. The 500th litre yields £1.40 worth of extra utility. Marginal consumer surplus is now 10p (i.e. £1.40 – £1.30).

By the time she gets to the 900th litre, Tanya's marginal utility has fallen to £1.30. There is no additional consumer

Figure 4.2 Tanya's consumer surplus from petrol

surplus to be gained. Her total consumer surplus is at a maximum. She thus buys 900 litres, where $P = MU$.

Her total consumer surplus is the sum of all the marginal consumer surpluses: the sum of all the 900 vertical lines between the price and the MU curve. This is shown by the total area between P and MU up to 900 litres (i.e. the pink shaded area in Figure 4.2).

This analysis can be expressed in general terms. In Figure 4.3, if the price of a commodity is P_1 , the consumer will consume Q_1 . The person's total expenditure (TE) is

Figure 4.3 Consumer surplus

Definitions

Total consumer surplus The excess of a person's total utility from the consumption of a good (TU) over the total amount that person spends on it (TE):

$$TCS = TU - TE.$$

Rational consumer behaviour The attempt to maximise total consumer surplus.

THRESHOLD CONCEPT 8

RATIONAL DECISION MAKING INVOLVES CHOICES AT THE MARGIN

THINKING LIKE AN ECONOMIST

Rational decision making involves weighing up the marginal benefit and marginal cost of any activity. If the marginal benefit exceeds the marginal cost, it is rational to do the activity (or to do more of it). If the marginal cost exceeds the marginal benefit, it is rational not to do it (or to do less of it).

Let's take the case of when you go to the supermarket to do shopping for the week. Assume that you have £50 to spend. Clearly, you will want to spend it wisely. With each item you consider buying, you should ask yourself what its marginal benefit is to you: in other words, how much you would be prepared to spend on it. This will depend on the prices and benefits of alternatives. Thus if you were considering spending £3 from the £50 on wholemeal bread, you should ask yourself whether the £3 would be better spent on some alternative, such as white bread, rolls or crackers. The *best* alternative (which might be a combination of products) is the marginal opportunity cost. If the answer is that you feel you are getting better value for money by spending it on the wholemeal bread, then you are saying that the marginal benefit exceeds the marginal opportunity cost. It is an efficient use of your money to buy the wholemeal bread and forgo the alternatives.

Most decisions are more complex than this, as they involve buying a whole range of products. In fact, that is what you are doing in the supermarket. But the principle is still the same. In each case, a rational decision involves weighing up marginal benefits and marginal costs.

This is another example of a *threshold concept* because it is a way of thinking about economic problems. It is a general

principle that can be applied in a whole host of contexts: whether it is individuals deciding what to buy, how much to work, what job to apply for, or whether to study for a degree or take a job; or firms deciding how much to produce, whether to invest in new capacity or new products, or what type of people to employ and how many; or governments deciding how much to spend on various projects, such as roads, hospitals and schools, or what rates of tax to impose on companies that pollute the environment.

In each case, better decisions will be made by weighing up marginal costs and marginal benefits.

1. Assume that a firm is selling 1000 units of a product at £20 each and that each unit on average costs £15 to produce. Assume also that to produce additional units will cost the firm £19 each and that the price will remain at £20. To produce additional products will therefore reduce the average profit per unit. Should the firm expand production? Explain.
2. Assume that a ferry has capacity for 500 passengers. Its operator predicts that it will typically have only 200 passengers on each of its midweek sailings over the winter. Assume also that each sailing costs the company £10 000. This means that midweek winter sailings cost the company an average of £10 000/200 = £50 per passenger. Currently tickets cost £60. Should the company consider selling stand-by tickets during the winter for (a) less than £60; (b) less than £50? (Clue: think about the marginal cost of taking additional passengers.)

P_1Q_1 , shown by area 1. Total utility (TU) is the area under the marginal utility curve: i.e. areas 1 + 2. Total consumer surplus ($TU - TE$) is shown by area 2.

If a good were free, why would total consumer surplus equal total utility? What would be the level of marginal utility at the equilibrium level of consumption?

Marginal utility and the demand curve for a good

An individual's demand curve

Individual people's demand curve for any good will be the same as their marginal utility curve for that good, where utility is measured in money.

This is demonstrated in Figure 4.4, which shows the marginal utility curve for a particular person and a particular good. If the price of the good were P_1 , the person would consume Q_1 , where $MU = P_1$. Thus point *a* would be one point on that person's demand curve. If the price fell to P_2 , consumption would rise to Q_2 , since this is where $MU = P_2$. Thus point *b* is a second point on the demand curve. Likewise if

Figure 4.4 An individual person's demand curve

price fell to P_3 , Q_3 would be consumed. Point *c* is a third point on the demand curve.

Thus as long as individuals seek to maximise consumer surplus and hence consume where $P = MU$, their demand curve will be along the same line as their marginal utility curve.

The market demand curve

The market demand curve will simply be the (horizontal) sum of all individuals' demand curves and hence *MU* curves.

The shape of the demand curve. The price elasticity of demand will reflect the rate at which *MU* diminishes. If there are close substitutes for a good, it is likely to have an elastic demand, and its *MU* will diminish slowly as consumption increases. The reason is that increased consumption of this product will be accompanied by decreased consumption of the alternative product(s). Since total consumption of this product plus the alternatives has increased only slightly (if at all), the marginal utility will fall only slowly.

For example, the demand for a certain brand of petrol is likely to have a fairly high price elasticity, since other brands are substitutes. If there is a cut in the price of Texaco petrol (assuming the prices of other brands stay constant), then consumption of Texaco petrol will increase a lot. The *MU* of Texaco petrol will fall slowly, since people consume less of other brands. Petrol consumption *in total* may be only slightly greater, and hence the *MU* of petrol only slightly lower.

? Why do we get less total consumer surplus from goods where our demand is relatively elastic?

Shifts in the demand curve. How do shifts in demand relate to marginal utility? For example, how would the marginal utility of (and hence demand for) tea be affected by a rise in the price of coffee? The higher price of coffee would cause less coffee to be consumed. This would increase the marginal utility of tea since if people are drinking less coffee, their desire for tea is higher. The *MU* curve (and hence the demand curve) for tea thus shifts to the right.

? How would marginal utility and market demand be affected by a rise in the price of a complementary good?

Weaknesses of the one-commodity version of marginal utility theory

A change in the consumption of one good will affect the marginal utility of substitute and complementary goods. It will also affect the amount of income left over to be spent on other goods. Thus, a more satisfactory explanation of demand would involve an analysis of choices between goods, rather than looking at one good in isolation.

What is more, deriving a demand curve from a marginal utility curve measured in money assumes that money itself has a constant marginal utility. The trouble is that it does not. If people have a rise in income, they will consume more. Other things being equal, the marginal utility of the goods that they consume will diminish. Thus an extra £1 of consumption will bring less satisfaction than previously. In other words, it is likely that the *marginal utility of money diminishes as income rises*.

Unless a good occupies only a tiny fraction of people's expenditure, a fall in its price will mean that their real income has increased: i.e. they can afford to purchase more goods in general. As they do so, the marginal utility of their money will fall. We cannot, therefore, legitimately use money to measure utility in an absolute sense. We can, however, still talk about the relative utility that we get from various goods for a given increase in expenditure.

The following sections thus look at the choice between goods, and how it relates to marginal utility.

The optimum combination of goods consumed

We can use marginal utility analysis to show how a rational person decides what combination of goods to buy. Given that we have limited incomes, we have to make choices. It is not just a question of choosing between two obvious substitutes, like a holiday in Greece and one in Spain, but about allocating our incomes between all the goods and services we might like to consume. If you have, say, an income of £20 000 per year, what is the optimum 'bundle' of goods and services for you to spend it on?

The rule for rational consumer behaviour is known as the **equi-marginal principle**. This states that a consumer will get the highest utility from a given level of income when the ratio of the marginal utilities is equal to the ratio of the prices. Algebraically, this is when, for any pair of goods, A and B, that are consumed:

$$\frac{MU_A}{MU_B} = \frac{P_A}{P_B} \quad (1)$$

To understand this, suppose that the last unit of good A you consumed gave three times as much utility as the last unit of B. Yet good A only cost twice as much as good B. You would obviously gain by increasing your consumption of A and cutting your purchases of B. But as you switched from B to A, the marginal utility of A would fall due to diminishing marginal utility, and conversely the marginal utility of B would rise.

To maximise utility you would continue this substitution of A for B until the ratios of the marginal utilities (MU_A/MU_B) equalled the ratio of the prices of the two goods (P_A/P_B). At this point, no further gain can be made by switching from one good to another. This is the optimum combination of goods to consume.

Equation (1) is a specific example of the general equi-marginal principle in economics, which applies to all rational

Definition

Equi-marginal principle (in consumption) Consumers will maximise total utility from their incomes by consuming that combination of goods where

$$\frac{MU_A}{MU_B} = \frac{P_A}{P_B}$$

BOX 4.2

THE MARGINAL UTILITY REVOLUTION: JEVONS, MENGER, WALRAS

EXPLORING ECONOMICS

Solving the diamonds–water paradox

What determines the market value of a good? We already know the answer: demand and supply. So if we find out what determines the position of the demand and supply curves, we will at the same time be finding out what determines a good's market value.

This might seem obvious. Yet for years economists puzzled over just what determines a good's value.

Some economists like Karl Marx and David Ricardo concentrated on the supply side. For them, value depended on the amount of resources used in producing a good. This could be further reduced to the amount of labour time embodied in the good. Thus, according to the labour theory of value, the more labour that was directly involved in producing the good, or indirectly in producing the capital equipment used to make the good, the more valuable would the good be.

Other economists looked at the demand side. But here they came across a paradox.

Adam Smith in the 1760s gave the example of water and diamonds. 'How is it', he asked, 'that water which is so essential to human life, and thus has such a high "value-in-use", has such a low market value (or "value-in-exchange")? And how is it that diamonds which are relatively so trivial have such a high market value?' The answer to this paradox had to wait over a hundred years until the marginal utility revolution of the 1870s. William Stanley Jevons (1835–82) in England, Carl Menger (1840–1921) in Austria and Léon Walras (1834–1910) in Switzerland all independently claimed that the source of the market value of a good was its marginal utility, not its total utility.

This was the solution to the diamonds–water paradox. Water, being so essential, has a high total utility: a high 'value in use'. But for most of us, given that we consume so much already, it has a very low marginal utility. Do you leave the cold tap running when you clean your teeth? If you do, it shows just how trivial water is to you at the margin. Diamonds, on the

other hand, although they have a much lower total utility, have a much higher marginal utility. There are so few diamonds in the world, and thus people have so few of them, that they are very valuable at the margin. If, however, a new technique were to be discovered of producing diamonds cheaply from coal, their market value would fall rapidly. As people had more of them, so their marginal utility would rapidly diminish.

Marginal utility still only gives the demand side of the story. The reason why the marginal utility of water is so low is that supply is so plentiful. Water is very expensive in Saudi Arabia! In other words, the full explanation of value must take into account both demand and supply.

? The diagram illustrates a person's MU curves of water and diamonds. Assume that diamonds are more expensive than water. Show how the MU of diamonds will be greater than the MU of water. Show also how the TU of diamonds will be less than the TU of water. (Remember: TU is the area under the MU curve.)

choices between two alternatives, whether in production, consumption, employment or whatever.

The multi-commodity version of marginal utility and the demand curve

How can we derive a demand curve from the above analysis?

Let us simply reinterpret equation (1) so that it relates the MU and P of good A to the MU and P of any other good. In

other words, the equation would be the same for goods B, C, D, E and any other good. For any given income, and given prices for good A and all other goods, the quantity a person will demand of good A will be that which satisfies equation (1). One point on the individual's demand curve for good A has been determined.

If the price of good A now falls, such that

$$\frac{MU_A}{MU_B} > \frac{P_A}{P_B} \quad (\text{and similarly for goods C, D, E, etc.})$$

the person would buy more of good A and less of all other goods (B, C, D, E, etc.), until equation (1) is once more satisfied. A second point on the individual's demand curve for good A has been determined.

Further changes in the price of good A would bring further changes in the quantity demanded, in order to satisfy equation (1). Further points on the individual's demand curve would thereby be derived.

The equi-marginal principle. The optimum amount of two alternatives consumed (or produced) will be where the marginal benefit ratios of the two alternatives are equal to their marginal cost ratios:

$$\frac{MU_A}{MU_B} = \frac{P_A}{P_B}$$

If the price of *another* good changed, or if the marginal utility of any good changed (including good A), then again the quantity demanded of good A (and other goods) would

change, until again equation (1) were satisfied. The changes in demand will be represented by a *shift* in the demand curve for good A.

BOX 4.3

TAKING ACCOUNT OF TIME

CASE STUDIES AND APPLICATIONS

Do you take a taxi or go by bus? How long do you spend soaking in the bath? Do you cook a meal from scratch, or will you get a take-away?

We have argued that if decisions are to be rational, they should involve weighing up the relative marginal utilities of these activities against their relative marginal costs. As economists, of course we are interested in considering all costs, including time. One of the opportunity costs of doing any activity is the sacrifice of time.

A take-away meal may be more expensive than one cooked at home, but it saves you time. Part of the cost of the home-cooked meal, therefore, is the sacrifice of time involved. The full cost is therefore not just the cost of the ingredients and the fuel used, but also the opportunity cost of the alternative activities you have sacrificed while you were cooking.

Given the busy lives many people lead in affluent countries, they often put a high value on time. Increased

sales of ready meals and the employment of home cleaners are consequences of this valuation.

Of course, leisure activities also involve a time cost. The longer you spend doing pleasurable activity 'a', the less time you will have for doing pleasurable activity 'b'. The longer you laze in the bath, the less TV you will be able to watch (unless you have a TV in the bathroom).

1. We have identified that consumers face limits on their income and time. Can you think of any other constraints that we face when making consumption decisions?
2. Give some examples of business opportunities that could arise as a consequence of people being 'cash-rich, but time-poor'.
3. If someone hires a cleaner, does this imply that they are 'cash-rich, but time-poor'? How about hiring a personal trainer?

Section summary

1. The satisfaction people get from consuming a good is called 'utility'. Total utility is the satisfaction gained from the total consumption of a particular good over a given period of time. Marginal utility is the extra satisfaction gained from consuming one more unit of the good.
2. The marginal utility tends to fall the more that people consume. This is known as the 'principle of diminishing marginal utility'.
3. The utility that people get from consuming a good will depend on the amount of other goods they consume. A change in the amount of other goods consumed, whether substitutes or complements, will shift the total and marginal utility curves.
4. 'Rational' consumers will attempt to maximise their consumer surplus. Consumer surplus is the excess of people's utility (measured in money terms) over their expenditure on the good. This will be maximised by purchasing at the point where the *MU* of a good is equal to its price.
5. In the simple case where the price and consumption of other goods is held constant, a person's *MU* curve will lie along the same line as that person's demand curve.
6. The market demand curve is merely the horizontal sum of the demand curves of all the individual consumers. The elasticity of the market demand curve will depend on the rate at which marginal utility diminishes as more is consumed. This in turn depends on the number and closeness of substitute goods. If there are close substitutes, people will readily switch to this good if its price falls, and thus marginal utility will fall only slowly. The demand will be elastic.
7. Measuring the marginal utility of a good in money avoids the problem of using some imaginary unit such as utils, but it assumes that money has a constant utility. In reality, the marginal utility of money is likely to decrease as income rises.
8. A more satisfactory way of analysing the demand for goods is to look at people's choices between goods. A consumer will maximise utility from a given income by consuming according to the 'equi-marginal principle'. This states that goods should be consumed in that combination which equates the MU/P ratio for each good.

4.2 THE TIMING OF COSTS AND BENEFITS

The exact timing of the costs incurred and the benefits received varies between different types of consumption. This has implications for the way the rational choice model is applied. In some cases, all the costs and benefits of a decision are virtually instantaneous with only a very small delay in time between them. For example, if you purchase a coffee the cost is immediate (unless you use a credit card) and the total pleasure from consuming the drink occurs shortly afterwards.

However, for a whole range of other consumption decisions all the costs and benefits are not instantaneous and occur over a more prolonged period of time. There may also be significant delays between the point in time the costs are incurred and the benefits received. This is called intertemporal choice.

Take the example of buying a consumer durable, such as a mobile phone, dishwasher or car. The major cost of purchasing many of these products is often immediate, or virtually so (unless paying by instalments), while the stream of benefits they provide occurs for months or years after the initial costs are paid. In other cases, all the benefits from consumption are instantaneous, while some of the costs occur in the future. For example, when considering whether or not to purchase cigarettes, the consumption benefits and monetary cost are fairly immediate, while the health costs occur in the future. The same would be true about decisions to purchase alcohol and unhealthy food. For a rational person, intertemporal decision making would be required in all of these examples.

Optimum consumption with intertemporal choice

How can the rational choice model be extended to analyse and explain these types of intertemporal choices?

In standard economic theory it is assumed that most people are impatient most of the time. They would prefer to consume the things they like immediately rather than having to wait until a later date. They would also prefer to delay any costs until later: i.e. paying for goods using a credit card.

This impatience can be illustrated by the following simple example. Imagine that it is 10:00am on Monday morning and you are given the choice between receiving a payment of £500 immediately or having to wait until 10:00am on Tuesday morning. When asked this type of question most people prefer to have the £500 immediately.

The key to understanding this impatience is to think about the point in time from which the decision is being judged. If a person prefers to receive £500 on Monday rather than having to wait until Tuesday, then the following must be true.

$$U^{\text{Monday}}: u(\text{£}500_{\text{Monday}}) > u(\text{£}500_{\text{Tuesday}})$$

This is simply stating that from the person's point of view on Monday (U^{Monday}), the utility from receiving the money on Monday ($u(\text{£}500_{\text{Monday}})$) is greater than the utility of having to wait until Tuesday ($u(\text{£}500_{\text{Tuesday}})$).

This does not mean that from their point of view on Tuesday that £500 received on Tuesday would give them any less pleasure than it would on Monday. In other words:

$$U^{\text{Monday}}: u(\text{£}500_{\text{Monday}}) = U^{\text{Tuesday}}: u(\text{£}500_{\text{Tuesday}})$$

From the person's point of view on Tuesday (U^{Tuesday}), £500 received on Tuesday provides the same utility as receiving the £500 on Monday, from their point of view on Monday. Impatience in this example means that judging the decision from Monday's perspective, receiving £500 immediately would give the person more pleasure than having to wait 24 hours.

What is the minimum amount by which the pay-off of £500 would have to increase in order for you personally to agree to wait for another 24 hours before receiving it?

Discounting: measuring impatience

From Monday's perspective, how much more utility does receiving £500 immediately provide rather than having to wait until Tuesday? To capture this impatience, standard economic theory uses a method of weighting future costs and benefits. It is called **exponential discounting** and multiplies any costs and benefits that occur in the future by a fraction of less than one to adjust them to what they are worth to the person immediately: i.e. their **present value**. This fraction is called the **discount factor**.

To illustrate this idea, assume a person is considering a consumption decision when all the costs occur immediately, while all the benefits occur in the future. To keep the example as simple as possible, assume the benefits all occur at one point in time in the future rather than being spread out over a number of days, weeks or months. The good costs £10,

Definitions

Exponential discounting A method of reducing future benefits and costs to a present value. The discount rate depends on just how much less, from the consumer's perspective, *future* utility and costs (from a decision made today) are than gaining the utility/incurred the costs *today*.

Present value (in consumption) The value a person places today on a good that will not be consumed until some point in the future.

Discount factor The value today of deciding to consume a good one period in the future as a proportion of the value when it is actually consumed.

which is payable immediately, and provides £20 of utility in exactly one month's time (perhaps there is a month's delay before it can be delivered). As all the costs are immediate, they are weighted at 100 per cent of their value. However, impatience means that the future benefits have to be weighted by a fraction of less than one to adjust them to what they are worth to the person immediately.

If the person's impatience could be captured by a monthly discount factor of, say, 0.9 then £20 of pleasure in a month would be worth £18 ($0.9 \times £20$) to that person today. The present value of the benefits from consuming the good (£18) would still be greater than the immediate cost (£10); so a rational person would purchase the product and be prepared to wait for delivery.

Levels of impatience will vary from one individual to another. The more impatient people are, the lower their discount factor and the less they will value benefits and costs that occur at some point in the future. For example, imagine that in the previous example a person's greater level of impatience could be captured by a discount factor of 0.4. This makes £20 of benefits received in a month's time worth only £8 to that person now. As the immediate cost of £10 is now greater than the discounted value of the future benefits, this more impatient individual would not purchase the good.

The further into the future any costs and benefits occur, the greater their values have to be reduced to adjust them to

what they are worth to an individual today. If the benefits from consuming the product all occur in two months' time the discount factor will be less than 0.9.

How is the discount factor for a two-month delay calculated? The per-period discount factor is the amount by which each discount factor in one period has to be multiplied in order to work out the discount factor for the following period. Assuming the size of the delay between each period remains the same (i.e. in this case it is always a month) the per-period discount factor remains constant. Therefore, the discount factor of 0.9 for a one-month delay would have to be multiplied by 0.9 to calculate the discount factor for a two-month delay. It would equal 0.81. A benefit of £20 in two months has a present value of $0.81 \times £20$ or £16.20.

- What discount factor is used to weight benefits that occur in three months' time for a person with a per-monthly discount factor of 0.9?
 - What does this make the present value of £20 of benefits received in three months' time?
- Assume that the good costs £10, which has to be paid today. How long would the maximum delay in months before receiving the £20 of benefits have to be before a person with a monthly discount of 0.9 would no longer purchase the good?

*LOOKING AT THE MATHS

How do we calculate the present value of the purchase of a product whose utility occurs over a period of time? Let us assume that a person's discount factor is 0.8. In other words, a good yielding £100 of benefits one period in the future would be valued at only $0.8 \times £100 = £80$ today.

But what about a product that yields utility in several future periods? The formula we use for calculating its present value (i.e. its utility over its lifetime expressed in a value today) is:

$$U = \sum_{t=0}^n \delta^t U_t \quad (1)$$

where U is the total present utility value of a good consumed over various time periods, $t = 0$ to $t = n$; δ is the discount factor applied for each time period t and U_t is the utility gained in each specific time period t .

Let us assume that a good has a life of three years and yields £100 of utility at the end of year 1, £300 at the end of year 2 and

£200 at the end of year 3. Its total present utility is not the simple sum of the three utilities that will be experienced; it is not $£100 + £300 + £200 = £600$. Instead it is found by applying the above formula. Again, let us assume that the discount factor is 0.8. Substituting the figures for the three years in equation (1) gives:

$$\begin{aligned} U &= (0.8 \times £100) + (0.8^2 \times £300) + (0.8^3 \times £200) \\ &= (0.8 \times £100) + (0.64 \times £300) + (0.512 \times £200) \\ &= £80 + £192 + £102.40 \\ &= £374.40 \end{aligned}$$

What is the present value (utility) of a good which yields £50 of utility at the end of year 1, £60 at the end of year 2, £100 at the end of year 3 and £50 at the end of year 4, assuming a discount factor of 0.9? Would it be worth the consumer paying £200 for it today?

Section summary

- The benefits, and sometimes the costs, of some consumer goods occur over a period of time rather than instantaneously. Consumers are thus faced with making intertemporal choices.
- Because consumers would generally rather have goods now than later, benefits (and costs) that occur in the future have to be discounted to give them a present value.
- The higher the discount factor, the lower will be the present value for any given future benefit or cost.

*4.3

INDIFFERENCE ANALYSIS

The limitations of the marginal utility approach to demand

Even though the multi-commodity version of marginal utility theory is useful in demonstrating the underlying logic of consumer choice, it still has a major weakness. Utility cannot be measured in any absolute sense. We cannot really say, therefore, by how much the marginal utility of one good exceeds another.

An alternative approach is to use *indifference analysis*. This does not involve measuring the *amount* of utility a person gains, but merely *ranking* various combinations of goods in order of preference. In other words, it assumes that consumers can decide whether they prefer one combination of goods to another. For example, if you were asked to choose between two baskets of fruit, one containing four oranges and three pears and the other containing two oranges and five pears, you could say which you prefer or whether you are indifferent between them. It does not assume that you can decide just *how much* you prefer one basket to another or just how much you like either.

The aim of indifference analysis, then, is to analyse, *without having to measure utility*, how a rational consumer chooses between two goods. As we shall see, it can be used to show the effect on this choice of (a) a change in the consumer's income and (b) a change in the price of one or both goods. It can also be used to analyse the income and substitution effects of a change in price.

Indifference analysis involves the use of *indifference curves* and *budget lines*.

Indifference curves

An *indifference curve* shows all the various combinations of two goods that give an equal amount of satisfaction or utility to a consumer.

To show how one can be constructed, consider the following example. Imagine that a supermarket is conducting a survey about the preferences of its customers for different types of fruit. One of the respondents is Ali, a student who likes a healthy diet and regularly buys fresh fruit. He is asked his views about various combinations of oranges and pears. Starting with the combination of 10 pears and 13 oranges, he is asked what other combinations he would like the same amount as this one. From his answers a table is constructed (Table 4.2). What we are saying here is that Ali would be equally happy to have any one of the combinations shown in the table.

This table is known as an *indifference set*. It shows alternative combinations of two goods that yield the same level of satisfaction. From this we can plot an indifference curve. We measure units of one good on one axis and units of the other good on the other axis. Thus in Figure 4.5, which is

Table 4.2 Combinations of pears and oranges that Ali likes the same amount as 10 pears and 13 oranges

Pears	Oranges	Point in Figure 4.5
30	6	a
24	7	b
20	8	c
14	10	d
10	13	e
8	15	f
6	20	g

based on Table 4.2, pears and oranges are measured on the two axes. The curve shows that Ali is indifferent as to whether he consumes 30 pears and 6 oranges (point *a*) or 24 pears and 7 oranges (point *b*) or any other combination of pears and oranges along the curve.

Notice that we are not saying *how much* Ali likes pears and oranges; merely that he likes all the combinations along the indifference curve the same amount. All the combinations thus yield the same (unspecified) utility.

The shape of the indifference curve

As you can see, the indifference curve we have drawn is not a straight line. It is bowed in towards the origin. In other words, its slope gets shallower as we move down the curve. Indifference curves are normally drawn this shape. But why?

Let us see what the slope of the curve shows us. It shows the rate at which the consumer is willing to exchange one good for the other, holding their level of satisfaction the same. For example, consider the move from point *a* to point *b* in Figure 4.5. Ali gives up 6 units of pears and requires 1 orange to compensate for the loss. The slope of the indifference curve is thus $-6/1 = -6$. Ignoring the negative sign, the slope of the indifference curve (that is, the rate at which the consumer is willing to substitute one good for the other) is known as the *marginal rate of substitution* (MRS). In this case, therefore, the $MRS = 6$.

Definitions

Indifference curve A line showing all those combinations of two goods between which a consumer is indifferent: i.e. those combinations that give the same level of utility.

Indifference set A table showing the same information as an indifference curve.

Marginal rate of substitution (between two goods in consumption) The amount of one good (*Y*) that a consumer is prepared to give up in order to obtain one extra unit of another good (*X*): i.e. $\Delta Y/\Delta X$.

Figure 4.5 An indifference curve

Note that as we move down the curve, the marginal rate of substitution diminishes as the slope of the curve gets less. For example, look at the move from point *e* to point *f*. Here the consumer gives up 2 pears and requires 2 oranges to compensate. Thus, along this section of the curve, the slope is $-2/2 = -1$ (and hence the $MRS = 1$).

The reason for a *diminishing marginal rate of substitution* is related to the *principle of diminishing marginal utility* that we looked at in section 4.1. This stated that individuals will gain less and less additional satisfaction the more of a good that they consume. This principle, however, is based on the assumption that the consumption of other goods is held *constant*. In the case of an indifference curve, this is not true. As we move down the curve, more of one good is consumed but *less* of the other. Nevertheless the effect on consumer satisfaction is similar. As Ali consumes more pears and fewer oranges, his marginal utility from pears will diminish, while that from oranges will increase. He will thus be prepared to give up fewer and fewer pears for each additional orange. MRS diminishes.

The relationship between the marginal rate of substitution and marginal utility

In Figure 4.5, consumption at point *a* yields equal satisfaction with consumption at point *b*. Thus the utility sacrificed by giving up six pears must be equal to the utility gained by consuming one more orange. In other words, the marginal utility of an orange must be six times as great as that of a pear. Therefore, $MU_{\text{oranges}}/MU_{\text{pears}} = 6$. But this is the same as the marginal rate of substitution. With X measured on the horizontal axis and Y on the vertical axis, then

$$MRS = \frac{MU_X}{MU_Y} = \text{slope of indifference curve (ignoring negative sign)}$$

? Although indifference curves will normally be bowed in towards the origin, on odd occasions they might not be. Which of the following diagrams correspond to which of the following? Explain the shape of each curve.

- (a) X and Y are left shoes and right shoes.
 (b) X and Y are two brands of the same product, and the consumer cannot tell them apart.
 (c) X is a good but Y is a 'bad' - like household refuse.

An indifference map

More than one indifference curve can be drawn. For example, referring back to Table 4.2, Ali could give another set of combinations of pears and oranges that all give him a higher (but equal) level of utility than the set shown in the table. This could then be plotted in Figure 4.5 as another indifference curve.

Although the actual amount of utility corresponding to each curve is not specified, indifference curves further out to the right would show combinations of the two goods that yield a higher utility, and curves further in to the left would show combinations yielding a lower utility.

In fact, a whole *indifference map* can be drawn, with each successive indifference curve showing a higher level of utility. Combinations of goods along I_2 in Figure 4.6 give a higher

Definitions

Diminishing marginal rate of substitution The more a person consumes of good X and the less of good Y , the less additional Y will that person be prepared to give up in order to obtain an extra unit of X : i.e. $\Delta Y/\Delta X$ diminishes.

Indifference map A graph showing a whole set of indifference curves. The further away a particular curve is from the origin, the higher the level of satisfaction it represents.

Figure 4.6 An indifference map

utility to the consumer than those along I_1 . Those along I_3 give a higher utility than those along I_2 , and so on. The term 'map' is appropriate here, because the indifference curves are rather like contours on a real map. Just as a contour joins all those points of a particular height, so an indifference curve shows all those combinations yielding a particular level of utility.

? Draw another two indifference curves on Figure 4.5, one outward from and one inward from the original curve. Read off various combinations of pears and oranges along these two new curves and enter them on a table like Table 4.2.

The budget line

We turn now to the **budget line**. This is the other important element in the analysis of consumer behaviour. Whereas indifference maps illustrate people's preferences, the actual choices they make will depend on their incomes. The budget line shows what combinations of two goods you are able to buy, given (a) your income available to spend on them and (b) their prices.

Just as we did with an indifference curve, we can construct a budget line from a table. The first two columns of Table 4.3 show various combinations of two goods X and Y

Table 4.3 Consumption possibilities for budgets of £30 and £40

Units of good X	Budget of £30		Budget of £40	
	Units of good Y	Point on budget line in Figure 4.7	Units of good X	Units of good Y
0	30	A	0	40
5	20	B	5	30
10	10	C	10	20
15	0	D	15	10
			20	0

Note: It is assumed that $P_X = \#2, P_Y = \#1$.

Figure 4.7 A budget line

that can be purchased assuming that (a) the price of X is £2 and the price of Y is £1 and (b) the consumer has a budget of £30 to be divided between the two goods.

In Figure 4.7, then, if you are limited to a budget of £30, you can consume any combination of X and Y along the line (or inside it). You cannot, however, afford to buy combinations that lie outside it: i.e. in the darker shaded area. This area is known as the *infeasible region* for the given budget.

We have said that the amount people can afford to buy will depend on (a) their budget and (b) the prices of the two goods. We can show how a change in either of these two determinants will affect the budget line.

A change in income

If the consumer's income (and hence budget) increases, the budget line will shift outwards, parallel to the old one. This is illustrated in the last two columns of Table 4.3 and in Figure 4.8, which show the effect of a rise in the consumer's budget from £30 to £40. (Note that there is no change in the prices of X and Y, which remain at £2 and £1 respectively.)

More can now be purchased. For example, if the consumer was originally purchasing 7 units of X and 16 units of Y (point *m*), this could be increased with the new budget of £40, to 10 units of X and 20 units of Y (point *n*) or any other combination of X and Y along the new higher budget line.

A change in price

The relative prices of the two goods are given by the slope of the budget line. The slope of the budget line in Figure 4.7 is $30/15 = 2$. (We are ignoring the negative sign: strictly speaking, the slope should be -2 .) Similarly, the slope of the

Definition

Budget line A graph showing all the possible combinations of two goods that can be purchased at given prices and for a given budget.

Figure 4.8 Effect of an increase in income on the budget line

new higher budget line in Figure 4.8 is $40/20 = 2$. But in each case this is simply the ratio of the price of X (£2) to the price of Y (£1).

Thus the slope of the budget line equals

$$\frac{P_X}{P_Y}$$

If the price of either good changes, the slope of the budget line will change. This is illustrated in Figure 4.9 which, like Figure 4.7, assumes a budget of £30 and an initial price of X of £2 and a price of Y of £1. The initial budget line is B_1 .

Now let us assume that the price of X falls to £1 but that the price of Y remains the same (£1). The new budget line will join 30 on the Y axis with 30 on the X axis. In other words, the line pivots outwards on point a . If, instead, the price of Y changed, the line would pivot on point b .

1. Assume that the budget remains at £30 and the price of X stays at £2, but that Y rises in price to £3. Draw the new budget line.
2. What will happen to the budget line if the consumer's income doubles and the prices of both X and Y double?

Figure 4.9 Effect on the budget line of a fall in the price of good X

Figure 4.10 The optimum consumption point

The optimum consumption point

We are now in a position to put the two elements of the analysis together: the indifference map and a budget line. This will enable us to show how much of each of the two goods the 'rational' consumer will buy from a given budget. Let us examine Figure 4.10.

The consumer would like to consume along the highest possible indifference curve. This is curve I_3 at point t . Higher indifference curves, such as I_4 and I_5 , although representing higher utility than curve I_3 , are in the infeasible region: they represent combinations of X and Y that cannot be afforded with the current budget. The consumer *could* consume along curves I_1 and I_2 , between points r and v , and s and u respectively, but they give a lower level of utility than consuming at point t .

The optimum consumption point for the consumer, then, is where the budget line touches (is 'tangential to') the highest possible indifference curve.

If the budget line is tangential to an indifference curve, they will have the same slope. (The slope of a curve is the slope of the tangent to it at the point in question.) But as we have seen, the slope of the budget line is

$$\frac{P_X}{P_Y}$$

and the slope of the indifference curve is

$$MRS = \frac{MU_X}{MU_Y}$$

Therefore, at the optimum consumption point

$$\frac{P_X}{P_Y} = \frac{MU_X}{MU_Y}$$

But this is the *equi-marginal principle* that we established in the first part of this chapter: only this time, using the indifference curve approach, there has been no need to measure utility. All we have needed to do is to observe, for any two combinations of goods, whether the consumer preferred one to the other or was indifferent between them.

K1 14
p113

*LOOKING AT THE MATHS

We can express the optimum consumption point algebraically. With a limited budget of B , the objective is to maximise utility subject to this budget constraint. This can be expressed as

$$\text{Max } TU(X, Y) \quad (1)$$

subject to the budget constraint that

$$P_x X + P_y Y = B \quad (2)$$

Equation (1) is known as the 'objective function' and says that the objective is to maximise utility, which depends on the consumption of two goods, X and Y . For example, assume that the utility function is

$$TU = X^{3/4} Y^{1/4}$$

This is known as a 'Cobb-Douglas utility function' and will give smooth convex indifference curves. Assume also that the price of X is 4, the price of Y is 2 and the budget is 64. Thus:

$$4X + 2Y = 64$$

Rearranging this constraint to express X in terms of Y gives

$$X = 16 - \frac{Y}{2}$$

By first substituting this value of X into the utility function (so that it is expressed purely in terms of Y) and then differentiating the resulting equation and setting it equal to zero, we can solve for the value of Y and then X that yields the maximum utility for the given budget. The answer is:

$$X = 12 \text{ and } Y = 8$$

The workings of this are given in Maths Case 4.1 on the student website.

An alternative method, which is slightly longer but is likely to involve simpler calculations, involves the use of 'Lagrangian multipliers'. This method is explained, along with a worked example, in Maths Case 4.2.

The effect of changes in income

As we have seen, an increase in income is represented by a parallel shift outwards of the budget line (assuming no change in the price of X and Y). This will then lead to a new optimum consumption point on a higher indifference curve. A different consumption point will be found for each different level of income.

In Figure 4.11, a series of budget lines are drawn representing different levels of consumer income. The corresponding optimum consumption points (r , s , t , u) are shown. Each point is where the new higher budget line just touches the highest possible indifference curve.¹ The line

¹ We can always draw an indifference curve that will be tangential to a given budget line. Just because we only draw a few indifference curves on a diagram, it does not mean that there are only a few possible ones. We could draw as many as we liked. Again it is rather like the contours on a real map. They may be drawn at, say, 10 metre intervals. We could, however, if we liked, draw them at 1 metre or even 1cm intervals, or at whatever height was suitable to our purpose. For example, if the maximum height of a lake were 32.45 metres above sea level, it might be useful to draw a contour at that height to show what land might be liable to flooding.

Figure 4.11 Effect on consumption of a change in income

joining these points is known as the **income-consumption curve**.

If your money income goes up and the price of goods does not change, we say that your **real income** has risen. In other words, you can buy more than you did before. But your real income can also rise even if you do not earn any more money. This will happen if prices fall. For the same amount of money, you can buy more goods than previously. We analyse the effect of a rise in real income caused by a fall in prices in just the same way as we did when money income rose and prices stayed the same. Provided the **relative** prices of the two goods stay the same (i.e. provided they fall by the same percentage), the budget line will shift outwards parallel to the old one.

Income elasticity of demand and the income-consumption curve

The income-consumption curve in Figure 4.11 shows that the demand for both goods rises as income rises. Thus both goods have a positive income elasticity of demand: they are both normal goods.

Definitions

Income-consumption curve A line showing how a person's optimum level of consumption of two goods changes as income changes (assuming the prices of the goods remain constant).

Real income Income measured in terms of how much it can buy. If your **money** income rises by 10 per cent, but prices rise by 8 per cent, you can buy only 2 per cent more goods than before. Your **real** income has risen by 2 per cent.

Now let us focus just on good X. If the income-consumption curve became flatter at higher levels of income, it would show an increasing proportion of income being spent on X. The flatter it became, the higher would be the income elasticity of demand for X.

If, by contrast, X were an inferior good, such as cheap margarine, its demand would fall as income rose; its income elasticity of demand would be negative. This is illustrated in Figure 4.12. Point *b* is to the left of point *a*, showing that at the higher income B_2 , less X is purchased.

1. The income-consumption curve in Figure 4.12 is drawn as positively sloped at low levels of income. Why?
2. Show the effect of a rise in income on the demand for X and Y where, this time, Y is the inferior good and X is the normal good. Is the income-consumption curve positively or negatively sloped?

Figure 4.12 Effect of a rise in income on the demand for an inferior good

***BOX 4.4 LOVE AND CARING**

An economic approach to family behaviour

We have been using indifference analysis to analyse a single individual's choices between two goods. The principles of rational choice, however, can be extended to many other fields of human behaviour. These include situations where people are members of groups and where one person's behaviour affects another. Examples include how friends treat each other, how sexual partners interrelate, how parents treat children, how chores are shared out in a family, how teams are organised, how people behave to each other at work, and so on.

In all these cases, decisions constantly have to be made. Generally, people try to make the 'best' decisions – ones which will maximise the interests of the individual or the members of the group: decisions that are 'rational'. This will involve weighing up (consciously or subconsciously) the costs and benefits of alternative courses of action to find out which is in the individual's or group's best interests.

One of the pioneers of this approach was Gary Becker (1930–2014). Becker was a professor at Chicago University from 1970 and was a member of the 'Chicago school', a group of economists from the university who advocate the market as the best means of solving economic problems.

Gary Becker attempted to apply simple economic principles of rational choice to a whole range of human activities, including racial and sexual discrimination, competition in politics and criminal behaviour. Much of his work, however, focused on the family, a field previously thought to be the domain of sociologists, anthropologists and psychologists. Even when family members are behaving lovingly and unselfishly, they nevertheless, according to Becker, tend to behave 'rationally' in the economists' sense of trying to maximise their interests, only in this case their

'interests' include the welfare of the other members of their family.

A simple illustration of this approach is given in the diagram below. It assumes, for simplicity, that there are just two members of the family, Judy and Warren. Warren's consumption is measured on the horizontal axis; Judy's on the vertical. Their total joint income is given by Y_T . The line $Y_T Y_T$ represents their consumption possibilities. If Warren were to spend their entire joint income on himself, he would consume at point *g*. If Judy were to spend their entire joint income on herself, she would consume at point *f*.

The effect of changes in price

If either X or Y changes in price, the budget line will 'pivot'. Take the case of a reduction in the price of X (but no change in the price of Y). If this happens, the budget line will swing outwards. We saw this effect in Figure 4.9 (on page 118). These same budget lines are reproduced in Figure 4.13, but this time we have added indifference curves.

The old optimum consumption point was at *j*. After the reduction in the price of good X, a new optimum consumption point is found at *k*.

- ?** Illustrate on an indifference diagram the effects of the following:
- A rise in the price of good X (assuming no change in the price of Y).
 - A fall in the price of good Y (assuming no change in the price of X).

Figure 4.13 Effect of a fall in the price of good X

CASE STUDIES AND APPLICATIONS

Let us assume that Warren works full-time and Judy works part-time. As a result, Warren earns more than Judy. He earns Y_W ; she earns Y_J . If each spent their own incomes on themselves alone, they would consume at point *a*.

But now let us assume that Warren loves Judy, and that he would prefer to consume less than Y_W to allow her to consume more than Y_J . His preferences are shown by the indifference curves. Each curve shows all the various combinations of consumption between Warren and Judy that give Warren equal satisfaction. (Note that because he loves Judy, he gets satisfaction from her consumption: her happiness gives him pleasure.)

Warren's optimum distribution of consumption between himself and Judy is at point e_W . This is the highest of his indifference curves that can be reached with a joint income of Y_T . At this point he consumes C_W ; she consumes C_J .

If he loved Judy 'as himself' and wanted to share their income out equally, then the indifference curves would be shallower. The tangency point to the highest indifference curve would be on the 45° line OE. Consumption would be at point e_E .

Similar indifference curves could be drawn for Judy. Her optimum consumption point might be at point e_J . But if she loved Warren 'as herself', her optimum point would then be at point e_E .

Some interesting conclusions can be drawn from this analysis:

- Income redistribution (i.e. consumption redistribution) within the family can be to the benefit of all the members. In the case we have been considering, both Warren and Judy gain from a redistribution of income from point *a* to point e_W .

The only area of contention is between points e_W and e_J . Here negotiation would have to take place. This might be in return for some favour. 'If you'll let me have the money I need for that new coat, I'll do the washing up for a whole month.'

- In the case of each one loving the other as themselves, there is no area of contention. They are both happiest with consumption at point e_E .
- In the case of 'extreme love', where each partner would prefer the other to have more than themselves, point e_W would be above point e_E , and point e_J would be below point e_E . In this case, each would be trying to persuade the other to have more than they wanted. Here a different type of negotiation would be needed. 'I'll only let you buy me that coat if you let me do the washing up for a whole month.'
- Some forms of consumption benefit both partners. Household furniture or a new car would be cases in point. Any such purchases would have the effect of shifting the consumption point out beyond line $Y_T Y_T$, and could lead to both partners consuming on a higher indifference curve. This shows the 'economic' advantages of the collective consumption that can be experienced in households or other groups (such as clubs).

- If Judy earned more than Warren, show how much income she would redistribute to him if (a) she cared somewhat for him; (b) she loved him 'as herself'. Draw her indifference curves in each of these two cases.
- In the case where they both love each other 'as themselves', will their two sets of indifference curves be identical?

A series of budget lines could be drawn, all pivoting round point a in Figure 4.13. Each one represents a different price of good X, but with money income and the price of Y held constant. The flatter the curve, the lower the price of X. At each price, there will be an optimum consumption point. The line that connects these points is known as the *price-consumption curve*.

Deriving the individual's demand curve

We can use the analysis of price changes to show how in theory a person's demand curve for a product can be derived. To do this we need to modify the diagram slightly.

Let us assume that we want to derive a person's demand curve for good X. What we need to show is the effect on the consumption of X of a change in the price of X assuming the prices of all other goods are held constant. To do this we need to redefine good Y. Instead of being a *single* good, Y becomes the total of *all other* goods. But what units are we to put on the vertical axis? Each of these other goods will be in different units: litres of petrol, loaves of bread, kilograms of cheese, numbers of haircuts, etc. We cannot add them all up unless we first convert them to a common unit. The answer is to measure them as the total amount of money spent on them: i.e. what is *not* spent on good X.

With expenditure on all other goods plotted on the vertical axis and with income, tastes and the price of all other goods held constant, we can now derive the demand curve for X. This is demonstrated in Figure 4.14.

We illustrate the changes in the price of X by pivoting the budget line on the point where it intersects the vertical axis. It is then possible, by drawing a price-consumption line, to show the amount of X demanded at each price. It is then a simple matter of transferring these price-quantity relationships on to a demand curve. In Figure 4.14, each of the points a , b , c and d on the demand curve in the lower part of the diagram corresponds to one of the four points on the price-consumption curve. (Note that P_2 is half of P_1 , P_3 is one-third of P_1 and P_4 is one-quarter of P_1 .)

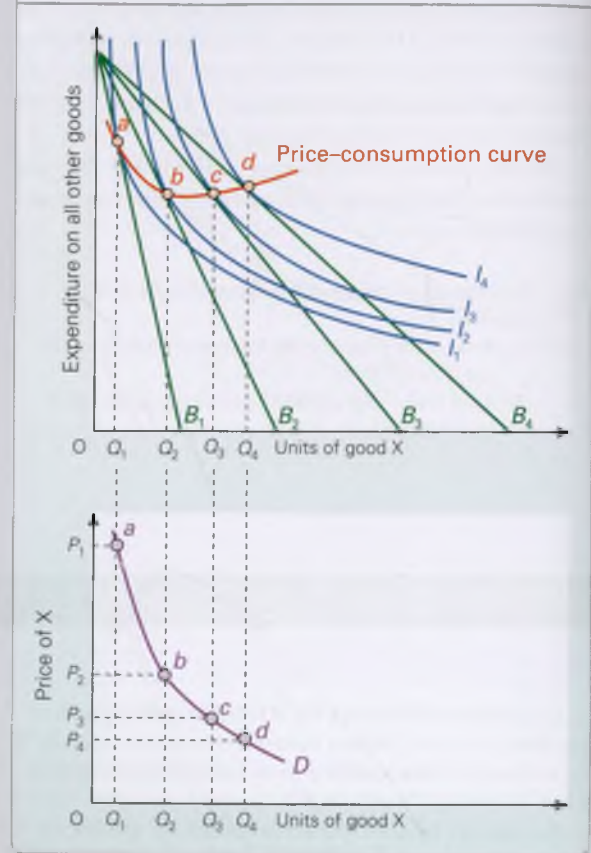

? As quantity demanded increases from Q_1 to Q_2 in Figure 4.14, the expenditure on all other goods decreases. (Point b is lower than point a .) This means, therefore, that the person's total expenditure on X has correspondingly increased. What, then, can we say about the person's price elasticity of demand for X between points a and b ? What can we say about the price elasticity of demand between points b and c , and between points c and d ?

The income and substitution effects of a price change

In Chapter 2 we argued that when the price of a good rises, consumers will purchase less of it for two reasons:

- They cannot afford to buy so much. This is the *income effect*.

Figure 4.14 Deriving the demand curve for good X from a price-consumption curve

- The good is now more expensive relative to other goods. Therefore consumers substitute alternatives for it. This is the *substitution effect*.

We can extend our arguments from Chapter 2 by demonstrating the income and substitution effects with the use of indifference analysis. Let us start with the case of a normal good and show what happens when its price changes.

Definitions

Price-consumption curve A line showing how a person's optimum level of consumption of two goods changes as the price of one of the two goods changes (assuming that income and the price of the other good remain constant).

Income effect of a price change That portion of the change in quantity demanded that results from the change in real income.

Substitution effect of a price change That portion of the change in quantity demanded that results from the change in the relative price of the good.

Figure 4.15

The income and substitution effects of a rise in the price of good X if X is a normal good

A normal good

In Figure 4.15 the price of **normal good X** has risen and the budget line has pivoted inwards from B_1 to B_2 . The consumption point has moved from point f to point h . Part of this shift in consumption is due to the substitution effect and part is due to the income effect.

The substitution effect. To separate these two effects a new budget line is drawn, parallel to B_2 but tangential to the original indifference curve I_1 . This is the line B_{1a} . Being parallel to B_2 , it represents the new price ratio (i.e. the higher price of X). Being tangential to I_1 , however, it enables the consumer to obtain the same utility as before: in other words, there is no loss in real income to the consumer. By focusing, then, on B_{1a} , which represents no change in real income, we have excluded the income effect. The movement from point f to point g is due purely to a change in the relative prices of X and Y. The movement from Q_{x_1} to Q_{x_2} is the substitution effect.

The income effect. In reality, the budget line has shifted to B_2 and the consumer is forced to consume on a lower indifference curve I_2 : real income has fallen. Thus the movement from Q_{x_2} to Q_{x_3} is the income effect.

In the case of a normal good, therefore, the income and substitution effects of a price change reinforce each other. They are both negative: they *both* involve a *reduction* in the quantity demanded as price *rises* (and vice versa).²

² It is important not to confuse the income effect of a price change with the simple effect on demand of an increase in income. In the latter case, a rise in income will cause a rise in demand for a normal good – a positive effect (and hence there will be a positive income elasticity of demand). In the case of a price reduction, although for a normal good the resulting rise in real income will still cause a rise in demand, it is in the opposite direction from the change in price – a negative effect with respect to price (and hence there will be a negative price elasticity of demand).

The bigger the income and substitution effects, the higher will be the price elasticity of demand for good X.

Illustrate on two separate indifference diagrams the income and substitution effects of the following:

- A decrease in the price of good X (and no change in the price of good Y).
- An increase in the price of good Y (and no change in the price of good X).

An inferior good

As we saw above, when people's incomes rise, they will buy less of **inferior goods** such as poor-quality margarine and cheap powdered instant coffee, since they will now be able to afford better-quality goods instead. Conversely, when their income falls, they will have to reduce their living standards: their consumption of inferior goods will thus rise.

The substitution effect. If the price of an inferior good (good X) rises, the substitution effect will be in the same direction as for a normal good: i.e. it will be negative. People will consume less X relative to Y, since X is now more expensive relative to Y. For example, if the price of inferior-quality margarine (good X) went up, people would tend to use better-quality margarine or butter (good Y) instead. This is illustrated in Figure 4.16 by a movement along the original indifference curve (I_1) from point f to point g . The quantity of X demanded falls from Q_{x_1} to Q_{x_2} .

Figure 4.16

The income and substitution effects of a rise in the price of good X if X is an inferior (non-Giffen) good

Definitions

Normal good A good whose demand increases as income increases.

Inferior good A good whose demand decreases as income increases.

The income effect. The income effect of the price rise, however, will be the opposite of that for a normal good: it will be positive. The reduction in real income from the rise in price of X will tend to increase the consumption of X, since with a fall in real income more inferior goods will now be purchased – including more X. Thus point *h* is to the right of point *g*: the income effect increases quantity back from Q_{x_2} to Q_{x_3} .

A Giffen good: a particular type of inferior good

If the inferior good were to account for a very large proportion of a consumer's expenditure, a change in its price would have a significant effect on the consumer's real income, resulting in a large income effect. It is conceivable, therefore, that this large abnormal income effect could outweigh the normal substitution effect. In such a case, a rise in the price of X would lead to more X being consumed!

This is illustrated in Figure 4.17, where point *h* is to the right of point *f*. In other words, the fall in consumption (Q_{x_2} to Q_{x_1}) as a result of the substitution effect is more than offset by the rise in consumption (Q_{x_2} to Q_{x_3}) as a result of the large positive income effect.

Such a good is known as a **Giffen good**, after Sir Robert Giffen (1837–1910), who is alleged to have claimed that the consumption of bread by the poor rose when its price rose. Bread formed such a large proportion of poor people's consumption that, if its price went up, the poor could not afford to buy so much meat, vegetables, etc., and had to buy more bread instead. It is possible that in countries in Africa today

with very low incomes, staple foods such as manioc (cassava) and maize are Giffen goods. Naturally, such cases must be very rare indeed and some economists remain unconvinced of their existence, except as a theoretical possibility.

Could you conceive of any circumstances in which one or more items of your expenditure would become Giffen goods? Apply the same analysis to an elderly couple on a state pension.

The usefulness of indifference analysis

Indifference analysis has made it possible to demonstrate the logic of 'rational' consumer choice, the derivation of the individual's demand curve, and the income and substitution effects of a price change. All this has been done without having to measure utility.

Nevertheless there are limitations to the usefulness of indifference analysis:

- In practice, it is virtually impossible to derive indifference curves, since it would involve a consumer having to imagine a whole series of different combinations of goods and deciding in each case whether a given combination gave more, equal or less satisfaction than other combinations.
- Consumers may not behave 'rationally', and hence may not give careful consideration to the satisfaction they believe they will gain from consuming goods. They may behave impetuously.
- Indifference curves are based on the satisfaction that consumers believe they will gain from a good. This belief may well be influenced by advertising. Consumers may be disappointed or pleasantly surprised, however, when they actually consume the good. In other words, consumers are not perfectly knowledgeable. Thus the 'optimum consumption' point may not in practice give consumers maximum satisfaction for their money.
- Certain goods are purchased only now and again, and then only one at a time. Examples would include consumer durables such as cars, televisions and washing machines. Indifference curves are based on the assumption that marginal increases in one good can be traded off against marginal decreases in another. This will not be the case with consumer durables.

Figure 4.17 The income and substitution effects of a rise in the price of good X if X is a Giffen good

Definition

Giffen good An inferior good whose demand increases as its price increases as a result of a positive income effect larger than the normal negative substitution effect.

BOX 4.5

CONSUMER THEORY: A FURTHER APPROACH

EXPLORING ECONOMICS

Characteristics theory

Characteristics theory was developed in the mid-1960s by Kelvin Lancaster. He argued that people demand goods not for their own sake, but for the characteristics they possess.

Take cars, for example. When choosing between the different makes, consumers do not just consider their relative prices, they also consider their attributes: comfort, style, performance, durability, reliability, fuel consumption, etc. It is these characteristics that give rise to utility.

Characteristics theory, then, is based on four crucial assumptions:

- All goods possess various characteristics.
- Different brands possess them in different proportions.
- The characteristics are measurable: they are 'objective'.
- The characteristics (along with price and income) determine consumer choice.

Let us assume that you are choosing between three different goods or brands of a good (e.g. a foodstuff). Each one has a different combination of two characteristics (e.g. protein and calories). Your choices can be shown graphically.

The choice between brands of a product: each brand has different characteristics

The levels of two characteristics are shown on the two axes. An indifference map can be constructed, showing the different combinations of the two characteristics that yield given levels of utility. Thus any combination of the two characteristics along indifference curve I_4 in the diagram gives a higher level of utility than those along I_3 , and so on. The shape of the indifference curves (bowed in) illustrates a diminishing marginal rate of substitution between the two characteristics.

The amounts of the two characteristics given by the three brands are shown by the three rays. The more that is consumed of each brand, the further up the respective ray will the consumer be. Thus at x_1 , the consumer is gaining Q_{a1} of characteristic A and Q_{b1} of characteristic B.

Assume that, for the same money, the consumer could consume at x_1 with brand (1), x_2 with brand (2) and x_3 with brand (3). The consumer will consume brand (1): x_1 is on a higher indifference curve than x_2 or x_3 .

Now assume that the price of brand (2) falls. For a given expenditure, the consumer can now move up the brand (2) ray. But not until the price has fallen enough to allow consumption at point x_4 will the consumer consider switching from brand (1). If price falls enough for consumption to be at point x_5 , clearly the consumer will switch.

The characteristics approach has a number of advantages over conventional indifference curve analysis in explaining consumer behaviour.

- It helps to explain brand loyalty. When price changes, people will not necessarily gradually move from one brand to another. Rather they will stick with a brand until a critical price is reached. Then they will switch brands all at once.
- It allows the choice between several goods to be shown on the same diagram. Each good or brand has its own ray.
- It helps to explain the nature of substitute goods. The closer substitutes are, the more similar will be their characteristics and hence the closer will be their rays. The closer the rays, the more likely it is that there will be a shift in consumption to one good when the price of the other good changes.
- A change in the quality of a good can be shown by rotating its ray.

There are weaknesses with the approach, however:

- Some characteristics cannot be measured. Such characteristics as beauty, taste and entertainment value are subjective: they are in the mind of the consumer.
- Only two characteristics can be plotted. Most goods have several characteristics.

1. Make a list of the characteristics of shoes. Which are 'objective' and which are 'subjective'?
2. If two houses had identical characteristics, except that one was near a noisy airport and the other was in a quiet location, and if the market price of the first house were £280 000 and that of the second £300 000, how would that help us to put a value on the characteristic of peace and quiet?

Characteristics theory is examined in more detail in Case Study 4.6 on the student website.

Section summary

- The indifference approach to analysing consumer demand avoids having to measure utility.
- An indifference curve shows all those combinations of two goods that give an equal amount of satisfaction to a consumer. An indifference map can be drawn with indifference curves further to the north-east representing higher (but still unspecified) levels of satisfaction.
- Indifference curves are usually drawn convex to the origin. This is because of a diminishing marginal rate of substitution between the two goods. As more of one good is purchased, the consumer is willing to give up less and less of the other for each additional unit of the first. The marginal rate of substitution is given by the slope of the indifference curve, which equals MU_X/MU_Y .
- A budget line can be drawn on an indifference diagram. A budget line shows all those combinations of the two goods that can be purchased for a given amount of money, assuming a constant price of the two goods. The slope of the budget line depends on the relative price of the two goods. The slope is equal to P_X/P_Y .
- The consumer will achieve the maximum level of satisfaction for a given income (budget) by consuming at the point where the budget line just touches the highest possible indifference curve. At this point of tangency, the budget line and the indifference curve have the same slope. Thus $MU_X/MU_Y = P_X/P_Y$, which is the 'equi-marginal principle' for maximising utility from a given income that was established in section 4.1.
- If the consumer's real income (and hence budget) rises, there will be a parallel outward shift of the budget line. The 'rational' consumer will move to the point of tangency of this new budget line with the highest indifference curve. The line that traces out these optimum positions for different levels of income is known as the 'income-consumption curve'.
- If the price of one of the two goods changes, the budget line will pivot on the axis of the other good. An outward pivot represents a fall in price; an inward pivot represents an increase in price. The line that traces the tangency points of these budget lines with the appropriate indifference curves is called a 'price-consumption curve'.
- By measuring the expenditure on all other goods on the vertical axis and by holding their price constant and money income constant, a demand curve can be derived for the good measured on the horizontal axis. Changes in its price can be represented by pivoting the budget line. The effect on the quantity demanded can be found from the resulting price-consumption curve.
- The effect of a change in price on quantity demanded can be divided into an income and a substitution effect. The substitution effect is the result of a change in relative prices alone. The income effect is the result of the change in real income alone.
- For a normal good, the income and substitution effects of a price rise will both be negative and will reinforce each other. With an inferior good, the substitution effect will still be negative but the income effect will be positive and thus will to some extent offset the substitution effect. If the good is 'very' inferior and the (positive) income effect is bigger than the (negative) substitution effect, it is called a Giffen good. A rise in the price of a Giffen good will thus cause a rise in the quantity demanded.
- Indifference analysis, although avoiding having to measure utility, nevertheless has limitations. Indifference curves are difficult to derive in practice; consumers may not behave rationally; the 'optimum' consumption point may not be optimum if the consumer lacks knowledge of the good; indifference curves will not be smooth for items where single units each account for a large proportion of income.

END OF CHAPTER QUESTIONS

- Imagine that you had £10 per month to allocate between two goods, A and B. Imagine that good A cost £2 per unit and good B cost £1 per unit. Imagine also that the utilities of the two goods are those set out in the table below. (Note that the two goods are not substitutes for each other, so that the consumption of one does not affect the utility gained from the other.)
 - What would be the marginal utility ratio (MU_A/MU_B) for the following combinations of the two goods: (i) 1A, 8B; (ii) 2A, 6B; (iii) 3A, 4B; (iv) 4A, 2B? (Each combination would cost £10.)
 - Show that where the marginal utility ratio (MU_A/MU_B) equals the price ratio (P_A/P_B), total utility is maximised.
 - If the two goods were substitutes for each other, why would it not be possible to construct a table like the one given here?

The utility gained by a person from various quantities of two goods: A and B

Good A			Good B		
Units per month	MU (utils)	TU (utils)	Units per month	MU (utils)	TU (utils)
0	–	0.0	0	–	0.0
1	11.0	11.0	1	8.0	8.0
2	8.0	19.0	2	7.0	15.0
3	6.0	25.0	3	6.5	21.5
4	4.5	29.5	4	5.0	26.5
5	3.0	32.5	5	4.5	31.0
			6	4.0	35.0
			7	3.5	38.5
			8	3.0	41.5
			9	2.6	44.1
			10	2.3	46.4

2. Is it reasonable to assume that people seek to equate the marginal utility/price ratios of the goods that they purchase, if (a) they have never heard of 'utility', let alone 'marginal utility'; (b) marginal utility cannot be measured in any absolute way?
3. Consider situations where you might think about swapping items with someone. Why are such situations relatively rare? Can you think of circumstances in which this might be more common?
4. Explain why the price of a good is no reflection of the total value that consumers put on it.
- *5. Sketch a person's indifference map for two goods X and Y. Mark the optimum consumption point. Now illustrate the following (you might need to draw a separate diagram for each):
 - (a) A rise in the price of good X, but no change in the price of good Y.
 - (b) A shift in the person's tastes from good Y to good X.
 - (c) A fall in the person's income and a fall in the price of good Y, with the result that the consumption of Y remains constant (but that of X falls).
- *6. Distinguish between a normal good, an inferior good and a Giffen good. Use indifference curves to illustrate your answer.
- *7. Assume that commuters regard bus journeys as an inferior good and car journeys as a normal good. Using indifference curves, show how (a) a rise in incomes and (b) a fall in bus fares will affect the use of these two modes of transport. How could people's tastes be altered so that bus journeys were no longer regarded as an inferior good? If tastes were altered in this way, what effect would it have on the indifference curves?

Taking other people into account	142
Implications for economic policy	146

In this chapter we examine consumer choices when people have only limited information and when they do not necessarily behave as the 'rational' consumers we examined in Chapter 4.

When we buy goods or services there is often the risk that the benefits will not turn out as we had expected. The quality may be poorer or the good may not last as long as we had anticipated. In section 5.1 we look at consumption decisions when consumers are faced with uncertainty. We also look at how consumers may take out insurance to safeguard against uncertainty and at how the firms providing insurance may behave.

In section 5.2 we look at how people actually behave when buying goods and services. They might not have the time to weigh up the costs and benefits or all possible purchases. Instead they may behave impulsively or according to simple rules of thumb. Economists conduct experiments and surveys to see just how consumers do behave in various situations and we shall examine some of their findings.

5.1

DEMAND UNDER CONDITIONS OF RISK AND UNCERTAINTY

The problem of imperfect information

In the previous chapter, we assumed that when we buy a good or service, we know the price and how much value we put on it. In many cases this is a reasonable assumption. When you buy a bar of chocolate, you know how much you are paying for it and have a good idea how much you will like it. But what about a mobile phone, or a car, or a laptop, or any other *consumer durable*? In each of these cases you are buying something that will last you a long time, and the further into the future you look, the less certain you can be of its costs and benefits to you.

Take the example of purchasing a laptop computer that costs you £300. If you pay cash, your immediate outlay involves no uncertainty: it is £300. But the computer can break down. In 12 months' time you could face a repair bill of £100. In other words, when you buy the laptop, you are uncertain as to the full 'price' you will have to pay over its lifetime.

Good decision making requires good information.

Where information is poor, decisions and their outcomes are also likely to be poor.

If the costs of the laptop are uncertain, so too are the benefits. You might have been attracted in the first place by the description in an online advert or at a shop. Once you have used the laptop for a while, however, you might discover things you had not anticipated. Perhaps it takes longer than you had anticipated to boot up, or to connect to the Internet or to run various types of software/games.

Buying consumer durables thus involves uncertainty. So too does the purchase of assets, whether a physical asset such as a house or financial assets such as shares. In the case of assets, the uncertainty is over their future *price*. If you buy shares in a company, what will happen to the price? Will it shoot up, thus enabling you to sell them at a large profit, or will it fall? You cannot know for certain.

The problems surrounding making decisions today based on expectations of the future are explored in Threshold Concept 9.

Definition

Consumer durable A consumer good that lasts a period of time, during which the consumer can continue gaining utility from it.

THRESHOLD CONCEPT 9

PEOPLE'S ACTIONS DEPEND ON THEIR EXPECTATIONS

THINKING LIKE AN ECONOMIST

Many, if not most, economic actions are taken before the benefits are enjoyed. You work first and get paid at the end of the month; you buy something in a shop today, and consume it later. In the case of a bar of chocolate, you may consume it fairly soon and pretty well all at once, in the case of many 'consumer durables', such as electrical goods, you will enjoy them over a much longer period.

It is the same with firms. What they produce today will be sold at some point in the future. In other words, firms typically incur costs first and receive revenues later. In the case of investing in new buildings or equipment, it may be a very long time before the firm starts seeing profits from the investment.

In each of these cases, then, the decision is made to do something now in anticipation of what will happen in the future. The threshold concept here is that decision making is only as good as the information on which it is based. If your expectations turn out to be wrong, a seemingly good decision may turn out disastrously. Part of what we do as economists is to examine how people get information and on what basis they form their expectations; part of what we do is to forecast the future.

When information about the future is imperfect, as it nearly always will be, there are risks involved in basing decisions on such information. Businesses constantly have to live with risk: risk that market prices will decline, that costs will rise, that machinery will break down, that competitors will launch new

products, and so on. But in our everyday lives, we too face risks because of poor information about the future. Do you spend money on a holiday in this country and risk having a wet week? Do you go to the cinema to see a film, only to find out that you don't enjoy it?

Sometimes you lack information simply because you have not taken the time or paid the money to acquire it. This could apply to the specifications of a product. A little research could give you the information you require. Sometimes, however, the information is simply not available – at least not in the form that will give you certainty. A firm may do market research to find out what consumers want, but until a product is launched, it will not be certain how much will be sold. A market analyst may give you a forecast of what will happen to stock market prices or to the dollar/euro exchange rate, but analysts frequently get it wrong.

1. *What risks are involved in buying the latest version of the iPhone? Compare these with the risks of buying a house?*
2. *Give some examples of ways in which it is possible to buy better information. Your answer should suggest that there is profitable business to be made in supplying information.*
3. *Is there a role for government intervention in the provision of information? (We return to this in Chapter 12).*

Attitudes towards risk and uncertainty

So how will uncertainty affect people's behaviour? The answer is that it depends on their attitudes towards taking a gamble. To examine these attitudes let us assume that people do at least know the chances involved when taking a gamble (i.e. they know the exact *probabilities* of different outcomes occurring). In other words, they operate under conditions of risk rather than uncertainty.

Explain the difference between 'risk' and 'uncertainty' (see Chapter 2, pages 66–76).

Consider the following example. Imagine that as a student you only have £105 left to spend out of your student loan and have no other income or savings. You are thinking of buying an instant lottery ticket/scratch card. The lottery ticket costs £5 and there is a 1 in 10 or 10 per cent chance that it will be a winning ticket. A winning ticket pays a prize of £50. Would you buy the lottery ticket? This will depend on your attitude towards risk.

In order to explain people's attitude towards risk it is important to understand the concept of expected value. The **expected value** of a gamble is the amount the person would earn on average if the gamble was repeated on many occasions. To calculate the expected value of a gamble you simply multiply each possible outcome by the probability that outcome will occur. These values are then added together.

In our example the gamble has only two possible outcomes – you purchase a winning ticket or a losing ticket. There is a 10 per cent chance it is a winning ticket, which will give you a total of £150 to spend (£100 left out of your loan after you have purchased the ticket plus a £50 prize). There is a 90 per cent chance it is a losing ticket, in which case you will only have £100 left to spend out of your student loan. Therefore, the expected value of this gamble is:

$$EV_{\text{gamble}} = 0.1(\text{£}150) + 0.9(\text{£}100) = 105$$

Probability it is a winning ticket Outcome from a winning ticket Probability it is a losing ticket Outcome from a losing ticket

If you do not purchase the ticket you will have £105 to spend for sure.

$$EV_{\text{no gamble}} = 1(105) = 105$$

There are three possible categories of attitude towards risk.

Risk neutral. If people are risk neutral, they will always choose the option with the highest expected value. Therefore, in this example, a student who is risk neutral would be indifferent between buying or not buying the instant lottery ticket, as each outcome has the same expected value of £105.

Risk averse. If people are risk averse they will never choose a gamble if it has the same expected value as a certain pay-off. Therefore, a student who is risk averse would definitely not buy the instant lottery ticket.

It is too simplistic, however, to say that a risk-averse person will never take risks. Such a person may choose a gamble if it has a greater expected value than a certain pay-off. If the probability of purchasing a winning instant lottery ticket in the previous example was 20 per cent instead of 10 per cent, then a risk-averse student might buy the ticket, as the expected value of the gamble (£110) is greater than the certain pay-off (£105).

Whether or not risk-averse people do take gambles depends on the strength of their aversion to risk, which will vary from one individual to another. The greater a person's level of risk aversion, the greater the expected value of a gamble they are willing to give up in order to obtain a certain pay-off.

The certain amount of money that gives a person the same utility as the gamble is known as the gamble's **certainty equivalent**. The more risk averse a person is, the lower the gamble's certainty equivalent for them. The expected value of a gamble minus a person's certainty equivalent of that gamble is called the **risk premium**. The more risk averse someone is, the greater their positive risk premium.

Risk loving. If people are risk loving they would always choose a gamble if it had the same expected value as the pay-off from not taking the gamble. Therefore, a risk-loving student would definitely purchase the lottery ticket.

Once again, it is too simplistic to say that risk-loving people will always choose a gamble. They may choose a certain-pay-off if it has a higher expected value than the gamble. For a risk-loving person the certainty equivalent of a gamble is greater than its expected value. For example, if the probability of purchasing a winning instant lottery ticket in the previous example was 1 per cent instead of 10 per cent, then even a risk-loving student might choose not to buy the ticket. It would depend on the extent to which that person enjoyed taking risks. The more risk loving people are, the greater the return from a certain pay-off they are willing to sacrifice in order to take a gamble. Because the certainty equivalent of a gamble is greater than its expected value the risk premium is negative.

1. What is the expected value of the above lottery ticket gamble if the chances of purchasing a winning ticket with a prize of £50 are 30 per cent? How much of the expected value of the gamble is a risk-averse person willing to sacrifice if they decide against purchasing the ticket? If they were indifferent between purchasing and not purchasing the ticket, what is their certainty equivalent and risk premium of the gamble?

Definitions

Expected value The average value of an outcome of an activity when the same activity takes place many times.

Certainty equivalent The guaranteed amount of money that an individual would view as equally desirable as the expected value of a gamble. Where a person is risk averse, the certainty equivalent is less than the expected value.

Risk premium The expected value of a gamble minus a person's certainty equivalent.

2. What is the expected value of the lottery ticket gamble if the chances of purchasing a winning ticket are 1 per cent? How much of the certain pay-off is a risk-loving person willing to sacrifice if they decide to purchase the lottery ticket? If they were indifferent between purchasing and not purchasing the ticket what is their certainty equivalent and risk premium of the gamble?

Diminishing marginal utility of income and attitudes towards risk taking

Avid gamblers may be risk lovers. People who spend lots of money on various online betting websites or at the race track may enjoy the thrill of taking a risk, knowing that there is always the chance that they might win. On average, however, such people will lose. After all, the bookmakers have to take their cut and thus the odds they offer are generally unfavourable.

Most people, however, are risk averse most of the time. We prefer to avoid insecurity. But is there a simple reason for this? Economists use marginal utility analysis to explain why.

They argue that the gain in utility to people from an extra £100 is less than the loss of utility from forgoing £100. Imagine your own position. You have probably adjusted your standard of living to your income, or are trying to do so. If you unexpectedly gained £100 that would be very nice: you could buy some new clothes or have a meal out. But if you lost £100, you might have serious difficulties in making ends meet. Thus if you were offered the gamble of a 50:50 chance of winning or losing £100, you might well decline the gamble.

? Which gamble would you be more likely to accept, a 60:40 chance of gaining or losing £10 000, or a 50:50 chance of gaining or losing £1? Explain why.

This risk-averse behaviour accords with the principle of *diminishing marginal utility*. In the previous chapter we focused on the utility from the consumption of individual goods: Lucy and her cups of tea; Ollie and his packets of crisps. In the case of each individual good, the more we consume, the less satisfaction we gain from each additional unit: the marginal utility falls. But the same principle applies if we look at our *total* consumption. The higher our level of total consumption, the less additional satisfaction will be gained from each additional £1 spent.

What we are saying here is that there is a *diminishing marginal utility of income*. The more you earn, the lower will be the utility gained from each *extra* £1. If a person on £15 000 per year earned an extra £1000, they will feel a lot better off: their marginal utility from that income will be relatively very high. If a person already earning £500 000 per year earned an extra £1000, however, their gain in utility will be far less.

Do you think that this provides a moral argument for redistributing income from the rich to the poor? Does it prove that income should be so redistributed?

Why, then, does a diminishing marginal utility of income make us risk averse? The answer is illustrated in Figure 5.1, which shows the *total* utility you get from your income.

The slope of this curve gives the *marginal* utility of your income. As the marginal utility of income diminishes, so the

Definition

Diminishing marginal utility of income Where each additional pound earned yields less additional utility than the previous pound.

Figure 5.1 The total utility of income

curve gets flatter. Assume a person experiences 70 units or utils of pleasure from spending £5000 on the goods they like. This is shown at point *a* on Figure 5.1.

If the person's income now rises from £5000 to £10 000 their total utility increases by 30 utils, from 70 to 100 utils. This is shown as the movement along the total utility curve from point *a* to point *b*. A similar rise in income from £10 000 to £15 000 leads to a move from point *b* to point *c*. This time, however, total utility has increased by only 16 utils, from 100 to 116 utils. Marginal utility has diminished.

Now assume that your income is £10 000 and you are offered the following gamble: a 50:50 chance of gaining an extra £5000 or losing £5000. Effectively, then, you have an equal chance of your income rising to £15 000 or falling to £5000. The expected value of the gamble is £10 000 – the same as the pay-off from not taking the gamble.

At an income of £10 000, your total utility is 100. If your gamble pays off and increases your income to £15 000, your total utility will rise to 116: i.e. an increase of 16. If it does not pay off, you will be left with only £5000 and a utility of 70 utils: i.e. a decrease of 30. Therefore you have a 50:50 chance of experiencing either 116 or 70 utils of pleasure. Your *average* or expected utility will be $(116 + 70)/2 = 93$ utils.

This point can be illustrated on Figure 5.1 by drawing a straight line or chord between points *a* and *c*. Points along this chord represent all the possible weighted averages of the utility at point *a* and point *c*. In this example, because the probability is 50:50, expected utility is represented half way along the chord at point *e*. As you can see from the *TU* curve, the expected utility from the gamble is the same as the utility experienced from receiving £8000 for certain (point *d*). This is the certainty equivalent of the gamble.

The risk premium is £2000: i.e. the expected value of £10 000 minus the certainty equivalent of £8000. For this individual, £10 000 for certain provides greater utility than the gamble. They would always prefer a certain pay-off in this case as long as it was greater than £8000. Hence risk aversion is part of rational utility-maximising behaviour.

If people are generally risk averse, why do so many around the world take part in national lotteries?

Most of the time we do not know the exact chances involved of taking a gamble. In other words, we operate under conditions of *uncertainty*. We often have to make judgements about what we think are the different likelihoods of various outcomes occurring. There is evidence that in some circumstances people are not very good at making probabilistic judgements and are prone to making systematic errors. This is discussed in more detail in section 5.2 (see page 138).

Insurance: a way of removing risks

Insurance is the opposite of gambling. It removes the risk. For example, every day you take the risk that you will either

lose your mobile phone or drop and break it. In either case you will have to incur the cost of purchasing a new handset to replace it. Alternatively, you can remove the risk by taking out an appropriate insurance policy that pays out the cost of a new handset if the original one gets lost or broken.

Given that many people are risk averse, they may be prepared to pay a premium for an insurance policy even though it will leave them with less than the expected value of not buying the insurance and taking the gamble. The total premiums paid to the insurance companies, and hence the revenue generated, will be *more* than the amount the insurance companies pay out: that is, after all, how such companies make a profit.

But does this mean that the insurance companies are less risk averse than their customers? Why is it that the insurance companies are prepared to shoulder the risks that their customers were not? The answer is that the insurance company is able to *spread its risks*.

The spreading of risks

Take the following simple example. Assume you have £100 000 worth of assets (i.e. savings, car, property, etc.). You drive your car to school/university every day and there is a 1 in 20 (or 5 per cent) chance that at some point during the year you will be responsible for an accident that results in your car being a write-off. Assume the market value of the car is currently £20 000 and remains unchanged for the following 12 months. The expected value of taking the gamble for the year (i.e. not purchasing comprehensive car insurance) is $0.95(100\ 000) + 0.05(80\ 000) = £99\ 000$.

If you are risk averse you would be willing to pay more than an additional £1000 to purchase a fully comprehensive car insurance policy that covers you for a year. For example, you may be willing to pay £1100 (over and above a simple third-party insurance) for an annual policy that pays out the full £20 000 if you have the accident and are responsible for it. Having paid the extra £1100 out of your total assets of £100 000, you would be left with £98 900 for sure. If you are risk averse, this may give you a higher level of utility than not purchasing the insurance and taking the gamble that you are not responsible for an accident where your car is a write-off.

The insurance company, however, is not just insuring you. It is insuring many others drivers. Assume that it has many customers with exactly the same assets as you and facing the same 5 per cent risk every year of causing an accident that results in their car being a write-off. As the number of its customers increases, the outcome each year will become much closer to

Definition

Spreading risks (for an insurance company) The more policies an insurance company issues and the more independent the risks of claims from these policies are, the more predictable will be the number of claims.

its expected or average value. Therefore, the insurance company can predict with increasing confidence that, on average, 5 out of every 100 of its customers will cause an accident every year and make a claim on their own insurance for £20 000, while the other 95 out of every 100 will not cause an accident and so not make a claim on their insurance for their own car.

This means that the insurance company will pay out £100 000 in such claims for every 100 of its customers. This works out as an average pay-out of £1000 per customer. If each customer is willing to pay £1100 extra for such a policy, the insurance company will generate more in revenue from its customers than it is paying out in claims. Assuming that the administrative costs of providing each policy per customer is less than £100, the insurance company can make a profit.

This is an application of the *law of large numbers*. What is unpredictable for an individual becomes highly predictable in the mass. The more people the insurance company insures, the more predictable the final outcome becomes. In other words, an insurance company will be able to convert your *uncertainty* into their *risk*.

In reality, people taking out insurance will not all have the same level of wealth and the same chances of having an accident. However, using statistical data the insurance company will be able to work out the average chances of an event occurring for people in similar situations. Basing premiums on average chances can, however, create some problems for the insurance company, which will be discussed later in the chapter.

The independence of risks

The spreading of risks does not just require that there should be a large number of policies. It also requires the risks to be *independent*. This means that if one person makes a claim it does not increase the chances of another person making a claim too. If the risks are independent in the previous example, then if one person has a car accident the chances of another person having a car accident remain unchanged at 5 per cent.

Now imagine a different example. If an insurance company insured 1000 houses *all in the same neighbourhood*, and then there were a major fire in the area, the claims would be enormous. The risks of fire would *not* be independent, as if one house catches fire it increases the chances of the surrounding houses catching fire. If, however, a company provided fire insurance for houses scattered all over the country, the risks *are* independent.

1. Why are insurance companies unwilling to provide insurance against losses arising from war or 'civil insurrection'?
2. Name some other events where it would be impossible to obtain insurance.
3. Explain why an insurance company could not pool the risk of flooding in a particular part of a country? Does your answer imply that insurance against flooding is unobtainable?

Another way in which insurance companies can spread their risks is by *diversification*. The more types of insurance a company offers (car, house, life, health, etc.), the greater the likelihood the risks would be independent.

Problems for unwary insurance companies

A major issue for insurance companies is that they operate in a market where there is significant *asymmetric information*. Asymmetric information exists in a market if one party has some information that is relevant to the value of that transaction that the other party does not have. In the insurance market the buyer often has private information about themselves that the insurance company does not have access to.

Asymmetric information is often split into two different types – unobservable characteristics and unobservable actions. Each separate type of asymmetric information can potentially generate a different problem. Unobservable characteristics could generate the problem of *adverse selection*; unobservable actions could generate the problem of *moral hazard*. We consider each in turn.

Potential problems caused by unobservable characteristics – adverse selection

Different potential consumers of insurance will have different characteristics. Take the case of car insurance: some drivers may be very skilful and careful, while others may be less able and enjoy the thrill of speeding. Or take the case of life assurance: some people may lead a very healthy lifestyle by eating a well-balanced diet and exercising regularly; others may eat large quantities of fast food and do little or no exercise.

In each of these cases the customer is likely to know more about their own characteristics than the insurance company. These characteristics will also influence the cost to the firm of providing insurance. For example, less able drivers are more

Definitions

Law of large numbers The larger the number of events of a particular type, the more predictable will be their average outcome.

Independent risks Where two risky events are unconnected. The occurrence of one will not affect the likelihood of the occurrence of the other.

Diversification Where a firm expands into new types of business.

Asymmetric information Where one party in an economic relationship has better information than another.

likely to be involved in an accident and make a claim on their insurance than more able drivers. The problems this might cause can best be explained with a simple numerical example.

In the previous car insurance example, considered earlier (page 132), we assumed that all the customers had the same characteristics: i.e. they all had a 5 per cent chance per year of being responsible for a car accident where damage to their own car costs, on average, £20 000. In reality, because of their different characteristics, the chances of having a car accident will vary from one customer to another. To keep the example simple, we will assume that an insurance company has only two types of potential customer. One half of them are very skilful drivers and have a 1 per cent chance per year of causing a car accident, while the other half are less able drivers who each have a 9 per cent chance per year of causing an accident. The problem for the insurance company is that when a customer purchases the insurance they do not know if they are a skilful or a less able driver.

When faced with this situation the insurance company could set a profit-making risk premium on the assumption that half of its customers will be highly competent drivers, while the other half will have relatively poor driving skills. Using the law of large numbers, the firm can predict that 5 per cent of its customers will make a claim and so the average pay-out would be £1000 per customer (i.e. £20 000/20). Once again, assuming administration costs of less than £100 per customer, the insurance company could potentially make a profit on each policy.

The problem is that the skilful drivers might find this premium very unattractive. For them the expected value of the gamble (i.e. not taking out the insurance) is $0.99(100\ 000) + 0.01(80\ 000) = \#99\ 800$. Taking out the extra insurance would leave them with £98 900: i.e. their initial wealth of £100 000 minus the premium of £1100. Unless they were very risk averse, the maximum amount they would be willing to pay is likely to be far lower than £1100.

On the other hand, the less skilful drivers might find the offer from the insurance company very attractive. Their expected value from taking the gamble is $0.91(100\ 000) + 0.09(80\ 000) = \#98\ 200$. Their maximum willingness to pay is likely to be greater than £1100. In fact,

if they were all risk averse they would all purchase the policy if it was £1800, as this would leave them with £98 200 – the same as the expected value of the gamble.

The insurance company could end up with only the less able drivers purchasing the insurance. If this happens, then 9 out of every 100 customers would make a claim of 20 000 each. The average pay-out per customer would be £1800. Therefore the firm would be paying out far more in claims than it would be generating from the premiums.

If, however, the insurer *knew* a potential customer was a skilful driver, then it could offer the insurance policy at a much lower price: one that the risk-averse skilful driver would be willing to pay. If all the customers purchasing the policy were skilful drivers, then 1 in 100 would make a claim for £20 000. The average claim per customer would only be £200. All the skilful and risk-averse customers would be willing to pay more than £200 for the insurance policy.

But if the insurance company does not know who is careful and who is not, this asymmetric information will block mutually beneficial trade from taking place.

This example has illustrated the problem of *adverse selection* in insurance markets. This is where customers with the least desirable characteristics from the sellers' point of view (i.e. those with the greatest chance of making a claim) are more likely to take out the insurance policy at a price based on the average risk of *all* the potential customers. This can result in the insurance market for low-risk individuals collapsing even though mutually beneficial trade would be possible if symmetric information were present.

The potential problem of adverse selection is not unique to the insurance market. Unobservable characteristics are present in many other markets and may relate to the buyer, the seller or the product that is being traded. A well-known example is that of a second-hand car dealer who sells a 'lemon' (a car with faults) to an unsuspecting buyer who does not have the technical knowledge to check on the car. Another is a shop buying second-hand items paying a low price for a valuable antique from a seller who does not know its value. Table 5.1 provides some other examples.

We can define adverse selection more generally as follows. It is Key Idea 16.

Table 5.1 Adverse selection in various markets

Market	Hidden characteristic	Informed party	Uninformed party
The labour market	Innate ability of the worker/ preference for working hard	The potential employee: i.e. the seller of labour services	The employer: i.e. the buyer of labour services
The credit market	Ability of people to manage their money effectively	The customer applying for credit	The firm lending the money
A street market with haggling	How much the person is willing to pay	The customer	The seller of the product
The electronic market: e.g. eBay	The quality/condition of the product	The seller of the product	The buyer of the product

Adverse selection A market process whereby buyers, sellers or products with certain unobservable characteristics (e.g. high risk or low quality) are more likely to enter the market at the current market price. This process can have a negative impact on economic efficiency and cause some potentially profitable markets to collapse.

Tackling the problem of adverse selection. Are there any ways that the potential problems caused by adverse selection can be overcome? One way would be for the party who is uninformed about the relevant characteristics of the other parties to ask them for information. For example, an insurance company may require people to fill out a questionnaire giving details about their lifestyle and family history, or undergo a medical, so that the company can assess the particular risk and set an appropriate premium. There may need to be legal penalties for people caught lying! This process of the uninformed trying to get the information from the informed is called 'screening'.

An alternative would be for the person or party who is informed about the relevant characteristics taking action to reveal it to the uninformed person or party. This is called 'signalling'. For example, a potentially hardworking and intelligent employee could signal this fact to potential employers by obtaining a good grade in an economics degree or working for a period of time as an unpaid intern.

What actions can either the buyers or sellers take in each of the examples in Table 5.1 to help overcome some of the potential problems caused by the unobservable characteristics?

Potential problems caused by unobservable actions – moral hazard

Imagine in the previous example if the different characteristics of the drivers were perfectly observable to the insurance company: i.e. the insurance company could identify which drivers were more able or careful and could charge them a lower premium than those who were less able or careful. The company might still face problems caused by *unobservable actions* – again, a problem of asymmetric information.

Once drivers have purchased comprehensive insurance their driving behaviour may change. All types of driver now have an incentive to take less care when they are driving. If they are involved in an accident, all the costs will be covered by the insurance policy and so the marginal benefit from taking greater care will have fallen. This will result in the chances of a skilful driver having an accident rising above 1 per cent and of the less skilful driver rising above 9 per cent.

The problem for the insurer is that these changes in driving behaviour are difficult to observe. The companies may end up in a position where the amount of money claimed by

both the skilful and less skilful drivers increases above the revenue that they are collecting in premiums based on the risk before the insurance was taken out.

This is called **moral hazard** and can more generally be defined as where the actions/behaviour of one party to a transaction change in a way that reduces the pay-off to the other party. It is caused by a change in incentives once a deal has been reached. It can only exist if there are unobservable actions.

Moral hazard Following a deal, the actions/behaviour of one party to a transaction may change in a way that reduces the pay-off to the other party. In the context of insurance, it refers to customers taking more risks when they have insurance than when they do not have insurance.

The problem of moral hazard may occur in many different markets and different situations.

- Once a person has a permanent contract of employment they might not work as hard as the employer would have expected.
- If someone else is willing to pay your debts (e.g. your parents) it is likely to make you less careful in your spending! A similar type of argument has been used for not cancelling the debts of poor countries.
- If a bank knows that it will be bailed out by the government and not allowed to fail, it may undertake more risky lending strategies.
- If you hire a car, you may be rough with the clutch or gears, knowing that you will not bear the cost of the extra wear and tear on the car.
- When working in teams, some people may slack, knowing that more diligent members of the team will cover for them (giving them a 'free ride').

Tackling moral hazard. What are the most effective ways of reducing moral hazard? One approach would be for the uninformed party to devote more resources to *monitoring* the actions and behaviour of the informed party – in other words, to reduce the asymmetry of information. Examples

Definitions

Adverse selection in the insurance market Where customers with the least desirable characteristics from the sellers' point of view are more likely to purchase an insurance policy at a price based on the average risk of all the potential customers.

Moral hazard Where one party to a transaction has an incentive to behave in a way which reduces the pay-off to the other party.

include: insurance companies employing loss adjusters to assess the legitimacy of claims; lecturers using plagiarism detection software to discourage students from attempting to pass off other people's work as their own. However, monitoring may often be difficult and expensive.

An alternative is to change the terms of the deal so that the party with the unobservable actions has an incentive to behave in ways which are in the interests of the uninformed party. Examples include: employees who take sick leave being required to produce a medical certificate to prevent

people taking 'sickies'; students doing group project work being assessed on their own contribution to the project rather than being given the same mark as everyone else in the group, thereby discouraging free riding.

How will the following reduce the moral hazard problem?

- (a) A no-claims bonus in an insurance policy.
- (b) Having to pay the first so many pounds of any insurance claim (an 'excess').
- (c) The use of performance-related pay

Section summary

1. When people buy consumer durables, they may be uncertain of their benefits and any future costs. When they buy financial assets, they may be uncertain of what will happen to their price in the future. Buying under these conditions of imperfect knowledge is therefore a form of gambling.
2. The expected value of a gamble is the amount the person would earn on average if the gamble were repeated on many occasions. If we know the expected value of such gambles we are said to be operating under conditions of risk. If we do not know the expected value, we are said to be operating under conditions of uncertainty.
3. People can be divided into risk lovers, those who are risk averse and those who are risk neutral. Because of the diminishing marginal utility of income, it is rational for people to be risk averse (unless gambling is itself pleasurable).
4. Insurance is a way of eliminating risks for policy holders. If people are risk averse they will be prepared to pay premiums in order to obtain insurance. Insurance companies, on the other hand, are prepared to take on these risks because they can pool risk by selling a large number of policies. According to the law of large numbers, what is unpredictable for a single policy holder becomes highly predictable for a large number of them provided that their risks are independent of each other.
5. Insurance markets arise as an institutional response to risk aversion. Their existence potentially makes society 'better off' as they can increase individual utility. Insurance market failure may arise as a result of asymmetric information, through either adverse selection or moral hazard. Adverse selection is where customers with the least desirable characteristics from the sellers' point of view are more likely to purchase an insurance policy at a price based on the average risk of all the potential customers. Moral hazard occurs when insured people have an incentive to take more risks.
6. Both adverse selection and moral hazard are likely to occur in a range of economic relationships whenever there is a problem of asymmetric information. They can both be reduced by tackling asymmetry of information. Better information can be provided by screening, signalling or monitoring, or there can be incentives for providing more accurate information.

5.2 BEHAVIOURAL ECONOMICS

The field of behavioural economics has developed rapidly over the past 20 years. It integrates some simple insights from psychology into standard economic theory in an attempt to improve its ability to explain and predict behaviour. Here we focus on consumer behaviour. In Chapter 9 we look at the contribution of behavioural economics to explaining the behaviour of firms.

What is behavioural economics?

It is important to understand that the development of modern behavioural economics is not an attempt to replace mainstream economic theory. It aims, instead, to complement and enhance existing theory.

Standard economic theory

In order to understand fully what behavioural economics is, it is useful to think back to standard economic theories. These are built on the key assumption that people attempt to maximise their own self-interest – that they make 'rational choices'. They do this by accurately assessing all the costs and benefits involved when making even the most complicated of decisions. They then successfully make choices that maximise their own happiness. In most theories it is assumed that people's happiness depends only on the pay-offs to themselves.

However, this does not mean that economists actually believe that everyone in the real world makes rational choices. They accept that real human beings make mistakes

and often care about the pay-offs to others. What economists are assuming is that the people in their theoretical models behave in a rational and selfish manner.

But why assume that people in theories, such as consumer choice, behave differently from people in the real world? This is an example of *abstraction*. If theories built upon this simplified view of human behaviour can effectively explain and predict real-world behaviour, then it is a useful assumption to make.

The alternative would be to assume that people in the theories are as complicated as their real-world counterparts. This would introduce much greater complexity into the analysis and make it much more difficult to understand and apply. If the simpler model is doing a good job at explaining and predicting real-world behaviour, why make it any more complicated than it needs to be?

How appropriate are the assumptions of standard models? Economists have also argued that rational choice does generally approximate to human behaviour because:

- People will tend to make mistakes in a haphazard and random manner that cancel each other out.
- Those individuals who do not behave in a manner that is consistent with perfect rationality and self-interest will be driven out of the market by competitive forces.
- People will learn how to make rational decisions from experience.

To what extent does conventional economic theory successfully explain and predict real-world behaviour? In many instances it does a pretty good job, which explains why this

textbook and many others are full of economic theories built on these assumptions. But sometimes people's behaviour seems to run counter to traditional theory. We examine such occasions in this section and in Chapter 9.

Evidence on human behaviour and the challenge to standard theory

Part of the basis for behavioural economics is evidence from research using laboratory experiments. These have produced some results that are inconsistent with the predictions of mainstream theory. For example, studies found that people appear to have a far greater dislike of losses than would be predicted by mainstream theories. They also appear to be willing to pay to avoid outcomes that they believe are unfair.

Some evidence from some naturally occurring data also appears to be inconsistent with mainstream theory. The financial crisis demonstrated a real-world situation where people seemed to make repeated mistakes. Also, large amounts of money contributed by individuals to charities every year suggest that people are influenced by the impact of their decisions on the utility of others. Other studies have found evidence of behaviour that is inconsistent with the rational choice model in a number of areas, including (a) gym membership; (b) the housing market; (c) trading in financial markets; (d) the labour supply decisions of taxi drivers.

A number of theories have been developed, therefore, that are more consistent with some of the results in the research literature. Some of the more influential of these theories will be briefly explained in the remainder of this section.

BOX 5.1

EXPERIMENTAL ECONOMICS

EXPLORING ECONOMICS

A way of understanding human behaviour

In Chapter 1 (see page 27) we explained that economics is a social science, with methodologies in common with the natural sciences; both construct models which can be used to explain and predict.

In the natural sciences it is common to use experiments to test models or to determine their design features. This, however, was generally not the case with economics. But with the rise of behavioural economics, the use of experiments has become increasingly popular, both for research and teaching purposes.

An experiment will normally involve simulating some economic scenario, with various actors, such as buyers and sellers, or firms and employees. Volunteers (perhaps students!) will play the role of these actors and be offered various incentives, such as cash or forfeits, to see how these affect behaviour. The idea of these incentives is to mimic real-world situations. Often the simulation is set up in the form of a game with the incentive being simply to win.

In these experimental 'laboratories' economists can study how people behave under a range of conditions, changing one variable at a time.

Experiments are now a well-established method of looking at consumer behaviour, but are also increasingly being used by policy makers to understand outcomes that traditional theory might not predict (see Box 5.4).

It is important to realise that experiments do not always suggest that rationality is a mistaken assumption. In many circumstances individuals do behave in exactly the way traditional theory suggests – but in many other circumstances they do not. Experiments can help to understand why individuals behave the way they do and how changing incentives will affect this behaviour.

What are the limitations of using laboratory experiments and games to understand consumer behaviour?

Bounded rationality

A person might in principle want to maximise utility, but faces complex choices and imperfect information. Sometimes it *would* be possible to obtain better information. But on other occasions people may decide that it is not worth the time and effort, and perhaps expense, of getting more information. Their ability to be 'rational' is thus limited or '*bounded*' by the situation in which they find themselves.

Too much choice and limited information

Although choice is generally thought to be a good thing, sometimes consumers can be baffled by having too much choice and this can hamper their decision making. They do not have the time and information to look through all the alternatives.

A well-known experiment conducted by Sheena Iyengar and Mark Lepper¹ suggested that, in some circumstances, choice may be bad for consumers. The experiment involved setting up stalls offering shoppers the chance to sample a number of jams. It showed that while shoppers were most attracted to the stall that offered 24 samples, they were in fact 10 times more likely actually to buy when offered only 6 varieties. Too much choice appeared to hinder decision making and so to reduce consumers' utility.

Limited information is a particular problem with consumer durables. For example, when purchasing a laptop computer, a customer may be unsure about (a) how well it will perform, (b) how useful it will be and (c) the chances it will break down.

Although people may not know the exact costs and benefits of many decisions for certain, will they still attempt to be rational? In many cases the answer is yes. They simply do the best they can.

How good are you at making probabilistic judgements? Here is an interesting example. Suppose that one out of every hundred people in the population has a genetic medical condition. There is a test for this medical condition that is 99 per cent accurate. This means that if a person has the condition, the test returns a positive result with a 99 per cent probability; and if a person does not have the condition, it returns a negative result with 99 per cent probability. If a person's test comes back positive (and you know nothing else about that person), what is the probability that s/he has the medical condition?

Heuristics

To simplify the choice problem, people often revert to using mental short-cuts, referred to as *heuristics*, which require only modest amounts of time and effort. A heuristic technique is any approach to problem-solving, such as deciding what to buy, which is practical and sufficient for the purpose, but not necessarily optimal.

¹ Sheena S. Iyengar and Mark R. Lepper, 'When choice is demotivating: can one desire too much of a good thing?', *Journal of Personality and Social Psychology*, vol. 79, no. 6 (American Psychological Association, 2000).

For example, people may resort to making the best guess, or to drawing on past experiences of similar choices that turned out to be good or bad. Sometimes, when people are likely to face similar choices again, they resort to *trial and error*. They try a product. If they like it, they buy it again; if not, they don't.

On other occasions, they may use various *rules of thumb*: buying what their friends do, or buying products on offer or buying trusted brands. For example, people may have found that a particular brand of products is to their liking. When they want a new type of product, they may thus decide to use the same brand, even though they have never bought that particular product before. For example, you may have had a Sony TV before and liked it and so, when buying a laptop, choose a Sony. This 'brand loyalty' is something that companies recognise and strive to develop in their customers.

These rules of thumb can lead to estimates that are reasonably close to the utility people will actually get and can save on time and effort. However, they sometimes lead to systematic and predictable misjudgements about the likelihood of certain events occurring.

Behavioural economists seek to understand the different assumptions people make and their different responses in situations of bounded rationality. Such an understanding is also important to those working in the advertising and marketing industry: they want to know the most effective ways of influencing people's spending decisions.

Framing and the reference point for decisions

As we have seen, the use of heuristics can be consistent with the assumption of people attempting to maximise their self-interest under conditions of bounded rationality. Sometimes, however, people will make decisions that seem to run counter to rational choice theory – even allowing for limited time and information and the use of heuristics. This is because of the way they perceive or 'frame' their decisions.

Framing options affects choice

In traditional models of consumer choice, individuals aim to maximise their utility when choosing between goods, or bundles of goods. The context in which the choices are offered or made is not considered. Yet in real life we see that

Definitions

Bounded rationality When the ability to make rational decisions is limited by lack of information or the time necessary to obtain such information or by a lack of understanding of complex situations.

Heuristic A mental short-cut or rule of thumb that people use when trying to solve complex problems or when faced with limited information. They reduce the computational or research effort required but sometimes lead to systematic errors.

context is important; people will often make different choices when they are perceived, or **framed**, in different ways. For example, people will buy more of a good when it is flagged up as a special offer than they would if there is no mention of an offer, *even though the price is the same*.

This principle has led to the development of **nudge theory**, which underpins many marketing techniques. Here people can be persuaded to make a particular choice by framing it in an optimistic way or presenting it in a way that makes it easy to decide. We look at governments' use of nudge theory in Box 5.4 (see page 144).

Biases when assessing the likelihood of uncertain events

People's choices also reflect various biases or preconceptions they may have. This can make choices less than optimal.

Biased use of information. People tend to give a disproportionate weight to single events that are easy to imagine or retrieve from memory. Here are some potential examples of this heuristic:

- A tendency to overweight the single experience of a friend or relative and underweight the experience of a large number of consumers you have never met. For example, assume that you are thinking of buying a particular laptop and are trying to determine its reliability. A friend has recently purchased the same model and has had to send it back to the manufacturer for costly repairs. This may lead you to underestimate the reliability of this particular model and overestimate the chances of it breaking down. When making the probability assessment you underweight the information from a survey based on the experience of 10 000 users of the same laptop.
- A tendency to assign too much weight to the most recent information that can be retrieved from memory and not enough weight to older information. For example, you may have bought a particular type of cheese in the past, but have not done so for a while. You see it again in a supermarket, but because you cannot remember how much you liked it, you stick to a different type which you have consumed recently and know you like.
- Hindsight bias – events that actually take place are easier to imagine and visualise than those that do not.

Therefore, people have a tendency to (a) overestimate the chances that an event would happen after it has actually occurred; (b) underestimate the chances that an event would happen that did not occur. For example, after watching their team lose, football fans believe that the tactics chosen by the manager were always more likely to fail than they actually were before the game began.

Gambler's fallacy. This is the false belief that past outcomes have an impact on the likelihood of the next outcome occurring when, in reality, they are independent of one another. For example, assume a coin is tossed four times and comes up heads each time. You may mistakenly believe that a tail is more likely on the next toss. Another example is the choice of holiday destination. Assume that the actual chances of it being a sunny week in a particular resort is 50:50. Last year you went there and it rained. So you think, let's go there this year and because it rained last year it is more likely to be sunny this year.

The reference point for decision making

We saw in section 5.1 that people tend to be loss averse. The diminishing marginal utility of income makes this rational behaviour. But depending on how a choice is framed, the choice may seem to be at odds with rational behaviour. For example, take the following two ways that the same choice could be framed:

- 'If you switch to using this environmentally friendly product it will save you £200 per year in lower energy costs.'
- 'If you don't switch to using this environmentally friendly product you are wasting £200 per year in higher energy costs.'

The first presentation may lead to people perceiving the £200 as a potential gain; the reference point is the current situation before the choice is made. The second presentation is designed to switch the consumer's reference point to having switched, so that the £200 is perceived as a loss of not switching. If people are more sensitive to a potential loss than a forgone gain, then presenting the choice in the second way is more likely to persuade people to purchase the environmentally friendly product. Again, the advertising and marketing industry is well aware of this.

The reference point used by people to judge an outcome as a gain or a loss could be influenced by a range of factors. For example, it might be influenced by the following:

- *Their expectations.* Imagine that Dean and Jon are both students on an economics course. They have both exerted the same level of effort writing an assessed essay and each receives a mark of 60 per cent. Will they both be equally happy? If Dean expected to get 70 per cent, then this might be his reference point. He might 'code' the result as a 10 percentage point loss and feel very unhappy. If Jon, on the other hand, expected to get a mark of 50 per cent, he

Definitions

Framing The way in which a choice is presented or understood. A person may make different decisions depending on whether a choice is presented optimistically or pessimistically.

Nudge theory The theory that positive reinforcement or making the decision easy can persuade people to make a particular choice. They are 'nudged' into so doing.

*** BOX 5.2 THE ENDOWMENT EFFECT**EXPLORING
ECONOMICS**An example of loss aversion**

Consider the following two slightly different situations for the same person, Clare: (a) she is thinking of buying a good such as a coffee mug; (b) she has already purchased it and now owns it. In each case we can think of a way of measuring her valuation of that good.

In the first case it could be measured as the maximum amount she is willing to pay for the mug. This is known as her willingness to pay (WTP). In the second case it could be measured as the minimum amount she needs to be offered in order for her to be willing to sell it to someone else. This is known as her willingness to accept (WTA).

Apart from a few exceptions, traditional economic theory predicts that ownership of a product should have no impact on peoples' valuation of that product. Therefore, their WTP for the product should be equal to their WTA for the same product.

This means that utility functions and indifference curves should be unaffected by people purchasing and owning a product. For example, the diagram illustrates Clare's total utility from coffee mugs. If she purchases one mug, her utility increases from 0 to U_1 ; i.e. she moves from point a to point b along her utility function. If she were then to sell this mug, her total utility would decrease from U_1 to 0: i.e. she would move back along the same utility function from point b to point a , merely giving up the utility from owning the mug. In other words, her utility function is reversible. As the gain in utility from buying the mug is the same as the loss in utility from selling the same mug, WTP should equal WTA.

The endowment effect: when WTA is greater than WTP

In a famous study, Kahneman, Knetsch and Thaler¹ carried out a series of experiments with students on a Law and Economics degree at Cornell University. They were randomly divided into two equal-sized groups. Students in one group were each given a coffee mug and told that they could sell it if they wished. They were asked for their WTA. Students in the other group could each examine the mugs and make an offer to buy one. They were asked their WTP. The authors found that the median WTA

of the students who were given the mugs was \$5.25 whereas the median WTP in the other group was only \$2.25.

As the students had been randomly allocated into the two groups, standard theory predicts that WTP should be equal to WTA. However, the evidence suggests that those who were given ownership of the mugs at the start of the experiment valued them far more than those who were not.

A similar exercise was carried out with pens. In this experiment the median WTP remained constant at \$1.25, while the median WTA varied between \$1.75 and \$2.50. Once again, ownership seemed to have an impact on valuation.

After purchase, ownership becomes the new reference point

One explanation for these results is that ownership of a good influences a person's reference point. Those who do not already own the good perceive (or 'code') its purchase as a *gain* in utility and would move from point a to b in the diagram. However, once they have purchased a good its ownership is included in their reference point. Selling the good would be coded as a *loss*.

If people are loss averse then the sale of the good has a much bigger negative impact on their utility than the gain in utility from purchasing the product. This creates a discrete kink in the utility function at point b ; the utility function is no longer reversible. Sale of the good would cause a movement from b to a^L . The negative impact on utility of selling the good (U_1 to U^L) is greater than the gain in utility from purchasing the good (0 to U_1). This discrete kink in the utility function helps to illustrate people's WTA being greater than their WTP.

1. What explanations other than the endowment effect could help to explain any differences between a buyer's WTP and a seller's WTA?
2. * Illustrate the impact of the endowment effect on indifference curves.

1 D. Kahneman, J. L. Knetsch and R. H. Thaler, 'Experimental tests of the endowment effect and the Coase theorem', *Journal of Political Economy*, vol. 98, no. 6 (1990), pp. 1352-75.

Impact of the endowment effect

might code the result as a gain of 10 percentage points and feel much happier. A similar argument could be made if a worker was expecting to receive a real wage increase of 3 per cent but only received one of 2 per cent.

- *By making comparisons with others.* If customers obtain a 10 per cent discount on a product they purchase, they may initially feel happy and code the outcome as a gain. However, if they subsequently find out that other customers obtained a 20 per cent discount on the same product, this might change their reference point and they might begin to code the outcome as a loss.
- *Adjusting slowly to a changed income/asset position.* Contestants on the game show *Who Wants to be a Millionaire?* who have already won £16 000 may still take a 50:50 gamble of winning another £16 000 (i.e. having a total prize of £32 000) or losing £15 000 (i.e. having a total prize of £1000). When asked why they took the gamble, participants are likely to explain that even if they lose they will still have £1000 more than before they played the game. Comments such as these suggest that the contestants' reference point while playing the game remains at their income level *before* playing the game: i.e. every pay-off is coded as a gain. However, as they play the game, their income/asset position is changing. When they take the gamble they have already won £16 000. If their perception of their income position had fully adjusted, the reference income level would include the £16 000 and the chances of losing would be coded as a £15 000 loss.

Reference dependent loss aversion. People are generally loss averse – we saw this in section 5.1 (pages 139–41) when looking at the diminishing marginal utility of income. However, this loss aversion can be amplified by the reference point for a decision. The theory of *reference dependent loss aversion* is illustrated by the *endowment effect*, sometimes known as *divestiture aversion*. This is where people ascribe more value to things when they already own them, and are faced with selling them or otherwise giving them up, than when they are merely considering purchasing or acquiring them in the first place. In other words, when the reference point is one of ownership of an item, people put a higher value on it than when the reference point is one of non-ownership.

Definitions

Reference dependent loss aversion Where people value (or 'code') outcomes as either losses or gains in relation to a reference point. This can mean that losses are disliked more than would be predicted by standard diminishing marginal utility.

Endowment effect (or divestiture aversion) The hypothesis that people ascribe more value to things when they own them than when they are merely considering purchasing or acquiring them – in other words, when the reference point is one of ownership rather than non-ownership.

This suggests that the dislike of losses may be even stronger than is predicted by diminishing marginal utility of income in conventional economic theory (see page 131). Box 5.2 examines the endowment effect and shows how it produces a discrete kink or change in the slope of the utility function at the reference point.

According to rational choice theory, the money you've already spent – known as 'sunk costs' (see page 156) – should be excluded from decision making. However, there is considerable evidence that it does affect consumer behaviour. Using loss aversion, can you explain why this might be the case.

Present bias and self-control issues

Traditional theory assumes that if people plan to do something at some specific point in time in the future, such as going to a lecture at 10am next Monday, they do indeed do so when the time arrives. This is referred to as *time consistency*.

The only reason time-consistent people would change their mind is if new information came to light about the relative size of the costs and benefits of their decisions. For example, at 3:00pm on Monday you might plan to go to the gym at 5:00pm on Monday. However, at 4:00pm you might change your mind because you find out your best friend is coming to see you at 5:00pm. This is still time-consistent behaviour, as the only reason you have changed your mind is because information has changed: the opportunity cost of going to the gym turns out to be greater than you had thought at 3:00pm.

In practice, people often exhibit *time-inconsistent* behaviour. This is likely when some of the costs or benefits occur before other ones. People may then change their minds. For example, you may plan to start revising at 10:00am on Monday, but when that time arrives you may instead watch TV or play a computer game and plan to start revising on Tuesday!

Many people make New Year's resolutions; most do not stick to them! People are weak willed; people put things off.

Can you think of any other examples of decisions where people often change their mind with the passage of time once the costs or benefits become immediate.

Behavioural economists refer to this form of time inconsistency as *present bias*. This is where people put a greater

Definitions

Time consistency Where a person's preferences remain the same over time. For example, it is time consistent if you plan to buy a book when your student loan arrives and then actually do so when it does.

Present bias Time-inconsistent behaviour whereby people give greater weight to present pay-offs relative to future ones than would be predicted by standard discounting techniques.

weight on present benefits and/or costs than would be implied by a standard discounting approach. This means that they put excess weight on the costs of doing things they don't like doing, but believe are good for them (such as exercise or dieting); and excess weight on the benefits of doing things they want to do, but believe are bad for them (such as eating lots of chocolates or going out rather than revising). According to the well-known saying, 'hard work often pays off after time, but laziness pays off now'.

This suggests that when comparing pay-offs (benefits minus costs) in, say, a month with those today, people use a higher discount factor than when comparing pay-offs between two points in time a month apart, but both in the future. See Box 5.3 for a more detailed example.

Present bias helps explain why many people have difficulty in sticking to commitments. Indeed, some behavioural economists have actually created a website called *stickK*,

which enables people to make their own commitment contracts to help them stick to their plans.

Taking other people into account

Our behaviour as consumers, as in many other aspects of our lives, is often influenced by other people – both the effect we have on them and the effect they have on us.

Reciprocity

We start by looking at the effect of our consumption on other people. Behavioural economists have tried to develop utility functions that capture the idea that consumers care about the pay-offs to other people as well as themselves.

For example, having *altruistic* preferences in economics means that you might be willing in some circumstances to increase the pay-offs to another person or group of people at

* BOX 5. MODELLING PRESENT BIAS

A case study of gym attendance

A student, Jake, is considering whether or not to go to the gym at 5:00pm for an hour after his classes have finished for the day. Assume he has paid a monthly membership fee and there are no additional charges per visit. Therefore, the only cost of going to the gym is the opportunity cost of his time: e.g. giving up the chance to watch TV or meet his friends. To make the example as simple as possible, assume that all the benefits, such as health and general feelings of well-being, occur in the hour after he has finished at 6:00 pm.

If the benefits and opportunity cost of going to the gym can be valued at £20 and £10 respectively, will he decide to go? Are the discounted benefits greater than the discounted costs? Does the decision change with the passage of time? If Jake makes the decision at 3:00pm, will he still plan to go when considering the decision at 5:00pm?

Time-consistent behaviour

To begin with, consider the decision from his point of view at 3:00pm. At this moment in time, all the costs and benefits are in the future. Assuming he is impatient, the value of these costs and benefits at 5:00pm and 6:00pm respectively need to be adjusted to their value to Jake at 3:00pm.

Let δ (Jake's per hourly discount factor) = 0.9. Using standard exponential discounting, the costs (C) that occur in two hours' time (i.e. at 5:00pm) need to be multiplied by $\delta \times \delta$ (or δ^2) to adjust their value to the student at 3:00pm. The benefits (B), which all occur in three hours' time (i.e. at 6:00pm), need to be multiplied by $\delta \times \delta \times \delta$ (or δ^3) to adjust their value to the student at 3:00pm. The net benefit in

pounds (NB) (i.e. benefit minus cost) from his point of view at 3:00pm, is given by the following:

$$\begin{aligned} NB^{3pm} &= \delta^3 B_{6pm} - \delta^2 C_{5pm} = 0.729(20) \\ &\quad - 0.81(10) = 14.58 - 8.1 = 6.48 \end{aligned}$$

Although the benefits occur one hour after the costs, their greater discounted value means that at 3:00pm Jake will plan to go to the gym at 5:00pm.

Now consider the decision from his point of view at 5:00pm. The costs are immediate while the benefits are an hour away. Therefore, they have to be weighted by 1 and δ respectively, giving:

$$\begin{aligned} NB^{5pm} &= \delta B_{6pm} - C_{5pm} = 0.9(20) - 1(10) \\ &= 18 - 10 = 8 \end{aligned}$$

When 5:00pm arrives, therefore, Jake will follow through on his intention of going to the gym.

This simple example illustrates how the standard model of exponential discounting with a constant discount factor per period of time imposes time consistency (try using different values for δ , B and C and you will see that this remains so). The weighting factor used to adjust the benefits at 6:00pm is always 90 per cent of the size of the weighting factor used to adjust the costs at 5:00pm. This percentage difference remains the same no matter from what point in time the decision is being judged.

Therefore, if Jake discovers no new information about the size of the costs and benefits with the passage of time, his preferences remain the same. If at 3:00pm he plans to go to the gym at 5:00pm, he will indeed go to the gym when 5:00pm arrives.

a personal cost to yourself: e.g. making donations to a charity or buying presents for people (see also Box 4.4 on page 120, which looks at love and caring for another person). Having spiteful preferences, on the other hand, means that you might be willing to *reduce* the pay-offs of another person or group of people at a cost to yourself.

Evidence from experiments suggests that the same people are often willing to increase the pay-offs to others at a personal cost to themselves in some situations while reducing the pay-offs to others at a personal cost to themselves in other situations. In other words, people can have both altruistic and spiteful preferences.

To capture these ideas, behavioural economists have developed a number of models of *reciprocity*. Some of these suggest that people may experience an increase in their own utility by being kind to people they believe have been kind to them. Their utility may also increase if they are unkind to people they believe have been unkind to them.

Definition

Reciprocity (in economics) Where people's behaviour is influenced by the effects it will have on others.

Are such models consistent with standard theories of rational behaviour?

Relativity matters

Not only are we likely to consider the effect we have on others and be motivated by either altruism or spite, but we are also likely to be influenced by other people's behaviour. For example, if you are making a choice about buying a car, you might be influenced by the car your brother drives; if he chooses an Audi, perhaps you would like a more expensive car, a Mercedes possibly (assuming that you have graduated

CASE STUDIES AND APPLICATIONS

Time-inconsistent behaviour: present bias

In the real world we often observe people behaving in a *time-inconsistent* way. They plan to do things at points in time when all the costs and benefits occur in the future. However, they have a tendency to change their mind with the passage of time once some of the costs or benefits are experienced immediately.

A more formal study carried out by DellaVigna and Malmendier (2006)¹ analysed data from three health clubs in the USA where consumers had a choice between paying \$80 per month with no payment per visit or \$10 per visit with no monthly fee. The authors found that 80 per cent of those who chose the monthly membership option ended up paying more per visit on average than they would have paid if they had simply opted to pay per visit. These customers overestimated how many times they would go and did not learn from their mistakes as they did not change their membership.

One simple way the previous model can be extended to capture this type of behaviour idea is called *quasi-hyperbolic discounting*. All the costs and benefits, apart from those that occur immediately, are now multiplied by an additional weighting factor (β). What happens in the previous example if $\beta = 0.5$?

Jake will still plan to go to the gym from his perspective at 3:00pm as shown below:

$$NB^{3pm} = \beta\delta^3 B_{6pm} - \beta\delta^2 C_{5pm} = 0.3645(20) - 0.405(10) \\ = 7.29 - 4.05 = +3.24$$

By multiplying both costs and benefits by a constant fraction of 0.5 their relative weighting has not changed: i.e. the weighting factor used to adjust the benefits is still 90 per cent of the one used to adjust the costs. This would be true from any vantage point (i.e. 1:00pm, 2:00pm, etc.) as long as the costs and benefits were both in the future and remained an hour apart.

However, things change once the costs become immediate. Having planned to go to the gym at 3:00pm, Jake now changes his mind when 5:00pm finally arrives. The costs are now immediate and hence are not multiplied by β .

$$NB^{5pm} = \beta\delta B_{6pm} - C_{5pm} = 0.45(20) - 10 \\ = 9 - 10 = -1$$

Once the costs become immediate, while the benefits are still an hour away, the difference between the weighting changes from 90 per cent to 45 per cent. This has the effect of magnifying the size of the immediate cost relative to the future benefit. This is an example of *present bias* and can create time-inconsistent preferences.

The quasi-hyperbolic discounting model illustrates a situation where a person's weighting of the present/immediate over a later point in time is even greater than would be suggested by standard models of exponential discounting.

1. The bias for the present will vary from one individual to another. What happens in the previous example if the student has a smaller bias for the present that can be captured by $\beta = 0.7$.
2. Imagine a decision where all the benefits occur exactly an hour before the costs. Assume the benefits = £10 and the costs = £20 Using the quasi-hyperbolic discounting model, show how a person's preferences will change with the passage of time.
3. Assume you have a present bias but are fully aware of the inconsistent nature of your preferences. What actions could you take to make sure you actually carry out your planned decisions?

¹ Stefano DellaVigna and Ulrike Malmendier, 'Paying not to go to the gym', *American Economic Review*, vol. 96, no. 3 (June 2006).

and now have a well-paid job!). If he switches to a Jaguar, then perhaps you will opt for a Porsche. You want a better (or faster or more expensive) car than your brother; you are concerned not only with your choice of car but with your *relative* choice.

This does not disprove that choice depends on perceived utility. But it does demonstrate that utility often depends on your consumption *relative* to that of other people. Again, this is something that the advertising industry is only too well aware of. Adverts often try to encourage you to buy a product by showing that *other* people are buying it.

Herding and 'grouphink'

Being influenced by what other people buy, and thus making relative choices, can lead to herd behaviour. A fashion might catch on; people might grab an item in a sale because

other people seem to be grabbing it as well; people might buy a particular share on the stock market because other people are buying it.

Now, part of this may simply be the use of a heuristic under bounded rationality; sometimes it may be a good rule of thumb to buy something that other people want, as they might know more about it than you do. But there is a danger in such behaviour: other people may also be buying it because other people are buying it, and this builds a momentum. Sales may soar and the price may be driven well above a level that reflects the utility people will end up gaining. People have been persuaded to buy various risky financial assets because other people have been buying them and hence their price has been rising. This type of behaviour helps us to understand some of the aspects of destabilising speculation that we examined in section 2.5 (page 72–73).

BOX 5.4

NUDGING PEOPLE

EXPLORING ECONOMICS

How to change behaviour without taking away choice

One observation of behavioural economists is that people make many decisions out of habit. They use simple rules, such as: 'I'll buy the more expensive item because it's bound to be better'; or 'I'll buy this item because it's on offer'; or 'I always take the car to work, so I don't need to consider alternatives'; or 'Other people are buying this, so it must be worth having'.

Given that people behave like this, how might they be persuaded to change their behaviour? Governments might want to know this. Are there 'nudges' which will encourage people to act in their own self-interest: e.g. stop smoking, take more exercise or eat more healthy food? Will these 'nudges' impose a cost on those people who are acting in a rational manner? Firms too will want to know how to sell more of their products or to motivate their workforce. Even parents might want to make use of behavioural economics.

Opting in versus opting out

An interesting example concerns 'opting in' versus 'opting out'. In some countries, with organ donor cards, or many company pension schemes or charitable giving, people have to opt in. In other words, they have to make the decision to take part. Many as a result do not, partly because they never seem to find the time to do so, even though they might quite like to. With the busy lives people lead, it's too easy to think, 'Yes, I'll do that some time', but never actually get round to doing it: i.e. they have present bias.

With an 'opt out' system, people are automatically signed up to the scheme, but can freely choose to opt out. Thus it would be assumed that organs from people killed in an accident who had not opted out could be used for transplants. If you did not want your organs to be used, you would have to join a register. It could be the same with charitable giving. Some firms add a small charitable contribution to the price of their products (e.g. airline tickets or utility bills), unless people opt out. Similarly, under UK pension arrangements introduced from 2012, firms automatically deduct pension contributions from employees' wages unless they opt out of the scheme.

Opt-in schemes have participation rates of around 60 per cent, while otherwise identical opt-out funds retain between 90 and 95 per cent of employees. It is no wonder that Adair Turner, in his report on pensions, urged legislation to push pension schemes to an opt-in default position and that policy is moving in this direction.¹

This type of policy can improve the welfare of those who make systematic mistakes (i.e. suffer from present bias) while imposing very limited harm on those who act in a time-consistent manner. If it is in the interests of someone to opt out of the scheme, they can easily do so. Policies such as these are an example of what behavioural economists call 'soft paternalism'.

The Behavioural Insights Team

The UK Coalition government (2010–15) established the Behavioural Insights Team (BIT) (also unofficially known as the Nudge Unit) in the Cabinet Office in 2010. A major objective of this team is to use ideas from behavioural economics to design policies that enable people to make better choices for themselves.

BIT was partially privatised in 2014 and is now equally owned by the UK government, the innovation charity Nesta and the Team's employees.

1. How would you nudge members of a student household to be more economical in the use of electricity?
2. How could the government nudge people to stop dropping litter?
3. In the 2011 Budget, the then Chancellor of the Exchequer, George Osborne, announced that charitable giving in wills would be exempt from inheritance tax. Do you think this will be an effective way of encouraging more charitable donations?

¹ Richard Reeves, 'Why a nudge from the state beats a slap', *Observer*, 20 July 2008.

BOX 5.5

IS ECONOMICS THE STUDY OF SELFISH BEHAVIOUR?

CASE STUDIES AND APPLICATIONS

Is what's best for the individual best for others?

Many of the choices we make are not made as individuals purely for ourselves. If you are a member of a family or living with friends, many of your 'consumption' decisions will affect the other members of the household and many of their decisions will affect you.

Some things will be decided jointly: what to have for dinner, what colour to paint the hall, whether to have a party. Put it another way: when you gain utility, the other members of the household will often gain too (e.g. from things 'jointly' consumed, such as central heating).

Sometimes, however, it is the other way round. When things are jointly purchased, such as food, then one person's consumption will often be at the expense of other members of the household. 'Who's finished all the milk?' 'I want to watch a different television programme.'

What we are saying is that when individuals are in a group, such as a family, a club or an outing with a group of friends, their behaviour will affect and be affected by the other members of the group. For this reason, we have to amend our simple analysis of 'rational' choice. Let us consider two situations. The first is where people are trying to maximise their own self-interest within the group. The second is where people are genuinely motivated by the interests of the other members – whether from feelings of love, friendship, moral duty or whatever. We will consider these two situations within a family.

Self-interested behaviour

If you do not consider the other members of the family, this could rebound on you. For example, if you do not clean out the bath after yourself, or do not do your share of the washing up, then you may have to 'pay the price'. Other family members may get cross with you or behave equally selfishly themselves.

When considering doing things for their own benefit, therefore, the 'rational' person would at the very least consider the reactions of the other members of the family. We could still use the concept of marginal utility, however, to examine such behaviour. If marginal utility were greater than the price ($MU > P$), it would be 'rational' to do more of any given activity. Here, though, marginal utility would include utility not only from directly consuming goods or services within the household, but also from the favourable reactions to you from other family members. Likewise, marginal utility would be reduced if there were any unfavourable reaction from other family members. The 'price' (i.e. the marginal cost to you) would include not only the monetary costs to you of consuming something, but also any other sacrifice you make in order to consume it. In other words, the price would be the full opportunity cost.

Take first the case of goods or services jointly consumed, such as a family meal. Do you offer to cook dinner? If you were motivated purely by self-interest, you would do so if the marginal benefit (i.e. marginal utility) to you exceeded the marginal cost to you. The marginal benefit would include the benefit to you of consuming the meal, plus any pleasure you got from the approval of other family members, plus any entitlement to being let off other chores. The marginal cost to you would include any monetary costs to you (e.g. of purchasing the ingredients) and the sacrifice of any alternative pleasurable activities that you had to forgo (such as watching television). Whether the actual preparation of the meal was

regarded as a marginal benefit or a marginal cost would depend on whether the individual saw it as a pleasure or a chore.

Clearly, these benefits and costs are highly subjective: they are as you perceive them. But the principle is simple: if you were behaving purely out of self-interest, you would cook the meal if you felt that you would gain more from doing so than it cost you.

Now take the case of consuming something individually where it deprives another household member of consuming it (such as taking the last yoghurt from the fridge). Again, if you were behaving purely out of self-interest, you would have to weigh up the pleasure from that yoghurt against the cost to you of incurring the irritation of other family members.

Behaviour in the interests of the family as a whole

However, most people are not totally selfish, especially when it comes to relating to other members of their family. In fact, family members are often willing to make personal sacrifices or put in considerable effort (e.g. with household chores or child rearing) for the sake of other family members, without being motivated by what they individually can get out of it.

In such cases, consumption decisions can be examined at two levels: that of the individual and that of the whole family.

As far as individuals are concerned, analysis in terms of their own marginal benefit and marginal cost would be too simplistic. Often it is a more accurate picture to see household members, rather than behaving selfishly, instead behaving in the self-interest of the whole household. So a decision about what food to buy for the family at the supermarket, if taken by an individual member, is likely to take into account the likes and dislikes of other family members, and the costs to the whole household budget. In other words, it is the whole family's marginal benefits and marginal costs that the individual family member is considering.

Other forms of altruism

It can be argued that unselfish behaviour within a family, or social circle, is not truly altruistic. After all, it is not unreasonable to suppose that others will treat you better as a consequence. But outside the circle of family and friends we do see behaviour that does appear to be altruistic. Individuals choose to give money to charity, to return other people's property when they find it and to give blood that will help save strangers.

This is a further area of economic theory that behavioural economists find interesting and it is providing a focus for economic research. The apparent contradiction between net utility maximisation and the actions of individuals provides an opportunity to gain further understanding about motivation and utility.

1. *Imagine that you are going out for the evening with a group of friends. How would you decide where to go? Would this decision-making process be described as 'rational' behaviour?*
2. *Think of some examples of altruistic behaviour towards strangers. In each case list some of the reasons why individuals might behave 'unselfishly'.*

Implications for economic policy

Governments, in designing policy, will normally attempt to change people's behaviour. They might want to encourage people to work harder, to save more, to recycle rubbish, to use their cars less, to eat more healthily, and so on. If the policy is to be successful, it is vital for the policy measures to contain appropriate incentives: whether it be a tax rise, a grant or subsidy, a new law or regulation, an advertising campaign or direct help.

But whether the incentives are appropriate depends on how people will respond to them, and to know that, the

policy makers will need to understand people's behaviour. This is where behavioural economics comes in. People might respond as rational maximisers; but they might not. It is thus important to understand how context affects behaviour and adjust policy incentives appropriately.

Remember the question we asked at the beginning of Chapter 4 (page 105): 'Do you ever purchase things irrationally? If so, what are they and why is your behaviour irrational?' Can you better explain this behaviour in the light of behavioural economics?

Section summary

1. Traditional economics is based on the premise that consumers act rationally, weighing up the costs and benefits of the choices open to them. Behavioural economics acknowledges that real-world decisions do not always appear rational; it seeks to understand and explain what economic agents actually do.
2. Experiments and observations provide useful insights into the ways individuals act when faced with choices and decisions. They allow economists to test existing models and theories, but also provide motivation for the construction of new theories of human behaviour.
3. People's ability to make rational decisions is bounded by limited information and time. Thus people resort to using heuristics – rules of thumb.
4. The choices they make may also depend on how these choices are framed – the way in which they are presented or are perceived. People can be nudged to frame choices differently.
5. Sometimes people appear to behave irrationally. This may be because of a biased use of information: putting undue weight on the experience of friends or on their own experiences, especially recent ones. It may be because of the belief that independent things are really connected (the gambler's fallacy).
6. Seemingly irrational behaviour may arise from the choice of reference point for decision taking. The reference point used by people to judge an outcome as a gain or a loss can be influenced by a range of factors, including their expectations, comparisons with others and adjusting slowly to new information.
7. People who are loss averse may value things more highly when they own them than when they are considering buying them (the endowment effect) or when the costs or benefits are immediate. This reference-dependent loss aversion may result in people giving additional weight to loss than would occur simply from the diminishing marginal utility of income.
8. Giving additional weight to immediate benefits or costs is called 'present bias' and can lead to time-inconsistent behaviour, with people changing their minds and not acting in accordance with previous plans.
9. Apparently irrational behaviour may also be the result of taking other people into account. Altruism and spite are two emotions affecting choice here. People may also be influenced by other people's tastes.
10. Governments, in devising policy, are increasingly looking at ways to influence people's behaviour by devising appropriate incentives. Behavioural economics provides useful insights here.

END OF CHAPTER QUESTIONS

1. A country's central bank (e.g. the Bank of England or the US Federal Reserve Bank) has a key role in ensuring the stability of the banking system. In many countries the central bank is prepared to bail banks out which find themselves in financial difficulties. Although this has the benefit of reducing the chance of banks going bankrupt and depositors losing their money, it can create a moral hazard. Explain why.
2. Discuss the EU ruling that gender may not be used to differentiate insurance premiums. Which insurance markets would be affected by outlawing age 'discrimination' in a similar manner? What would be the impact?
3. The European New Car Assessment Programme (Euro NCAP) carries out crash tests on new cars in order to assess the extent to which they are safer than the minimum required standard. The cars are given a percentage score in four different categories, including adult occupant protection and child occupant protection. An overall safety rating is then awarded. Based on the test results in November 2014, the Volvo V40 hatchback was judged to be the safest car on the market. If you observed that these cars were *more* likely to be involved in traffic accidents, could this be an example of adverse selection or moral hazard? Explain.
4. How does economics predict rational consumers will treat spending on credit cards compared with spending cash? Do you think that there are likely to be differences in the way people spend by each? If so, can you explain why?
5. How does behavioural economics differ from standard economics?
6. Give some example of heuristics that you use. Why do you use them?
7. For what reasons may branded products be more expensive than supermarkets' own-brand equivalents? How can behavioural economics help to explain this?
8. If you buy something in the shop on the corner when you know that the same item could have been bought more cheaply two miles up the road in the supermarket, is your behaviour irrational? Explain.
9. Why do gyms encourage people to take out monthly or even annual membership rather than paying per visit?
10. Many European countries operate organ donor schemes, some with schemes requiring that potential donors opt in, others with a system of opting out, or presumed consent. Explain why a system of presumed consent is likely to result in much higher numbers of donors. Does your answer suggest that all countries should move to presumed consent for organ donors?

Shifts in revenue curves	180
6.6 Profit maximisation	180
Short-run profit maximisation: using total curves	181
Short-run profit maximisation: using average and marginal curves	181
Some qualifications	184

So far we have assumed that supply curves are upward sloping: that a higher price will encourage firms to supply more. But just how much will firms choose to supply at each price? It depends largely on the amount of profit they will make. If a firm can increase its profits by producing more, it will normally do so.

Profit is made by firms earning more from the sale of goods than they cost to produce. A firm's total profit ($T\Pi$) is thus the difference between its total sales revenue (TR) and its total costs of production (TC):

$$T\Pi = TR - TC$$

In order then to discover how a firm can maximise its profit or even get a sufficient level of profit, we must first consider what determines costs and revenue.

The first four sections build up a theory of short-run and long-run costs. They show how output depends on the inputs used, and how costs depend on the amount of output produced. Section 6.5 then looks at revenue. Finally, in section 6.6, we bring cost and revenue together to see how profit is determined. In particular, we shall see how profit varies with output and how the point of maximum profit is found.

Chapter 4 went behind the demand curve. It saw how the 'rational' consumer weighs up the *benefits* (utility) of consuming various amounts of goods or combinations of goods against their *costs* (their price).

We now need to go behind the supply curve and find out just how the *rational producer* (or 'firm' as we call all producers) will behave.

In this case, we shall be looking at the benefits and costs to the firm of producing various quantities of goods and using various alternative methods of production. We shall be asking:

- How much will be produced?
- What combination of inputs will be used?
- How much profit will be made?

Profit and the aims of a firm

The traditional theory of supply, or *theory of the firm*, assumes that firms aim to *maximise profit*; this is a realistic

assumption in many cases. The traditional profit-maximising theory of the firm is examined in this and the following two chapters. First, we examine the general principles that govern how much a firm supplies. Then, in Chapters 7 and 8, we look at how supply is affected by the amount of competition a firm faces.

In some circumstances, however, firms may not seek to maximise profits. Instead they may seek to maximise sales, or the rate of growth of sales. Alternatively, they may have no *single* aim, but rather a series of potentially conflicting aims held by different managers in different departments of the firm. Sometimes there may be a conflict between the owners of the firm and those running it. Not surprisingly, a firm's behaviour will be influenced by what its objectives are: i.e. what it is trying to achieve. Chapter 9 looks at the implications of firms having different aims and objectives. It also considers some ideas from behavioural economics.

6.1 THE SHORT-RUN THEORY OF PRODUCTION

The cost of producing any level of output will depend on the amount of inputs (or 'factors of production') used and the price the firm must pay for them. Let us first focus on the quantity of factors used.

Output depends on the amount of resources and how they are used. Different amounts and combinations of inputs will lead to different amounts of output. If output is to be produced efficiently, then inputs should be combined in the optimum proportions.

Short- and long-run changes in production

If a firm wants to increase production, it will take time to acquire a greater quantity of certain inputs. For example, a manufacturer can use more electricity by turning on switches, but it might take a while to obtain and install more machines, and longer still to build a bigger, or a second, factory.

If the firm wants to increase output relatively quickly, it will only be able to increase the quantity of certain inputs. It can use more raw materials and more fuel. It may be able to use more labour by offering overtime to its existing workforce, or by recruiting extra workers if they are available. But it will have to make do with its existing buildings and most of its machinery.

The distinction we are making here is between *fixed factors* and *variable factors*. A *fixed* factor is an input that cannot be increased within a given time period (e.g. buildings). A *variable* factor is one that can.

The distinction between fixed and variable factors allows us to distinguish between the *short run* and the *long run*.

The short run is a time period during which at least one factor of production is fixed. Output can be increased only by using more variable factors. For example, if a coffee bar became more successful it could serve more customers per day in its existing shops, if there was space. It could increase the quantity of milk and coffee beans it purchases. It may be able to hire more staff, depending on conditions in the local labour market, and purchase additional coffee machines if

Definitions

Rational producer behaviour When a firm weighs up the costs and benefits of alternative courses of action and then seeks to maximise its net benefit.

Theory of the firm The analysis of pricing and output decisions of the firm under various market conditions, assuming that the firm wishes to maximise profit.

Fixed factor An input that cannot be increased in supply within a given time period.

Variable factor An input that can be increased in supply within a given time period.

Short run The period of time over which at least one factor is fixed.

Long run The period of time long enough for *all* factors to be varied.

BOX 6.1

MALTHUS AND THE DISMAL SCIENCE OF ECONOMICS

EXPLORING
ECONOMICS

Population growth + diminishing returns = starvation

The law of diminishing returns has potentially cataclysmic implications for the future populations of the world.

If the population of the world grows rapidly, then food output may not keep pace with it. There could be diminishing returns to labour as more and more people crowd on to the limited amount of land available.

This is already a problem in some of the poorest countries of the world, especially in sub-Saharan Africa. The land is barely able to support current population levels. Only one or two bad harvests are needed to cause mass starvation – witness the appalling famines in recent years in Ethiopia and Sudan.

The relationship between population and food output was analysed as long ago as 1798 by the Reverend Thomas Robert Malthus (1766–1834) in his *Essay on the Principle of Population*. This book was a bestseller and made Robert Malthus perhaps the best known of all social scientists of his day.

Malthus argued as follows:

I say that the power of population is indefinitely greater than the power in the earth to produce subsistence for man.

Population when unchecked, increases in a geometrical ratio. Subsistence increases only in an arithmetical ratio. A slight acquaintance with numbers will show the immensity of the first power in comparison with the second.¹

What Malthus was saying is that world population tends to double about every 25 years or so if unchecked. It grows geometrically, like the series 1, 2, 4, 8, 16, 32, 64, etc. But food output, because of diminishing returns, cannot keep pace with this. It is likely to grow at only an arithmetical rate, like the series 1, 2, 3, 4, 5, 6, 7, etc. It is clear that population, if unchecked, will soon outstrip food supply.

So what is the check on population growth? According to Malthus, it is starvation. As population grows, so food output per head will fall until, with more and more people starving, the death rate will rise. Only then will population growth stabilise at the rate of growth of food output.

Have Malthus' predictions been borne out by events? Two factors have mitigated the forces that Malthus described:

- The rate of population growth tends to slow down as countries become more developed. Although improved health prolongs life, this tends to be more than offset by a decline in the birth rate as people choose to have smaller families. This is illustrated in the table below. Population growth peaked in the 1960s, has fallen substantially since then and is projected to fall further in future decades.
- Technological improvements in farming have greatly increased food output per hectare. These include better fertilisers and the development of genetically modified crops. (See Case Study 6.1 on the student website for an example.)

The growth in food output has thus exceeded the rate of population growth in developed countries and in some developing countries too. Nevertheless, the Malthusian spectre is very real for some of the poorest developing countries, which are simply unable to feed their populations satisfactorily. It is these poorest countries of the world which have some of the highest rates of population growth – around 3 per cent per annum in many African countries.

A further cause for concern arises from the move in Asia towards a westernised diet, with meat and dairy products playing a larger part. This further increases pressure on the land, since cattle require considerably more grain to produce meat than would be needed to feed humans a vegetarian diet.

A third factor is cited by some commentators, who remain unconvinced of the strength of Malthus' gloomy prognostication for the world. They believe that he seriously underestimated humankind's capacity to innovate; perhaps human ingenuity is one resource that doesn't suffer from diminishing returns.

1. Why might it be possible for there to be a zero marginal productivity of labour on many family farms in poor countries and yet just enough food for all the members of the family to survive? (Illustrate using MPP and APP curves.)
2. The figures in the following table are based on the assumption that birth rates will fall faster than death rates. Under what circumstances might these forecasts underestimate the rate of growth of world population?

World population levels and growth: actual and projected

Year	Average annual rate of increase (%)			
	World population (billions)	World	More developed regions	Less developed regions
1950	2.5	1.8	1.2	2.1
1960	3.0	2.0	1.0	2.4
1970	3.7	1.9	0.7	2.3
1980	4.4	1.6	0.6	2.2
1990	5.3	1.4	0.4	1.7
2000	6.1	1.2	0.4	1.4
2010	6.9	1.1	0.3	1.3
2020	7.8	0.9	0.1	1.1
2030	8.5	0.8	0.0	0.9
2040	9.2	0.6	0.0	0.7
2050	9.7

there was space to install them. However, in the short run it could not extend its existing shops or have new ones built. This would take more time.

The long run is a time period long enough for all inputs to be varied. Given enough time, a firm can build additional factories and install new plant and equipment; a coffee shop can have new shops built.

The actual length of the short run will differ from firm to firm and industry to industry. It is not a fixed period of time. It might take a farmer a year to obtain new land, buildings and equipment; if so, the short run is any time period up to a year and the long run is any time period longer than a year. If it takes a mobile phone handset manufacturer two years to get a new factory built, the short run is any period up to two years and the long run is any period longer than two years.

1. How will the length of the short run for the airline depend on the state of the aircraft industry?
2. Up to roughly how long is the short run in the following cases?
 - (a) A firm supplying DJs for clubs and parties.
 - (b) Nuclear power generation.
 - (c) A street food wagon.
 - (d) 'Superstore Hypermarkets Ltd'.
 In each case specify your assumptions.

For the remainder of this section we will concentrate on short-run production.

The law of diminishing returns

Production in the short run is subject to *diminishing returns*. You may well have heard of 'the law of diminishing returns': it is one of the most famous of all 'laws' of economics. To illustrate how this law underlies short-run production let us take the simplest possible case where there are just two factors: one fixed and one variable.

Take the case of a farm. Assume the fixed factor is land and the variable factor is labour. Since the land is fixed in supply, output per period of time can be increased only by increasing the amount of workers employed. But imagine what would happen as more and more workers crowd on to a fixed area of land. The land cannot go on yielding more and more output indefinitely. After a point the additions to output from each extra worker will begin to diminish.

We can now state the law of diminishing (marginal) returns.

The law of diminishing marginal returns states that when increasing amounts of a variable factor are used with a given amount of a fixed factor, there will come a point when each extra unit of the variable factor will produce less extra output than the previous unit.

A good example of the law of diminishing returns is given in Case Study 6.1 on the student website. It looks at

diminishing returns to the application of nitrogen fertiliser on farmland.

The short-run production function: total physical product

Let us now see how the law of diminishing returns affects the total output of a firm in the short run. When a variable factor is added to a fixed factor the total output that results is often called **total physical product** (TPP).

The relationship between inputs and output is shown in a **production function**. In the simple case of the farm with only two factors – namely, a fixed supply of land (\bar{L}_n) and a variable supply of farm workers (L_b) – the short-run production function would be

$$TPP = f(\bar{L}_n, L_b)$$

This states that total physical product (i.e. the output of the farm) over a given period of time is a function of (i.e. depends on) the quantity of land and labour employed. The total physical output illustrated by the short-run production function shows the maximum output that can be produced by adding more of a variable input to a fixed input: i.e. it shows points that are all **technically efficient**.

In reality, total output from any given combination of inputs may be lower than the production function indicates because of inefficient management and methods of production. This issue is discussed in more detail in Box 7.5 in the next chapter. The level of technology is also assumed to be constant. (If there is technological progress, the whole production function would change.)

We could express the production function using an equation (an example is given in Box 6.4).

Alternatively, the production function could be expressed in the form of a table or a graph. Table 6.1 and Figure 6.1 show a hypothetical short-run production

Definitions

Law of diminishing (marginal) returns When one or more factors are held fixed, there will come a point beyond which the extra output from additional units of the variable factor will diminish.

Total physical product The total output of a product per period of time that is obtained from a given amount of inputs.

Production function The mathematical relationship between the output of a good and the inputs used to produce it. It shows how output will be affected by changes in the quantity of one or more of the inputs used in production holding the level of technology constant.

Technical efficiency The firm is producing as much output as is technologically possible given the quantity of factor inputs it is using.

Table 6.1 Wheat production per year from a particular farm

	Number of workers (Lb)	TPP	APP (= TPP/Lb)	MPP (= $\Delta TPP/\Delta Lb$)
a	0	0	—	3
	1	3	3	7
b	2	10	5	14
	3	24	8	12
c	4	36	9	4
	5	40	8	2
d	6	42	7	0
	7	42	6	-2
	8	40	5	

function for a farm producing wheat. The first two columns of Table 6.1 and the top diagram in Figure 6.1 show how total wheat output per year varies as extra workers are employed on a fixed amount of land.

With nobody working on the land, output will be zero (point *a*). As the first farm workers are taken on, wheat output initially rises more and more rapidly. The assumption behind this is that with only one or two workers

productivity is low, since the workers are spread too thinly. With more workers, however, they can work together – each, perhaps, doing some specialist job – and thus they can use the land more productively. In Table 6.1, output rises more and more rapidly up to the employment of the third worker (point *b*). In Figure 6.1 the *TPP* curve gets steeper up to point *b*.

After point *b*, however, diminishing marginal returns set in: output rises less and less rapidly, and the *TPP* curve correspondingly becomes less steeply sloped.

When point *d* is reached, wheat output is at a maximum: the land is yielding as much as it can. Any more workers employed after that are likely to get in each other's way. Thus beyond point *d* output is likely to fall again: eight workers actually produce less than seven workers.

All the points along the total physical product are technically efficient. Any point below it is technically inefficient. For example, if production were at point *e* with five workers producing 30 tonnes, it would be technically possible for those five workers to produce 40 tonnes at point *f*.

? What would happen to the *TPP* curve if the quantity of the fixed factor used in production were to increase to a new higher fixed level?

Figure 6.1 Wheat production per year (tonnes)

BOX 6.2

DIMINISHING RETURNS IN THE BREAD SHOP

CASE STUDIES AND APPLICATIONS

Is the baker using his loaf?

Just up the road from where John lives is a bread shop. Like many others, he buys his bread there on a Saturday morning. Not surprisingly, Saturday morning is the busiest time of the week for the shop and as a result it takes on extra assistants.

During the week only one assistant serves the customers, but on a Saturday morning there used to be five serving. But could they serve five times as many customers? No, they could not. There were diminishing returns to labour.

The trouble is that certain factors of production in the shop are fixed:

- The shop is a fixed size. It gets very crowded on Saturday morning. Assistants sometimes had to wait while customers squeezed past each other to get to the counter, and with five serving, the assistants themselves used to get in each other's way.

- There is only one cash till. Assistants frequently had to wait while other assistants used it.

- There is only one pile of tissue paper for wrapping the bread. Again the assistants often had to wait.

The fifth and maybe even the fourth assistant ended up serving very few extra customers.

John is still going to the same bread shop and they still have only one till and one pile of tissue paper. But now only three assistants are employed on a Saturday! The shop, however, is just as busy.

How would you advise the baker as to whether he should (a) employ four assistants on a Saturday; (b) extend his shop, thereby allowing more customers to be served on a Saturday morning; (c) extend his opening hours on a Saturday?

The short-run production function: average and marginal product

In addition to total physical product, two other important concepts are illustrated by a production function: namely, *average physical product* (APP) and *marginal physical product* (MPP).

Average physical product

This is output (TPP) per unit of the variable factor (Q_v). In the case of the farm, it is the output of wheat per worker.

$$APP = TPP/Q_v$$

Thus in Table 6.1 the average physical product of labour when four workers are employed is $36/4 = 9$ tonnes per year.

Marginal physical product

This is the extra output (ΔTPP) produced by employing one more unit of the variable factor.

Thus in Table 6.1 the marginal physical product of the fourth worker is 12 tonnes. The reason is that by employing the fourth worker, wheat output has risen from 24 tonnes to 36 tonnes: a rise of 12 tonnes.

In symbols, marginal physical product is given by

$$MPP = \Delta TPP / \Delta Q_v$$

Thus in our example:

$$MPP = 12/1 = 12$$

The reason why we divide the increase in output (ΔTPP) by the increase in the quantity of the variable factor (ΔQ_v) is that some variable factors can be increased only in multiple units. For example, if we wanted to know the MPP of

fertiliser and we found out how much extra wheat was produced by using an extra 20kg bag, we would have to divide this output by 20 (ΔQ_v) to find the MPP of one more kilogram.

Note that in Table 6.1 the figures for MPP are entered in the spaces between the other figures. The reason is that MPP can be seen as the *difference* in output *between* one level of input and another. Thus in the table the difference in output between five and six workers is 2 tonnes.

The figures for APP and MPP are plotted in the lower diagram of Figure 6.1. We can draw a number of conclusions from these diagrams:

- The MPP between two points is equal to the slope of the TPP curve between those two points. For example, when the number of workers increases from 1 to 2 ($\Delta Lb = 1$), TPP rises from 3 to 10 tonnes ($\Delta TPP = 7$). MPP is thus 7: the slope of the line between points g and h.
- MPP rises at first: the slope of the TPP curve gets steeper.
- MPP reaches a maximum at point b. At that point the slope of the TPP curve is at its steepest.
- After point b, diminishing returns set in. MPP falls. TPP becomes less steep.

Definitions

Average physical product Total output (TPP) per unit of the variable factor in question: $APP = TPP/Q_v$.

Marginal physical product The extra output gained by the employment of one more unit of the variable factor: $MPP = \Delta TPP / \Delta Q_v$.

- *APP* rises at first. It continues rising as long as the addition to output from the last worker (*MPP*) is greater than the average output (*APP*): the *MPP* pulls the *APP* up (see Box 6.3). This continues beyond point *b*. Even though *MPP* is now falling, the *APP* goes on rising as long as the

MPP is still above the *APP*. Thus *APP* goes on rising point *c*.

- Beyond point *c*, *MPP* is below *APP*. New workers add less to output than the average. This pulls the average down. *APP* falls.

BOX 6.3**THE RELATIONSHIP BETWEEN AVERAGES AND MARGINALS**

EXPLORING ECONOMICS

In this chapter we have just examined the concepts of *average* and *marginal* physical product. We shall be coming across several other average and marginal concepts later on. It is useful at this stage to examine the general relationship between averages and marginals. In all cases there are three simple rules that relate them.

To illustrate these rules, consider the following example.

Imagine a room with 10 people in it. Assume that the average age of those present is 20.

Now if a 20-year-old enters the room (the *marginal* age), this will not affect the average age. It will remain at 20. If a 56-year-old now comes in, the average age will rise: not to 56, of course, but to 23. This is found by dividing the sum of everyone's ages (276) by the number of people (12). If then a child of 10 were to enter the room, this would pull the average age down.

From this example we can derive the three universal rules about averages and marginals:

- If the marginal equals the average, the average will not change.
- If the marginal is above the average, the average will rise.
- If the marginal is below the average, the average will fall.

Suppose a course you are studying has five equally weighted pieces of coursework. Assume each one is marked out of 100 and your results are shown in the table below.

Coursework	1	2	3	4	5
Mark	60	60	70	70	20

Each number in the second row of the table is the *marginal* mark from each piece of coursework. Calculate your total and average number of marks after each piece of coursework.

Show how your average and marginal marks illustrate the three rules above.

*** BOX 6.4****THE RELATIONSHIP BETWEEN TPP, MPP AND APP**

EXPLORING ECONOMICS

Using calculus again

The total physical product of a variable factor (e.g. fertiliser) can be expressed as an equation. For example:

$$TPP = 100 + 32Q_f + 10Q_f^2 - Q_f^3 \quad (1)$$

where *TPP* is the output of grain in tonnes per hectare, and Q_f is the quantity of fertiliser applied in kilograms per hectare.

From this we can derive the *APP* function. *APP* is simply TPP/Q_f : i.e. output per kilogram of fertiliser. Thus:

$$APP = \frac{100}{Q_f} + 32 + 10Q_f - Q_f^2 \quad (2)$$

We can also derive the *MPP* function. *MPP* is the rate of increase in *TPP* as additional fertiliser is applied. It is thus the first derivative of *TPP*: $dTPP/dQ_f$. Thus:

$$MPP = 32 + 20Q_f - 3Q_f^2 \quad (3)$$

From these three equations we can derive the table shown.

Check out some figures by substituting values of Q_f into each of the three equations.

Maximum output (484 tonnes) is achieved with 8kg of fertiliser per hectare. At that level, *MPP* is zero: no additional output can be gained.

Q_f	<i>TPP</i>	<i>APP</i>	<i>MPP</i>
1	141	141	49
2	196	98	60
3	259	86	65
4	324	81	64
5	385	77	57
6	436	72	44
7	471	67	25
8	484	60	0
9	469	52	-31

This maximum level of *TPP* can be discovered from the equations by using a simple technique. If *MPP* is zero at this level, then simply find the value of Q_f where

$$MPP = 32 + 20Q_f - 3Q_f^2 = 0 \quad (4)$$

Solving this equation¹ gives $Q_f = 8$.

¹ By applying the second derivative test (see Appendix 1) you can verify that $Q_f = 8$ gives the *maximum* *TPP* rather than the *minimum*. (Both the maximum and the minimum point of a curve have a slope equal to zero.)

- As long as *MPP* is greater than zero, *TPP* will go on rising: new workers add to total output.
- At point *d*, *TPP* is at a maximum (its slope is zero). An additional worker will add nothing to output: *MPP* is zero.
- Beyond point *d*, *TPP* falls; *MPP* is negative.

1. What is the significance of the slope of the line *a-c* in the top part of Figure 6.1?
2. Given that there is a fixed supply of land in the world, what implications can you draw from Figure 6.1 about the effects of an increase in world population for food output per head? (See Box 6.1.)

Section summary

1. A production function shows the relationship between the amount of inputs used and the amount of output produced from them (per period of time). It assumes technical efficiency in production.
2. In the short run it is assumed that one or more factors (inputs) are fixed in supply. The actual length of the short run will vary from industry to industry.
3. Production in the short run is subject to diminishing returns. As greater quantities of the variable factor(s) are used, so each additional unit of the variable factor will add less to output than previous units: marginal physical product will diminish and total physical product will rise less and less rapidly.
4. As long as marginal physical product is above average physical product, average physical product will rise. Once *MPP* has fallen below *APP*, however, *APP* will fall.

6.2 COSTS IN THE SHORT RUN

We have seen how output changes as inputs are varied in the short run. We now use this information to show how costs vary with the amount a firm produces. Obviously, before deciding how much to produce, it has to know the precise level of costs for each level of output.

But first we must be clear on just what we mean by the word 'costs'. The term is used differently by economists and accountants.

Measuring costs of production

When measuring costs, economists always use the concept of *opportunity cost*. Remember from Chapter 1 how we defined opportunity cost. It is the cost of any activity measured in terms of the *sacrifice* made in doing it: in other words, the cost measured in terms of the value of the best alternative forgone.

How do we apply this principle of opportunity cost to a firm? First we must discover what factors of production it is using. Then we must measure the sacrifice involved. To do this it is useful to put factors into two categories.

Factors not owned by the firm: explicit costs

The opportunity cost of using factors not already owned by the firm is simply the price that the firm has to pay for them. Thus if the firm uses £100 worth of electricity, the opportunity cost is £100. The firm has sacrificed £100, which could have been spent on something else. The same would be true for machinery or buildings (factories/shops/units) that have been rented from other organisations. These costs are called *explicit costs* because they involve direct payment of money by firms.

Factors already owned by the firm: implicit costs

When the firm already owns factors (e.g. machinery), it does not as a rule have to pay out money to use them. Their

opportunity costs are thus *implicit costs*. They are equal to what the factors could earn for the firm in some alternative use, either within the firm or hired out to some other firm. Implicit costs do not involve actual cash outlays. They are less visible than explicit costs but just as important in decision making.

Here are some examples of implicit costs:

- A firm owns some buildings. The opportunity cost of using them in production for a year is the highest rent that could have been earned by letting them out to another firm over the same period.
- A firm draws £100 000 from the bank out of its savings in order to invest in new plant and equipment. The opportunity cost of this investment is not just the £100 000 (an explicit cost), but also the interest it thereby forgoes (an implicit cost).
- The owner of the firm could have earned £40 000 per annum by working for someone else. This £40 000 is then the opportunity cost of the owner's time running the business over the same period.

The opportunity costs of any decision in production are the implicit and explicit costs that are relevant to that

Definitions

Opportunity cost Cost measured in terms of the value of the best alternative forgone.

Explicit costs The payments to outside suppliers of inputs.

Implicit costs Costs that do not involve a direct payment of money to a third party, but which nevertheless involve a sacrifice of some alternative.

particular decision. By relevant we mean the costs that are incurred if the firm chose one particular course of action: e.g. expand output or stay in business. If a different decision is taken these costs would be avoided.

What implicit and explicit costs would a firm avoid if it decided not to expand production?

Some costs may remain unaffected by whatever decision a firm makes. These are not opportunity costs and so are irrelevant. They are called **sunk costs** and should be completely disregarded.

A sunk cost often exists when a firm has paid for a factor of production in the past and that factor of production no longer has value in any alternative uses. For example, a firm may have previously purchased a piece of machinery that is highly specialised and tailored to its own production process. If this machinery is of no value to any other firms and has no scrap value, the opportunity cost of using it is zero. No matter what decisions the firm makes in the future, the money used to purchase the machinery – its **historic cost** – is irrelevant. Not using the machine will not bring that money back – it cannot be recovered. In such a case, if the output from the machinery is worth more than the cost of all the *other* inputs involved, the firm might as well use the machine rather than let it stand idle.

It is important to remember that the cost of the machine was not always a sunk cost. Before its purchase, the opportunity cost of buying the machine was the money paid for it. It was only after its purchase that it became a sunk cost and had an opportunity cost of zero. The timing of a decision is crucial when deciding whether a cost is relevant or sunk.

The 'bygones' principle states that sunk costs should be ignored when deciding whether to produce or sell more or less of a product. Only those costs that can be avoided should be taken into account.

Costs and inputs

A firm's costs of production will depend on the factors of production it uses. The more factors it uses, the greater will its costs be. More precisely, this relationship depends on two elements:

- The productivity of the factors. The greater their physical productivity, the smaller will be the quantity of them required to produce a given level of output, and hence the lower will be the cost of that output. In other words, there is a direct link between *TPP*, *APP* and *MPP* and the costs of production.
- The price of the factors. The higher their price, the higher will be the costs of production.

In the short run, some factors are fixed in supply. Their total costs, therefore, are fixed, in the sense that they do not

Definitions

Sunk costs Costs that cannot be recouped (e.g. by transferring assets to other uses). Examples include specialised machinery or the costs of an advertising campaign.

Historic costs The original amount the firm paid for factors it now owns.

BOX 6.5

THE FALLACY OF USING HISTORIC COSTS

EXPLORING ECONOMICS

Or there's no point crying over spilt milk

If you fall over and break your leg, there is little point in saying 'If only I hadn't done that, I could have gone on that skiing holiday; I could have done so many other things [sigh].' Wishing things were different won't change history. You have to manage as well as you can with your broken leg.

It is the same for a firm. Once it has purchased some inputs, it is no good then wishing it hadn't. It has to accept that it has now got them, and make the best decisions about what to do with them.

Take a simple example. The local greengrocer decides in early December to buy 100 Christmas trees for £10 each. At the time of purchase, this represents an opportunity cost of £10 each, since the £10 could have been spent on something else. The greengrocer estimates that there is enough local demand to sell all 100 trees at £20 each, thereby making a reasonable profit.

But the estimate turns out to be wrong. On 23 December there are still 50 trees unsold. What should be done? At this stage the £10 that was paid for the trees is irrelevant. It is an historic cost. It cannot be recouped: the trees cannot be sold back to the wholesaler, nor can they be kept for next year.

In fact, the opportunity cost is now zero. It might even be negative if the greengrocer has to pay to dispose of any unsold trees. It might, therefore, be worth selling the trees at £10, £5 or even £1. Last thing on Christmas Eve it might even be worth giving away any unsold trees.

1. *Why is the correct price to charge (for the unsold trees) the one at which the price elasticity of demand equals -1 ? (Assume no disposal costs.)*
2. *Supermarkets have to pay for the rubbish they produce to be disposed of. Given this, what should they do with food that is approaching the sell-by date?*

BOX 6.6

ARE FIXED COSTS ALWAYS THE SAME AS SUNK COSTS?

EXPLORING
ECONOMICS

All sunk costs are fixed costs, but not all fixed costs are sunk costs

Within a given time period (i.e. the economic short run) some costs of production are completely insensitive to the quantity of output a firm produces. They remain the same whether the firm produces zero or a million units of output. These are called fixed costs. Other costs are responsive to the amount the firm produces. If it expands production, these costs will increase and if it reduces output they will fall. These are known as variable costs.

A variable cost can never be an example of a sunk cost as its size depends on the decision taken by a firm. A variable cost is always an opportunity cost. What about fixed costs? Is a fixed cost always a sunk cost? Could they be different in some circumstances?

Consider the following examples of costs that are likely to remain fixed for a number of different firms across a range of different sectors.

- Developing a new product – this could involve R&D.
- Advertising campaign to launch a new product.
- Physical capital:
 - machinery;
 - business premises.
- Human capital:
 - recruitment/training.
- Heating and lighting the business premises.
- Complying with government regulation.

If a firm temporarily shuts down then some of these costs cannot be avoided. For example, the costs of (a) developing a new product, (b) an advertising campaign and (c) complying

with government regulation can never be recovered. These categories of fixed cost are also examples of sunk costs. They remain the same no matter what the firm decides to do.

What about the cost of heating and lighting the business premises? Although these are fixed costs of production it is highly likely that they could be avoided if the firm temporarily shut down: i.e. with no staff in the building, the heating and lighting could simply be turned off. This is an example of a fixed cost that is *not* a sunk cost.

It may be possible for the firm to avoid some of the fixed costs associated with physical capital. If the firm temporarily shuts down, it might be able to rent the business premises and machinery to other firms. The higher the rental value of these assets, the greater the proportion of the fixed cost that is not a sunk cost.

The chances of a firm being able to rent out its physical capital to other businesses will depend on how much it has been tailored to its own particular use. Is the physical capital very specialised or is it more generic (such as a lorry) and so of value to a large number of other firms?

You need to think very carefully before deciding whether a fixed cost is also a sunk cost.

A firm currently rents a piece of machinery for £500 per month. The rental contract stipulates that this fee must be paid for the next 12 months. If the firm temporarily shut down it could rent the machinery to another business for £300 per month. To what extent is this fixed cost also a sunk cost?

vary with output. Rent on land is a **fixed cost**. It is the same whether the firm produces a lot or a little.

The total cost of using variable factors, however, does vary with output. The cost of raw materials is a **variable cost**. The more that is produced, the more raw materials are used and therefore the higher is their total cost.

? The following are some costs incurred by a sports footwear manufacturer. Assume the manufacturer wants to increase output over a relatively short time period: i.e. in the economic short run. Decide whether each one of the following is a fixed or a variable cost of expanding production in the short run or has some element of both. Clearly explain any assumptions you have made.

- (a) The cost of synthetic leather and mesh materials.
- (b) The fee paid to an advertising agency.
- (c) Wear and tear on machinery.
- (d) Business rates on the factory.
- (e) Electricity for heating and lighting.
- (f) Electricity for running the machines.
- (g) Basic minimum wages agreed with the union.
- (h) Overtime pay.
- (i) Depreciation of machines as a result purely of their age (irrespective of their condition).

Total cost

The **total cost** (TC) of production is the sum of the **total variable costs** (TVC) and the **total fixed costs** (TFC) of production:

$$TC = TVC + TFC$$

Consider Table 6.2 and Figure 6.2. They show the total costs for firm X of producing different levels of output (Q). Let us examine each of the three cost curves in turn.

Total fixed cost (TFC)

In our example, total fixed cost is assumed to be £12. Since this does not vary with output, it is shown by a horizontal straight line.

Definitions

Fixed costs Total costs that do not vary with the amount of output produced.

Variable costs Total costs that do vary with the amount of output produced.

Total cost The sum of total fixed costs and total variable costs: $TC = TFC + TVC$.

Table 6.2 Total costs for firm X

Output (Q)	TFC (£)	TVC (£)	TC (£)
0	12	0	12
1	12	10	22
2	12	16	28
3	12	21	33
4	12	28	40
5	12	40	52
6	12	60	72
7	12	91	103
.	.	.	.

Total variable cost (TVC)

With a zero output, no variable factors will be used. Thus $TVC = 0$. The TVC curve, therefore, starts from the origin.

The shape of the TVC curve follows from the law of diminishing returns. Initially, *before* diminishing returns set in, TVC rises less and less rapidly as more variable factors are added. Take the case of a factory with a fixed supply of machinery: initially as more workers are taken on the workers can do increasingly specialist tasks and make a fuller use of the capital equipment. This corresponds to the portion of the TPP curve that rises more rapidly (up to point b in Figure 6.1 on p. 152).

As output is increased beyond point m in Figure 6.2, diminishing returns set in. Since extra workers (the extra variable factors) are producing less and less extra output, the extra units of output they do produce will cost more and more in terms of wage costs. Thus TVC rises more and more rapidly. The TVC curve gets steeper. This corresponds to the

portion of the TPP curve that rises less rapidly (between points b and d in Figure 6.1).

Total cost (TC)

Since $TC = TVC + TFC$, the TC curve is simply the TVC curve shifted vertically upwards by £12.

Average and marginal costs

Average cost (AC) is cost per unit of production:

$$AC = TC/Q$$

Thus if it cost a firm £2000 to produce 100 units of a product, the average cost would be £20 for each unit (£2000/100).

Like total cost, average cost can be divided into the two components, fixed and variable. In other words, average cost equals **average fixed cost** ($AFC = TFC/Q$) plus **average variable cost** ($AVC = TVC/Q$):

$$AC = AFC + AVC$$

Definitions

Average (total) cost Total cost (fixed plus variable) per unit of output: $AC = TC/Q = AFC + AVC$.

Average fixed cost Total fixed cost per unit of output: $AFC = TFC/Q$.

Average variable cost Total variable cost per unit of output: $AVC = TVC/Q$.

Figure 6.2 Total costs for firm X

Marginal cost (MC) is the *extra* cost of producing *one more unit*: that is, the rise in total cost per one unit rise in output:

$$MC = \frac{\Delta TC}{\Delta Q}$$

For example, assume that a firm is currently producing 1 000 000 boxes of matches a month. It now increases output by 1000 boxes (another batch): $\Delta Q = 1000$. As a result, its total costs rise by £30: $\Delta TC = £30$. What is the cost of producing one more box of matches? It is

$$\frac{\Delta TC}{\Delta Q} = \frac{£30}{1000} = 3p$$

(Note that all marginal costs are variable, since, by definition, there can be no extra fixed costs as output rises.)

Given the *TFC*, *TVC* and *TC* for each output, it is possible to derive the *AFC*, *AVC*, *AC* and *MC* for each output using the above definitions.

For example, using the data of Table 6.2, Table 6.3 can be constructed.

? Fill in the missing figures in Table 6.3. (Note that the figures for *MC* come in the spaces between each level of output.)

What will be the shapes of the *MC*, *AFC*, *AVC* and *AC* curves? These follow from the nature of the *MPP* and *APP* curves that we looked at in section 6.1 above. You may recall that the typical shapes of the *APP* and *MPP* curves are like those illustrated in Figure 6.3.

Marginal cost (MC)

The shape of the *MC* curve follows directly from the law of diminishing returns. Initially, in Figure 6.4, as more of the variable factor is used, extra units of output cost less than previous units. *MC* falls. This corresponds to the rising portion of the *MPP* curve in Figure 6.3 and the portion of the *TVC* curve in Figure 6.2 to the left of point *m*.

Figure 6.3 Average and marginal physical product

Beyond a certain level of output, diminishing returns set in. This is shown as point *x* in Figure 6.4 and corresponds to point *b* in Figure 6.3 (and point *m* in Figure 6.2). Thereafter *MC* rises as *MPP* falls. Additional units of output cost more and more to produce, since they require ever-increasing amounts of the variable factor.

Average fixed cost (AFC)

This falls continuously as output rises, since *total* fixed costs are being spread over a greater and greater output.

Definitions

Marginal cost The extra cost of producing one more unit of output: $MC = \Delta TC / \Delta Q$.

Table 6.3 Total, average and marginal costs for firm X

Output (Q) (units)	TFC (£)	AFC (TFC/Q) (£)	TVC (£)	AVC (TVC/Q) (£)	TC (TFC + TVC) (£)	AC (TC/Q) (£)	MC ($\Delta TC / \Delta Q$) (£)
0	12	—	0	—	12	—	10
1	12	12	10	10	22	22	...
2	12	6	16	...	28	14	5
3	21	7	7
4	...	3	28	...	40	...	12
5	...	2.4	...	8	52	10.4	...
6	10	...	12	31
7	...	1.7	91	13	103	14.7	

Figure 6.4 Average and marginal costs

Average variable cost (AVC)

The shape of the AVC curve depends on the shape of the APP curve. As the average product of workers rises (up to point *c* in Figure 6.3), the average labour cost per unit of output (the AVC) falls: as far as point *y* in Figure 6.4. Thereafter, as APP falls, AVC must rise.

Average (total) cost (AC)

This is simply the vertical sum of the AFC and AVC curves. Note that as AFC gets less, the gap between AVC and AC narrows.

The relationship between average cost and marginal cost

This is simply another illustration of the relationship that applies between *all* averages and marginals (see Box 6.3).

As long as new units of output cost less than the average, their production must pull the average cost down. That is, if MC is less than AC, AC must be falling. Likewise, if new units cost more than the average, their production must drive the average up. That is, if MC is greater than AC, AC must be rising. Therefore, the MC crosses the AC at its minimum point (point *z* in Figure 6.4).

Since all marginal costs are variable, the same relationship holds between MC and AVC.

Why is the minimum point of the AVC curve at a lower level of output than the minimum point of the AC curve?

* LOOKING AT THE MATHS

The total, average and marginal cost functions can be expressed algebraically as follows:

$$TFC = a \quad (1)$$

$$TVC = bQ - cQ^2 + dQ^3 \quad (2)$$

$$TC = a + bQ - cQ^2 + dQ^3 \quad (3)$$

where *a* is the constant term representing fixed costs, and the signs of the terms in the TVC equation have been chosen to give TVC and TC curves shaped like those in Figure 6.2. Dividing each of the above by *Q* gives:

$$AFC = \frac{a}{Q} \quad (4)$$

$$AVC = b - cQ + dQ^2 \quad (5)$$

$$AC = \frac{a}{Q} + b - cQ + dQ^2 \quad (6)$$

Differentiating equation (3) or (2) gives:

$$MC = b - 2cQ + 3dQ^2 \quad (7)$$

A worked example of each of these is given in Maths Case 6.1 on the student website.

BOX 6.7

COST CURVES IN PRACTICE

EXPLORING ECONOMICS

When fixed factors are divisible

Are cost curves always the shape depicted in this chapter? The answer is no. Sometimes, rather than being U-shaped, the *AVC* and *MC* curves are flat-bottomed, like the curves in the diagram below. Indeed, they may be constant (and equal to each other) over a substantial range of output.

The reason for this is that fixed factors may sometimes not have to be in full use all the time. Take the case of a firm with 100 identical machines, each one requiring one person to operate it. Although the firm cannot use more than the 100 machines, it could use fewer: in other words, some of the

machines could be left idle. Assume, for example, that instead of using 100 machines, the firm uses only 90. It would need only 90 operatives and 90 per cent of the raw materials.

Similarly, if it used only 20 machines, its total variable costs (labour and raw materials) would be only 20 per cent. What we are saying here is that average variable cost remains constant – and over a very large range of output, using anything from 1 machine to 100 machines.

The reason for the constant *AVC* (and *MC*) is that by varying the amount of fixed capital used, the proportions used of capital, labour and raw materials can be kept the same and hence the average and marginal productivity of labour and raw materials will remain constant.

Only when all machines are in use (at Q_1) will *AVC* start to rise if output is further expanded. Machines may then have to work beyond their optimal speed, using more raw materials per unit of output (diminishing returns to raw materials), or workers may have to work longer shifts with higher (overtime) pay.

1. Assume that a firm has five identical machines, each operating independently. Assume that with all five machines operating normally, 100 units of output are produced each day. Below what level of output will *AVC* and *MC* rise?
2. Manufacturing firms like the one we have been describing will have other fixed costs (such as rent and managerial overheads). Does the existence of these affect the argument that the *AVC* curve will be flat bottomed?

Section summary

1. When measuring costs of production, we should be careful to use the concept of opportunity cost. In the case of factors not owned by the firm, the opportunity cost is simply the explicit cost of purchasing or hiring them. It is the price paid for them. In the case of factors already owned by the firm, it is the implicit cost of what the factor could have earned for the firm in its next best alternative use.
2. In the short run, some factors are fixed in supply. Their total costs are thus fixed with respect to output. In the case of variable factors, their total cost will increase as more output is produced and hence as more of the variable factor is used.
3. Total cost can be divided into total fixed and total variable costs. Total variable cost will tend to increase less rapidly

at first as more is produced, but then, when diminishing returns set in, it will increase more and more rapidly.

4. Marginal cost is the cost of producing one more unit of output. It will probably fall at first (corresponding to the part of the *TVC* curve where the slope is getting shallower), but will start to rise as soon as diminishing returns set in.
5. Average cost, like total cost, can be divided into fixed and variable costs. Average fixed cost will decline as more output is produced since total fixed cost is being spread over a greater and greater number of units of output. Average variable cost will tend to decline at first, but once the marginal cost has risen above it, it must then rise.

6.3 THE LONG-RUN THEORY OF PRODUCTION

In the long run, *all* factors of production are variable. There is time for the firm to build a new factory, to install new machines, to use different production techniques and to combine its inputs in whatever proportion and in whatever quantities it chooses.

In the long run, then, there are several decisions that a firm has to make: decisions about the scale and location of its operations and what techniques of production it should use. These decisions affect the costs of production. It is important, therefore, to get them right.

Table 6.4 Illustrating figures derived from a production function

	Number of machines					
	1	2	3	4	5	
Number of workers	1	4	7	13	13	12
	2	11	16	19	20	21
	3	16	21	24	25	26
	4	19	24	27	29	30
	5	21	25	28	30	32

The distinction between long-run and short-run production is illustrated in Table 6.4. The numbers in the table show the maximum output (the technically efficient output) that can be produced by employing different combinations of capital and labour. The impact of increasing the quantity of labour can be seen by working down each column. For example, if one worker is employed with one machine the maximum output that can be produced is 4. If a second worker is employed with one machine the total output is 11 and so on. The impact of increasing the amount of capital – i.e. the number of machines – can be seen by working across each row.

The scale of production

If a firm were to double all of its inputs – something it could do in the long run – would it double its output? Or will output more than double or less than double? We can distinguish three possible situations:

Increasing returns to scale. This is where a given percentage increase in inputs leads to a *larger* percentage increase in output. For example, look what happens in Table 6.4 if the both the number of workers and machines used in production are both doubled from 1 to 2. Total output increases from 4 to 16 (look diagonally downwards). In this case a 100 per cent increase in the inputs used in production leads to a 400 per cent increase in output. Production exhibits increasing returns to scale.

Constant returns to scale. This is where a given percentage increase in inputs leads to the *same* percentage increase in output. This is illustrated in Table 6.4 when the number of workers and machines are both increased from 2 to 3. This 50 per cent increase in inputs leads to a 50 per cent increase in output: i.e. total output increases from 16 to 24.

Decreasing returns to scale. This is where a given percentage increase in inputs leads to a *smaller* percentage increase in output. If, in the table, both the number of workers and machines are increased from 3 to 4 (a 33.3 per cent increase) then output increases from 24 to only 29 (a 20.8 per cent increase).

Notice the terminology here. The words ‘to scale’ mean that *all* inputs increase by the same proportion. Increasing and decreasing returns *to scale* are therefore quite different from increasing and diminishing returns to a variable factor (where only the *variable* factor increases). Returns to a variable factor is a characteristic of *short-run* production and can be illustrated in Table 6.4 by working down each of the columns – assuming labour is the variable factor and capital is the fixed factor.

Table 6.4 illustrates five different short-run production functions: i.e. where the number of machines remains constant at one, two, three, four or five. In each case explain if there are diminishing or increasing marginal returns?

Economies of scale

The concept of increasing returns to scale is closely linked to that of **economies of scale**. Whereas returns to scale focuses on how output changes in proportion to the quantity of inputs used in production, economies of scale looks at how costs change in proportion to the output produced. A firm experiences economies of scale if costs per unit of output fall as the scale of production increases: i.e. the proportionate increase in total costs is lower than the proportionate increase in output. Clearly, if a firm is getting increasing returns to scale from its factors of production, then as it produces more it will be using smaller and smaller amounts of factors per unit of output. Other things being equal, this means that it will be producing at a lower unit cost.

There are several reasons why firms are likely to experience economies of scale. Some are due to increasing returns to scale; some are not.

Specialisation and division of labour. In large-scale plants workers can often do simple, repetitive jobs. With this **specialisation and division of labour** less training is needed; workers can become highly efficient in their particular job, especially with long production runs; there is less time lost in workers switching from one operation to another; and supervision is easier. Workers and managers can be employed who have specific skills in specific areas.

Indivisibilities. Some inputs are of a minimum size: they are indivisible. The most obvious example is machinery. Take the case of a combine harvester. A small-scale farmer could

Definitions

Economies of scale When increasing the scale of production leads to a lower cost per unit of output.

Specialisation and division of labour Where production is broken down into a number of simpler, more specialised tasks, thus allowing workers to acquire a high degree of efficiency.

not make full use of one. They only become economical to use, therefore, on farms above a certain size. The problem of **indivisibilities** is made worse when different machines, each of which is part of the production process, are of a different size. For example, if there are two types of machine, one producing 6 units a day, and the other packaging 4 units a day, a minimum of 12 units would have to be produced, involving two production machines and three packaging machines, if all machines are to be fully utilised.

The 'container principle'. Any capital equipment that contains things (blast furnaces, oil tankers, pipes, vats, etc.) tends to cost less per unit of output the larger its size. The reason has to do with the relationship between a container's volume and its *surface area*. A container's cost depends largely on the materials used to build it and hence roughly on its surface area. Its output depends largely on its *volume*. Large containers have a bigger volume relative to surface area than do small containers.

For example, a container with a bottom, top and four sides, with each side measuring 1 metre, has a volume of 1 cubic metre and a surface area of 6 square metres (six surfaces of 1 square metre each). If each side were now to be doubled in length to 2 metres, the volume would be 8 cubic metres and the surface area 24 square metres (six surfaces of 4 square metres each). Thus an eightfold increase in capacity has been gained at only a fourfold increase in the container's surface area, and hence an approximate fourfold increase in cost.

Greater efficiency of large machines. Large machines may be more efficient in the sense that more output can be gained for a given amount of inputs. For example, only one worker may be required to operate a machine whether it be large or small. Also, a large machine may make more efficient use of raw materials.

By-products. With production on a large scale, there may be sufficient waste products to enable some by-product or by-products to be made.

Multi-stage production. A large factory may be able to take a product through several stages in its manufacture. This saves time and cost in moving the semi-finished product from one firm or factory to another. For example, a large cardboard-manufacturing firm may be able to convert trees or waste paper into cardboard and then into cardboard boxes in a continuous sequence.

All the above are examples of **plant economies of scale**. They are due to an individual factory or workplace or machine being large. There are other economies of scale, however, that are associated with the *firm* being large – perhaps with many factories.

Organisational economies. With a large firm, individual plants can specialise in particular functions. There can also be centralised administration of the firm; for example, one human resources department could administer all the wages. Often, after a merger between two firms, savings can be made by **rationalising** their activities in this way.

Spreading overheads. Some expenditures are economic only when the *firm* is large: for example, research and development – only a large firm can afford to set up a research laboratory. This is another example of indivisibilities, only this time at the level of the firm rather than the plant. The greater the firm's output, the more these **overhead** costs are spread.

Financial economies. Large firms are often able to obtain finance at lower interest rates than small firms, since they are seen by banks to be lower risk. They may be able to obtain certain inputs cheaper by buying in bulk.

Economies of scope. Often a firm is large because it produces a range of products. This can result in each individual product being produced more cheaply than if it was produced in a single-product firm. The reason for these **economies of scope** is that various overhead costs and financial and organisational economies can be shared among the products. For example, a firm that produces a whole range of DVD players, televisions and hard disk recorders can benefit from shared marketing and distribution costs and the bulk purchase of electronic components.

1. Which of the economies of scale we have considered are due to increasing returns to scale and which are due to other factors?
2. What economies of scale is a large department store likely to experience?

Diseconomies of scale

When firms get beyond a certain size, costs per unit of output may start to increase. There are several reasons for such **diseconomies of scale**:

- Management problems of co-ordination may increase as the firm becomes larger and more complex, and as lines of communication get longer. There may be a lack of personal involvement by management.

Definitions

Indivisibility The impossibility of dividing a factor into smaller units.

Plant economies of scale Economies of scale that arise because of the large size of a factory.

Rationalisation The reorganising of production (often after a merger) so as to cut out waste and duplication and generally to reduce costs.

Overheads Costs arising from the general running of an organisation, and only indirectly related to the level of output.

Economies of scope When increasing the range of products produced by a firm reduces the cost of producing each one.

Diseconomies of scale Where costs per unit of output increase as the scale of production increases.

- Workers may feel 'alienated' if their jobs are boring and repetitive, and if they feel that they are an insignificantly small part of a large organisation. Small to medium-sized companies often report that workers feel they 'make a difference'; this may be lost in a large firm and as a consequence lower motivation may lead to shoddy work.
- Industrial relations may deteriorate as a result of these factors and also as a result of the more complex interrelationships between different categories of worker. More levels of 'people management' may therefore be required.
- Production-line processes and the complex interdependencies of mass production can lead to great disruption if there are hold-ups in any one part of the firm.

Whether firms experience economies or diseconomies of scale will depend on the conditions applying in each individual firm.

 *Why are firms likely to experience economies of scale up to a certain size and then diseconomies of scale after some point beyond that?*

Location

In the long run, a firm can move to a different location. The location will affect the cost of production since locations differ in terms of the availability and cost of raw materials, suitable land and power supply, the qualifications, skills and experience of the labour force, wage rates, transport and communications networks, the cost of local services, and banking and financial facilities. In short, locations differ in terms of the availability, suitability and cost of the factors of production.

Transport costs will be an important influence on a firm's location. Ideally, a firm will wish to be as near as possible to both its raw materials and the market for its finished product. When market and raw materials are in different locations, the firm will minimise its transport costs by locating somewhere between the two.

In general, if the raw materials are more expensive to transport than the finished product, the firm should be located as near as possible to the raw materials. Thus heavy industry, which uses large quantities of coal and various ores, tends to be concentrated near the coal fields or near the ports. If, on the other hand, the finished product is more expensive to transport (e.g. bread and beer), the firm will probably be located as near as possible to its market.

When raw materials or markets are in many different locations, transport costs will be minimised at the 'centre of gravity'. This location will be nearer to those raw materials and markets whose transport costs are greater per mile.

 *How has the opening up of trade and investment between eastern and western Europe likely to have affected the location of industries within Europe that have (a) substantial economies of scale; (b) little or no economies of scale?*

The size of the whole industry

As an *industry* grows in size, this can lead to *external economies of scale* for its member firms. This is where a firm, whatever its own individual size, benefits from the *whole industry* being large. For example, the firm may benefit from having access to specialist raw material or component suppliers, labour with specific skills, firms that specialise in marketing the finished product, and banks and other financial institutions with experience of the industry's requirements. What we are referring to here is the *industry's infrastructure*: the facilities, support services, skills and experience that can be shared by its members.

- 
- Name some industries where external economies of scale are gained. What are the specific external economies in each case?
 - Would you expect external economies to be associated with the concentration of an industry in a particular region?

The member firms of a particular industry might experience *external diseconomies of scale*. For example, as an industry grows larger, this may create a growing shortage of specific raw materials or skilled labour. This will push up their prices, and hence the firms' costs.

The optimum combination of factors: the marginal product approach

In the long run, all factors can be varied. The firm can thus choose what techniques of production to use: what design of factory to build, what types of machine to buy, how to organise the factory, whether to use highly automated processes or more labour-intensive techniques. It must be very careful in making these decisions. After all, once it has built a factory and installed machinery, these then become fixed factors of production, and the subsequent 'short-run' time period may in practice last a very long time.

For any given scale, how should the firm decide what technique to use? How should it decide the optimum 'mix' of factors of production?

Definitions

External economies of scale Where a firm's costs per unit of output decrease as the size of the whole industry grows.

Industry's infrastructure The network of supply agents, communications, skills, training facilities, distribution channels, specialised financial services, etc. that supports a particular industry.

External diseconomies of scale Where a firm's costs per unit of output increase as the size of the whole industry increases.

The profit-maximising firm will obviously want to use the least costly combination of factors to produce any given output. It will therefore substitute factors, if by so doing it can reduce the cost of a given output. What then is the optimum combination of factors?

The simple two-factor case

Take first the simplest case where a firm uses just two factors: labour (L) and capital (K). The least-cost combination of the two will be where

$$\frac{MPP_L}{P_L} = \frac{MPP_K}{P_K}$$

in other words, where the extra product (MPP) from the last pound spent on each factor is equal. But why should this be so? The easiest way to answer this is to consider what would happen if they were not equal.

If they were not equal, it would be possible to reduce cost per unit of output by using a different combination of labour and capital. For example, if

$$\frac{MPP_L}{P_L} > \frac{MPP_K}{P_K}$$

more labour should be used relative to capital, since the firm is getting a greater physical return for its money from extra workers than from extra capital. As more labour is used per unit of capital, however, diminishing returns to labour set in. Thus MPP_L will fall. Likewise, as less capital is used per unit of labour, MPP_K will rise. This will continue until

$$\frac{MPP_L}{P_L} = \frac{MPP_K}{P_K}$$

At this point, the firm will stop substituting labour for capital.

Since no further gain can be made by substituting one factor for another, this combination of factors or 'choice of technique' can be said to be the most efficient. It is the least-cost way of combining factors for any given output. Efficiency in this sense of using the optimum factor proportions is known as **productive efficiency**.

The multi-factor case

Where a firm uses many different factors, the least-cost combination of factors will be where

$$\frac{MPP_a}{P_a} = \frac{MPP_b}{P_b} = \frac{MPP_c}{P_c} = \dots = \frac{MPP_n}{P_n}$$

where $a \dots n$ are different factors. This is a variant of the equi-marginal principle that we examined on page 111.

The reasons are the same as in the two-factor case. If any inequality exists between the MPP/P ratios, a firm will be able to reduce its costs by using more of those factors with a high MPP/P ratio and less of those with a low MPP/P ratio until they all become equal.

A major problem for a firm in choosing the least-cost technique is in predicting future factor price changes.

If the price of a factor were to change, the MPP/P ratios would cease to be equal. The firm, to minimise costs, would then like to alter its factor combinations until the MPP/P ratios once more became equal. The trouble is that, once it has committed itself to a particular technique, it may be several years before it can switch to an alternative one. Thus if a firm invests in labour-intensive methods of production and is then faced with an unexpected wage rise, it may regret not having chosen a more capital-intensive technique. While there is no simple solution to this issue, there are a number of companies that have made a business of predicting trends across different sectors to assist firms in their decision making.

If factor X costs twice as much as factor Y ($P_X/P_Y = 2$), what can be said about the relationship between the MPP s of the two factors if the optimum combination of factors is used?

* LOOKING AT THE MATHS

We can express the long-run production function algebraically. In the simple two-factor model, where capital (K) and labour (L) are the two factors, the production function is

$$TPP = f(K, L)$$

A simple and widely used production function is the **Cobb-Douglas production function**. This takes the form

$$TPP = AK^\alpha L^\beta$$

Box 6.8 demonstrates that where $\alpha + \beta = 1$ there are constant returns to scale; where $\alpha + \beta > 1$, there are increasing returns to scale; and where $\alpha + \beta < 1$, there are decreasing returns to scale.

A multiple-factor Cobb-Douglas production function would take the form

$$TPP = AF_1^\alpha F_2^\beta F_3^\gamma \dots F_n^\omega$$

where $F_1, F_2, F_3 \dots F_n$ are all the factors. For example, if there were six factors, n would be factor 6. Again, it can be shown that where $\alpha + \beta + \gamma + \dots + \omega = 1$, there are constant returns to scale; where $\alpha + \beta + \gamma + \dots + \omega > 1$, there are increasing returns to scale; and where $\alpha + \beta + \gamma + \dots + \omega < 1$, there are decreasing returns to scale.

Definitions

Productive efficiency The least-cost combination of factors for a given output.

Cobb-Douglas production function Like other production functions, this shows how output (TPP) varies with inputs of various factors (F_1, F_2, F_3 , etc.). In the simple two-factor case it takes the following form:

$$TPP = f(F_1, F_2) = AF_1^\alpha F_2^\beta$$

If $\alpha + \beta = 1$, there are constant returns to scale; if $\alpha + \beta > 1$, there are increasing returns to scale; if $\alpha + \beta < 1$, there are decreasing returns to scale.

*BOX 6.8

THE COBB–DOUGLAS PRODUCTION FUNCTION

EXPLORING
ECONOMICS

Exploring its properties

Let us take the simple Cobb–Douglas production function (see Looking at the Maths box on page 165):

$$TPP = AK^\alpha L^\beta \quad (1)$$

Returns to scale and the Cobb–Douglas production function

What would happen if you were to double the amount of both K and L used (in other words, the scale of production doubles)? If output doubles, there are constant returns to scale. If output more than doubles, there are increasing returns to scale; if it less than doubles, there are decreasing returns to scale. Let us see what happens when we double the amount of K and L in equation (1).

$$\begin{aligned} TPP &= A(2K^\alpha)(2L^\beta) \\ &= A2^\alpha K^\alpha 2^\beta L^\beta \\ &= A2^{\alpha+\beta} K^\alpha L^\beta \end{aligned}$$

If $\alpha + \beta = 1$, then $2^{\alpha+\beta} = 2$. Thus

$$TPP = 2AK^\alpha L^\beta$$

In other words, doubling the amount of K and L used has doubled output: there are constant returns to scale.

If $\alpha + \beta > 1$, then $2^{\alpha+\beta} > 2$. In this case, doubling inputs will more than double output: there are increasing returns to scale. Similarly, if $\alpha + \beta < 1$, then $2^{\alpha+\beta} < 2$ and there are decreasing returns to scale.

Finding the marginal physical products of labour and capital

The marginal physical product (MPP) of a factor is the additional output obtained by employing one more unit of that factor, while holding other factors constant. The MPP of either factor in the above Cobb–Douglas production function can be found by differentiating the function with respect to

that factor (see pages A:12–13 for the rules of partial differentiation). Thus

$$MPP_K = \frac{\partial(TPP)}{\partial K} = \alpha AK^{\alpha-1} L^\beta \quad (2)$$

and

$$MPP_L = \frac{\partial(TPP)}{\partial L} = \beta AK^\alpha L^{\beta-1} \quad (3)$$

For example, if the production function were

$$TPP = 4K^{3/4}L^{1/2} \quad (4)$$

and if $K = 81$ and $L = 36$, then, from equations (2) and (4),

$$\begin{aligned} MPP_K &= \alpha AK^{\alpha-1} L^\beta \\ &= \frac{3}{4} \times 4(81^{-1/4})(36^{1/2}) \\ &= 3 \times \frac{1}{3} \times 6 = 6 \end{aligned}$$

and $MPP_L = \beta AK^\alpha L^{\beta-1}$

$$\begin{aligned} &= \frac{1}{2} \times 4(81^{3/4})(36^{-1/2}) \\ &= 2 \times 27 \times \frac{1}{6} = 9 \end{aligned}$$

In other words, an additional unit of capital will produce an extra 6 units of output and an additional unit of labour will produce an extra 9 units of output.

Assume that the production function is given by

$$TPP = 36K^{1/3}L^{1/2}R^{1/4}$$

where R is the quantity of a particular raw material used.

- Are there constant, increasing or decreasing returns to scale?
- What is the marginal productivity of the raw material if $K = 8$, $L = 16$ and $R = 81$?

*The optimum combination of factors: the isoquant/isocost approach

This section is optional. You can skip straight to page 170 without loss of continuity.

A firm's choice of optimum technique can be shown graphically. This graphical analysis takes the simplest case of just two variable factors – for example, labour and capital. The amount of labour used is measured on one axis and the amount of capital used is measured on the other.

The graph involves the construction of *isoquants* and *isocosts*.

Isoquants

Imagine that a firm wants to produce a certain level of output: say, 5000 units per year. Let us assume that it estimates all the possible combinations of labour and capital that could produce that level of output. Once again this is

assuming technical efficiency in production. Some of these estimates are shown in Table 6.5.

Technique *a* is a capital-intensive technique, using 40 units of capital and only 5 workers. As we move towards technique *e*, labour is substituted for capital. The techniques become more labour intensive.

These alternative techniques for producing a given level of output can be plotted on a graph. The points are joined to form an *isoquant*. Figure 6.5 shows the 5000 unit isoquant corresponding to Table 6.5.

Definitions

Isoquant A line showing all the alternative combinations of two factors that can produce a given level of output.

Table 6.5

Various capital and labour combinations to produce 5000 units of output per year

	a	b	c	d	e
Units of capital (K)	40	20	10	6	4
Number of workers (L)	5	12	20	30	50

The isoquant shows the whole *range* of alternative ways of producing a given output. Thus Figure 6.5 shows not only points a to e from the table, but all the intermediate points too.

Like an indifference curve, an isoquant is rather like a contour on a map. As with contours and indifference curves, a whole series of isoquants can be drawn, each one representing a different level of output (TPP). The higher the output, the further out to the right will the isoquant be. Thus in Figure 6.6, isoquant I_5 represents a higher level of output than I_4 , and I_4 a higher output than I_3 , and so on.

- ?
1. Could isoquants ever cross?
 2. Could they ever slope upwards to the right? Explain your answers.

The shape of the isoquant. Why is the isoquant 'bowed in' towards the origin? This illustrates a diminishing **marginal rate of factor substitution (MRS)**. This, as we shall see very soon, is due to the law of diminishing returns.

The MRS^1 is the amount of one factor (e.g. K) that can be replaced by a 1 unit increase in the other factor (e.g. L), if output is to be held constant. So if 2 units of capital

¹ Note that we use the same letters MRS to refer to the marginal rate of factor substitution as we did in the previous chapter to refer to the marginal rate of substitution in consumption. Sometimes we use the same words too - just 'marginal rate of substitution' rather than the longer title. In this case we must rely on the context in order to tell which is being referred to.

($\Delta K = 2$) could be replaced by 1 unit of labour ($\Delta L = 1$) the MRS would be 2. Thus:

$$MRS = \frac{\Delta K}{\Delta L} = \frac{2}{1} = 2$$

The MRS between two points on the isoquant will equal the slope of the line joining those two points. Thus in Figure 6.7, the MRS between points g and h is 2 ($\Delta K/\Delta L = 2/1$). But this is merely the slope of the line joining points g and h (ignoring the negative sign).

When the isoquant is bowed in towards the origin, the slope of the isoquant will diminish as one moves down the curve, and so too, therefore, will the MRS diminish. Referring again to Figure 6.7, between points g and h the $MRS = 2$. Lower down the curve between points j and k , it has fallen to 1.

- ?
- Calculate the MRS moving up the curve in Figure 6.5 between each pair of points: $e-d$, $d-c$, $c-b$ and $b-a$. Does the MRS diminish moving in this direction?

The relationship between MRS and MPP . As one moves down the isoquant, total output, by definition, will remain the same. Thus the loss in output due to less capital being used (i.e. $MPP_K \times \Delta K$) must be exactly offset by the gain in output due to more labour being used (i.e. $MPP_L \times \Delta L$). Thus:

$$MPP_L \times \Delta L = MPP_K \times \Delta K$$

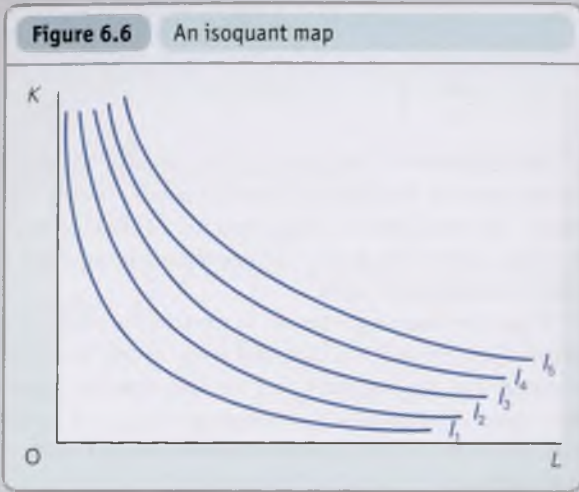

Definitions

Marginal rate of factor substitution The rate at which one factor can be substituted by another while holding the level of output constant:

$$MRS = \Delta F_1/\Delta F_2 = MPP_2/MPP_1$$

Figure 6.5 An isoquant

This equation can be rearranged as follows:

$$\frac{MPP_L}{MPP_K} = \frac{\Delta K}{\Delta L} (=MRS)$$

Thus the *MRS* is equal to the inverse of the marginal product ratios of the two factors.

Diminishing MRS and the law of diminishing returns. The principle of diminishing *MRS* is related to the law of diminishing returns. As one moves down the isoquant, increasing amounts of labour are being used relative to capital. This, given diminishing returns, would lead the *MPP* of labour to fall relative to the *MPP* of capital. But since $MRS = MPP_L/MPP_K$, if MPP_L/MPP_K diminishes, then, by definition, so must *MRS*.

The less substitutable factors are for each other, the faster *MRS* will diminish, and therefore the more bowed in will be the isoquant.

Isocosts

We have seen how factors combine to produce different levels of output, but how do we choose the level of output? This will involve taking costs into account.

Table 6.6 Combinations of capital and labour costing the firm £300 000 per year

Units of capital (at £20 000 per unit)	0	5	10	15
No. of workers (at a wage of £10 000)	30	20	10	0

Assume that factor prices are fixed. A table can be constructed showing the various combinations of factors that a firm can use for a particular sum of money.

For example, assuming that P_K is £20 000 per unit per year and P_L is £10 000 per worker per year, Table 6.6 shows various combinations of capital and labour that would cost the firm £300 000 per year.

These figures are plotted in Figure 6.8. The line joining the points is called an *isocost*. It shows all the combinations of labour and capital that cost £300 000.

As with isoquants, a series of isocosts can be drawn. Each one represents a particular cost to the firm. The higher the cost, the further out to the right will the isocost be.

- ?**
1. What will happen to an isocost if the prices of both factors rise by the same percentage?
 2. What will happen to the isocost in Figure 6.8 if the wage rate rises to £15 000?

The slope of the isocost equals

$$\frac{P_L}{P_K}$$

This can be shown in the above example. The slope of the isocost in Figure 6.8 is $15/30 = 1/2$. But this is P_L/P_K (i.e. £10 000/£20 000).

Isoquants and isocosts can now be put on the same diagram. The diagram can be used to answer either of two questions: (a) What is the least-cost way of producing a particular level of output? (b) What is the highest output that can be achieved for a given cost of production?

These two questions are examined in turn.

The least-cost combination of factors to produce a given level of output

First the isoquant is drawn for the level of output in question: for example, the 5000 unit isoquant in Figure 6.5. This is reproduced in Figure 6.9.

Then a series of isocosts are drawn representing different levels of total cost. The higher the level of total cost, the further out will be the isocosts.

The least-cost combination of labour and capital is shown at point *r*, where $TC = £400 000$. This is where the isoquant just touches the lowest possible isocost. Any other point on the isoquant (e.g. *s* or *t*) would be on a higher isocost.

Definitions

Isocost A line showing all the combinations of two factors that cost the same to employ.

Figure 6.8 An isocost

Comparison with the marginal productivity approach. We showed earlier that the least-cost combination of labour and capital was where

$$\frac{MPP_L}{P_L} = \frac{MPP_K}{P_K}$$

In this section it has just been shown that the least-cost combination is where the isoquant is tangential to an isocost (i.e. point *r* in Figure 6.9). Thus their slope is the same. The slope of the isoquant equals *MRS*, which equals MPP_L/MPP_K ; and the slope of the isocost equals P_L/P_K .

$$\therefore \frac{MPP_L}{MPP_K} = \frac{P_L}{P_K}$$

$$\therefore \frac{MPP_L}{P_K} = \frac{MPP_K}{P_L}$$

Thus, as one would expect, the two approaches yield the same result.

Highest output for a given cost of production

An isocost can be drawn for the particular level of total cost outlay in question. Then a series of isoquants can be drawn, representing different levels of output (*TPP*). This is shown in Figure 6.10. The higher the level of output, the further

Figure 6.9 The least-cost method of production

Figure 6.10 Maximising output for a given total cost

out will lie the corresponding isoquant. The point at which the isocost touches the highest isoquant will give the factor combination yielding the highest output for that level of cost. This will be at point *h* in Figure 6.10.

Again this will be where the slopes of the isocost and isoquant are the same: where $P_L/P_K = MRS$.

If the prices of factors change, new isocosts will have to be drawn. Thus in Figure 6.10, if the wage rate goes up, less labour can be used for a given sum of money. The isocost will swing inwards round point *x*. The isocost will get steeper. Less labour will now be used relative to capital.

* LOOKING AT THE MATHS

We can express the optimum production point algebraically. This can be done in either of two ways, corresponding to Figures 6.9 or 6.10. The method is similar to that used for finding the optimum consumption point that we examined on page 118.

(a) Corresponding to Figure 6.9

The first way involves finding the least-cost method of producing a given output (*Q*). This can be expressed as

$$\text{Min } P_K K + P_L L \quad (1)$$

subject to the output constraint that

$$Q = Q(K, L) \quad (2)$$

In other words, the objective is to find the lowest isocost (equation 1) to produce on a given isoquant (equation 2).

(b) Corresponding to Figure 6.10

The second involves finding the highest output that can be produced for a given cost. This can be expressed as

$$\text{Max } Q(K, L) \quad (3)$$

subject to the cost constraint that

$$P_K K + P_L L = C \quad (4)$$

In other words, the objective is to find the highest isoquant (equation 3) that can be reached along a given isocost (equation 4).

There are two methods of solving (a) and (b) for any given value of P_K , P_L and either *Q* (in the case of (a)) or *C* (in the case of (b)). The first involves substituting the constraint equation into the objective function (to express *K* in terms of *L*) and then finding the value of *L* and then *K* that minimises the objective function in the case of (a) or maximises it in the case of (b). This involves differentiating the objective function and setting it equal to zero. A worked example of this method is given in Maths Case 6.2 on the student website.

The second method, which is slightly longer but is likely to involve simpler calculations, involves the use of 'Lagrangian multipliers'. This method is explained, along with a worked example, in Maths Case 6.3. It is the same method as we used in Maths Case 4.2 when finding the optimal level of consumption of two products.

Postscript: decision making in different time periods

We have distinguished between the short run and the long run. Let us introduce two more time periods to complete the picture. The complete list then reads as follows.

Very short run (immediate run). All factors are fixed. Output is fixed. The supply curve is vertical. On a day-to-day basis, a firm may not be able to vary output at all. For example, a flower seller, once the day's flowers have been purchased from the wholesaler, cannot alter the amount of flowers available for sale on that day. In the very short run, all that may remain for a producer to do is to sell an already produced good.

 *Why are Christmas trees and fresh foods often sold cheaply on Christmas Eve? (See Box 6.5 on page 156.)*

Short run. At least one factor is fixed in supply. More can be produced, but the firm will come up against the law of diminishing returns as it tries to do so.

Long run. All factors are variable. The firm may experience constant, increasing or decreasing returns to scale. But although all factors can be increased or decreased, they are of a fixed *quality*.

Very long run. All factors are variable, *and* their quality and hence productivity can change. Labour productivity can increase as a result of education, training, experience and social factors. The productivity of capital can increase as a result of new inventions (new discoveries) and innovation (putting inventions into practice).

Improvements in factor quality will increase the output they produce: *TPP*, *APP* and *MPP* will rise. These curves will shift vertically upwards.

Just how long the 'very long run' is will vary from firm to firm. It will depend on how long it takes to develop new techniques, new skills or new work practices.

It is important to realise that decisions for all four time periods can be made *at* the same time. Firms do not make short-run decisions *in* the short run and long-run decisions *in* the long run. They can make both short-run and long-run decisions today. For example, assume that a firm experiences an

increase in consumer demand and anticipates that it will continue into the foreseeable future. It thus wants to increase output. Consequently, it makes the following four decisions today:

- (*Very short run*) It accepts that for a few days it will not be able to increase output. It informs its customers that they will have to wait. In some markets the firm may temporarily raise prices to choke off some of the demand.
- (*Short run*) It negotiates with labour to introduce overtime working as soon as possible, to tide it over the next few weeks. It orders extra raw materials from its suppliers. It launches a recruitment drive for new labour so as to avoid paying overtime longer than is necessary.
- (*Long run*) It starts proceedings to build a new factory. What would this involve? In some cases the firm may talk to the bank directly about finance and start investigating sites. A different approach might be to discuss requirements with a firm of consultants.
- (*Very long run*) It institutes a programme of research and development and/or training in an attempt to increase productivity.

1. *Could the long run and the very long run ever be the same length of time?*
2. *What will the long-run and very-long-run market supply curves for a product look like? How will the shape of the long-run curve depend on returns to scale?*
- *3. *In the very long run, new isoquants will have to be drawn as factor productivity changes. An increase in productivity will shift the isoquants inwards towards the origin: less capital and labour will be required to produce any given level of output. Will this be a parallel inward shift of the isoquants? Explain.*

Although we distinguish these four time periods, it is the middle two we are primarily concerned with. The reason for this is that there is very little the firm can do in the *very short run*. And concerning the *very long run*, although the firm will obviously want to increase the productivity of its inputs, it will not be in a position to make precise calculations of how to do it. It will not know precisely what inventions will be made, or just what will be the results of its own research and development.

Section summary

1. In the long run, a firm is able to vary the quantity it uses of all factors of production. There are no fixed factors.
2. If it increases all factors by the same proportion, it may experience constant, increasing or decreasing returns to scale.
3. Economies of scale occur when costs per unit of output fall as the scale of production increases. This can be due to a number of factors, some of which result directly from increasing (physical) returns to scale. These include the benefits of specialisation and division of labour, the use of larger and more efficient machines, and the ability to have a more integrated system of production. Other economies of scale arise from the financial and administrative benefits of large-scale organisations.
4. Long-run costs are also influenced by a firm's location. The firm will have to balance the needs to be as near as possible both to the supply of its raw materials and to its market. The optimum balance will depend on the relative costs of transporting the inputs and the finished product.
5. To minimise costs per unit of output, a firm should choose that combination of factors which gives an equal marginal product for each factor relative to its price: i.e. $MPP_a/P_a = MPP_b/P_b = MPP_c/P_c$, etc. (where a , b and c are different factors). If the MPP/P ratio for one factor is greater than for another, more of the first should be used relative to the second.
6. An isoquant shows the various combinations of two factors to produce a given output. A whole map of such

isoquants can be drawn with each isoquant representing a different level of output. The slope of the isoquant ($\Delta K/\Delta L$) gives the marginal rate of factor substitution (MPP_L/MPP_K). The bowed-in shape of isoquants illustrates a diminishing marginal rate of factor substitution, which in turn arises because of diminishing marginal returns.

7. An isocost shows the various combinations of two factors that cost a given amount to employ. It will be a straight line. Its slope is equal to the price ratio of the two factors (P_L/P_K).
8. The tangency point of an isocost with an isoquant represents the optimum factor combination. It is the point where MPP_L/MPP_K (the slope of the isoquant) = P_L/P_K (the slope of the isocost). By drawing a single isoquant touching the lowest possible isocost, we can show the least-cost combination of factors for producing a given output. By drawing a single isocost touching the highest possible isoquant, we can show the highest output obtainable for a given cost of production.
9. Four distinct time periods can be distinguished. In addition to the short- and long-run periods, we can also distinguish the very-short- and very-long-run periods. The very short run is when all factors are fixed. The very long run is where not only the quantity of factors but also their quality is variable (as a result of changing technology, etc.).

6.4 COSTS IN THE LONG RUN

We turn now to *long-run* cost curves. Since there are no fixed factors in the long run, there are no long-run fixed costs. For example, the firm may rent more land in order to expand its operations. Its rent bill therefore goes up as it expands its output. In the long run, then, all costs are variable costs.

Fixed costs and the time period. Fixed costs occur only in the short run, since in the long run all inputs can be varied.

Long-run average costs

Long-run average cost (LRAC) curves can take various shapes, but a typical one is shown in Figure 6.11.

It is often assumed that as a firm expands, it will initially experience economies of scale and thus face a downward-sloping *LRAC* curve. After a point, however, all such economies will have been achieved and thus the curve will flatten out. Then (possibly after a period of constant *LRAC*) the firm will get so large that it will start experiencing diseconomies of scale and thus a rising *LRAC*. At this stage, production and financial economies will begin to be offset by the managerial problems of running a giant organisation.

? Given the *LRAC* curve in Figure 6.11, what would the firm's long-run total cost curve look like?

Assumptions behind the long-run average cost curve

We make three key assumptions when constructing long-run average cost curves.

Factor prices are given. At each level of output, it is assumed that a firm will be faced with a given set of factor prices. If factor prices *change*, therefore, both short- and long-run

cost curves will shift. Thus an increase in nationally negotiated wage rates would shift the curves upwards.

However, factor prices might be different at *different* levels of output. For example, one of the economies of scale that many firms enjoy is the ability to obtain bulk discount on raw materials and other supplies. In such cases, the curve does *not* shift. The different factor prices are merely experienced at different points along the curve, and are reflected in the shape of the curve. Factor prices are still given for any particular level of output.

The state of technology and factor quality are given. These are assumed to change only in the *very* long run. If a firm gains economies of scale, it is because it is able to exploit *existing* technologies and make better use of the existing availability of factors of production.

Firms choose the least-cost combination of factors for each output. The assumption here is that firms operate efficiently: that they choose the cheapest possible way of producing any level of output. In other words, at every point along the *LRAC* curve, the firm will adhere to the cost-minimising formula (see page 164):

$$\frac{MPP_a}{P_a} = \frac{MPR_b}{R_b} = \frac{MPP_c}{P_c} = \dots = \frac{MPP_n}{P_n}$$

where $a \dots n$ are the various factors the firm uses.

If the firm did not choose the optimum factor combination, it would be producing at a point above the *LRAC* curve.

Definitions

Long-run average cost curve A curve that shows how average cost varies with output on the assumption that *all* factors are variable. (It is assumed that the least-cost method of production will be chosen for each output.)

Figure 6.11 A typical long-run average cost curve

Long-run marginal costs

The relationship between long-run average and *long-run marginal cost* curves is just like that between any other averages and marginals (see Box 6.3). This is illustrated in Figure 6.12.

If there are economies of scale (diagram (a)), additional units of output will add less to costs than the average. The *LRMC* curve must be below the *LRAC* curve and thus pulling the average down as output increases. If there are diseconomies of scale (diagram (b)), additional units of output will cost more than the average. The *LRMC* curve must be above the *LRAC* curve, pulling it up. If there are no economies or diseconomies of scale, so that the *LRAC* curve is horizontal,

Definitions

Long-run marginal cost The extra cost of producing one more unit of output assuming that all factors are variable. (It is assumed that the least-cost method of production will be chosen for this extra output.)

any additional units of output will cost the same as the average and thus leave the average unaffected (diagram (c)).

1. Explain the shape of the *LRMC* curve in diagram (d) in Figure 6.12.
2. What would the *LRMC* curve look like if the *LRAC* curve were 'flat bottomed', as in Figure 6.11?

The relationship between long-run and short-run average cost curves

Take the case of a firm which has just one factory and faces a short-run average cost curve illustrated by $SRAC_1$ in Figure 6.13.

In the long run, it can build more factories. If it thereby experiences economies of scale (due, say, to savings on administration), each successive factory will allow it to produce with a new lower *SRAC* curve. Thus with two factories it will face $SRAC_2$, with three factories $SRAC_3$, and so on. Each *SRAC* curve corresponds to a particular amount of the factor that is fixed in the short run: in this case, the factory.

Figure 6.12 The relationship between long-run average and marginal costs

Figure 6.13 Constructing long-run average cost curves from short-run average cost curves

(There are many more *SRAC* curves that could be drawn between the ones shown, since factories of different sizes could be built or existing ones could be expanded.)

From this succession of short-run average cost curves we can construct a long-run average cost curve, as shown in Figure 6.13. This is known as the *envelope curve*, since it envelopes the short-run curves.

Definitions

Envelope curve A long-run average cost curve drawn as the tangency points of a series of short-run average cost curves.

Will the envelope curve be tangential to the bottom of each of the short-run average cost curves? Explain why it should or should not be.

Long-run cost curves in practice

Firms do experience economies of scale. Some experience continuously falling *LRAC* curves, as in Figure 6.12(a). Others experience economies of scale up to a certain output and thereafter constant returns to scale.

Evidence is inconclusive on the question of diseconomies of scale. There is little evidence to suggest the existence of *technical* diseconomies, but the possibility of diseconomies due to managerial and industrial relations problems cannot be ruled out.

BOX 6.9

MINIMUM EFFICIENT SCALE

The extent of economies of scale in practice

Two of the most important studies of economies of scale are those by C. F. Pratten¹ in the late 1980s and by a group advising the European Commission² in 1997. Both studies found strong evidence that many firms, especially in manufacturing, experienced substantial economies of scale.

In a few cases, long-run average costs fell continuously as output increased. For most firms, however, they fell up to a certain level of output and then remained constant.

The extent of economies of scale can be measured by looking at a firm's *minimum efficient scale (MES)*. The *MES* is the size beyond which no significant additional economies of scale can be achieved: in other words, the point where the *LRAC* curve flattens off. In Pratten's studies, he defined this level as the minimum scale above which any possible doubling in scale would reduce average costs by less than 5 per cent (i.e. virtually the bottom of the *LRAC* curve). In the diagram, *MES* is shown at point *a*.

The *MES* can be expressed in terms either of an individual factory or of the whole firm. Where it refers to the minimum efficient scale of an individual factory, the *MES* is known as the *minimum efficient plant size (MEPS)*.

The *MES* can then be expressed as a percentage of the total size of the market or of total domestic production. Table (a), based on the Pratten study, shows *MES* for plants and firms in various industries. The first column shows *MES* as a percentage of total UK production. The second column shows *MES* as a percentage of total EU production. Table (b), based on the 1997 study, shows *MES* for various plants.

Expressing *MES* as a percentage of total output gives an indication of how competitive the industry could be. In some

Some evidence on economies of scale in the UK is considered in Box 6.9.

*Derivation of long-run costs from an isoquant map²

Cost curves are drawn on the assumption that, for any output, the least-cost combination of factors is used: that is, that production will take place at the tangency point of the isoquant and an isocost, where $MPP_L/MPP_K = P_L/P_K$; i.e. where $MPP_L/P_L = MPP_K/P_K$. By drawing a series of isoquants and isocosts, long-run costs can be derived for each output.

² This optional section is based on the material in the optional section on pages 166–70.

In Figure 6.14, isoquants are drawn for a hypothetical firm at 100 unit intervals. Up to 400 units of output, the isoquants are getting closer together. Thereafter, the gap between the isoquants widens again.

The line from *a* to *g* is known as the *expansion path*. It traces the tangency points of the isoquants and isocosts,

Definitions

Expansion path The line on an isoquant map that traces the minimum-cost combinations of two factors as output increases. It is drawn on the assumption that both factors can be varied. It is thus a long-run path.

CASE STUDIES AND APPLICATIONS

industries (such as footwear and carpets), economies of scale were exhausted (i.e. *MES* was reached) with plants or firms that were still small relative to total UK production and even smaller relative to total EU production. In such industries, there would be room for many firms and thus scope for considerable competition.

Table (b)

Plants	MES as % of total EU production
Aerospace	12.19
Agricultural machinery	6.57
Electric lighting	3.76
Steel tubes	2.42
Shipbuilding	1.63
Rubber	1.06
Radio and TV	0.69
Footwear	0.08
Carpets	0.03

Source: See footnote 2 below.

In other industries, however, even if a single plant or firm were large enough to produce the whole output of the industry in the UK, it would still not be large enough to experience the full potential economies of scale: the *MES* is greater than 100 per cent. Examples from Table (a) include factories producing cellulose fibres, and car manufacturers. In these industries, there is no possibility of competition from within the country. In fact, as long as the *MES* exceeds 50 per cent, there will not be room for more than one firm large enough to gain full economies of scale (unless they export). In this case, the industry is said to be a natural monopoly.

As we shall see in the next few chapters, when competition is lacking, consumers may suffer by firms charging prices considerably above costs.

A second way of measuring the extent of economies of scale is to see how much costs would increase if production

were reduced to a certain fraction of *MES*. The normal fractions used are $\frac{1}{2}$ or $\frac{1}{3}$ *MES*. This is illustrated in the diagram. Point *b* corresponds to $\frac{1}{2}$ *MES*; point *c* to $\frac{1}{3}$ *MES*. The greater the percentage by which *LRAC* at point *b* or *c* is higher than at point *a*, the greater will be the economies of scale to be gained by producing at *MES* rather than at $\frac{1}{2}$ *MES* or $\frac{1}{3}$ *MES*. For example, in Table (a) there are greater economies of scale to be gained from moving from $\frac{1}{2}$ *MES* to *MES* in the production of electric motors than in cigarettes.

The main purpose of the studies was to determine whether the single EU market is big enough to allow both economies of scale and competition. The tables suggest that in all cases, other things being equal, the EU market is indeed large enough for this to occur. The second study also found that 47 of the 53 manufacturing sectors analysed had scope for further exploitation of economies of scale.

In the 2007–13 research framework the European Commission agreed to fund a number of research projects, to conduct further investigations of *MES* across different industries and to consider the impact of the expansion of the EU.

1. Why might a firm operating with one plant achieve *MEPS* and yet not be large enough to achieve *MES*? (Clue: are all economies of scale achieved at plant level?)
2. Why might a firm producing bricks have an *MES* which is only 0.2 per cent of total EU production and yet face little effective competition from other EU countries?

2 European Commission/Economists Advisory Group Ltd, 'Economies of scale', *The Single Market Review*, Sub-series V, Volume 4 (Commission of the European Communities, Luxembourg, 1997).

Figure 6.14 Deriving an *LRAC* curve from an isoquant map

and thus shows the minimum-cost combinations of labour and capital to produce each output: the (long-run) total cost being given by the isocost.

Up to point *d*, less and less *extra* capital (*K*) and labour (*L*) are required to produce each extra 100 units of output. Thus long-run marginal cost is falling. Above point *d*, more and more extra *K* and *L* are required and thus *LRMC* rises.

Thus the isoquant map of Figure 6.14 gives an *LRMC* curve that is -shaped. The *LRAC* curve will therefore also be -shaped (only shallower) with the *LRMC* coming up through the bottom of the *LRAC*.

What would the isoquant map look like if there were
(a) continuously increasing returns to scale;
(b) continuously decreasing returns to scale?

Section summary

1. In the long run, all factors are variable. There are thus no long-run fixed costs.
2. When constructing long-run cost curves, it is assumed that factor prices are given, that the state of technology is given and that firms will choose the least-cost combination of factors for each given output.
3. The *LRAC* curve can be downward sloping, upward sloping or horizontal, depending in turn on whether there are economies of scale, diseconomies of scale or neither. Typically, *LRAC* curves are drawn saucer-shaped or -shaped. As output expands, initially there are economies of scale. When these are exhausted, the curve will become flat. When the firm becomes very large, it may begin to experience diseconomies of scale.

If this happens, the *LRAC* curve will begin to slope upwards again.

4. The long-run marginal cost curve will be below the *LRAC* curve when *LRAC* is falling, above it when *LRAC* is rising and equal to it when *LRAC* is neither rising nor falling.
5. An envelope curve can be drawn which shows the relationship between short-run and long-run average cost curves. The *LRAC* curve envelops the short-run *LRAC* curves: it is tangential to them.
6. Costs can be derived from an isoquant map. Long-run total costs are found from the expansion path, which shows the least-cost combination of factors to produce any given output. It traces out the tangency points of the isocosts and isoquants.

6.5 REVENUE

Remember that we defined a firm's total profit as its total revenue minus its total costs of production. So far in this chapter we have examined costs. We now turn to revenue.

As with costs, we distinguish between three revenue concepts: total revenue (*TR*), average revenue (*AR*) and marginal revenue (*MR*).

Total, average and marginal revenue

Total revenue (TR)

Total revenue is the firm's total earnings per period of time from the sale of a particular amount of output (Q). For example, if a firm sells 1000 units (Q) per month at a price of £5 each (P), then its monthly total revenue will be £5000: in other words, $£5 \times 1000$ ($P \times Q$). Thus

$$TR = P \times Q$$

Average revenue (AR)

Average revenue is the amount the firm earns per unit sold. Thus

$$AR = TR/Q$$

So if the firm earns £5000 (TR) from selling 1000 units (Q), it will earn £5 per unit. But this is simply the price! Thus

$$AR = P$$

(The only exception to this is when the firm is selling its products at different prices to different consumers. In this case, AR is simply the (weighted) average price.)

Marginal revenue (MR)

Marginal revenue is the extra total revenue gained by selling one more unit (per time period). So if a firm sells an extra 20 units this month compared with what it expected to sell, and in the process earns an extra £100, then it is getting an extra £5 for each extra unit sold: $MR = £5$. Thus

$$MR = \Delta TR/\Delta Q$$

We now need to see how each of these three revenue concepts (TR , AR and MR) varies with output. We can show this graphically in the same way as we did with costs.

The relationships will depend on the market conditions under which a firm operates. A firm that is too small to be able to affect market price will have different-shaped

revenue curves from a firm that is able to choose the price it charges. Let us examine each of these two situations in turn.

Revenue curves when price is not affected by the firm's output

Average revenue

If a firm is very small relative to the whole market, it is likely to be a **price taker**. That is, it has to accept the price given by the intersection of demand and supply in the whole market. But, being so small, it can sell as much as it is capable of producing at that price. This is illustrated in Figure 6.15.

The left-hand part of the diagram shows market demand and supply. Equilibrium price is £5. The right-hand part of the diagram looks at the demand for an individual firm that is tiny relative to the whole market. (Look at the differences in the scale of the horizontal axes in the two parts of the diagram.)

Being so small, any change in its output will be too insignificant to affect the market price. It thus faces a horizontal demand 'curve' at the price. It can sell 200 units, 600 units, 1200 units or whatever without affecting this £5 price.

Average revenue is thus constant at £5. The firm's average revenue curve must therefore lie along exactly the same line as its demand curve.

Definitions

Total revenue A firm's total earnings from a specified level of sales within a specified period: $TR = P \times Q$.

Average revenue Total revenue per unit of output. When all output is sold at the same price, average revenue will be the same as price: $AR = TR/Q = P$.

Marginal revenue The extra revenue gained by selling one more unit per period of time: $MR = \Delta TR/\Delta Q$.

Price taker A firm that is too small to be able to influence the market price.

Figure 6.15 Deriving a firm's AR and MR : price-taking firm

7	2	14	-4
.	.	.	.

Figure 6.16 Total revenue for a price-taking firm

Marginal revenue

In the case of a horizontal demand curve, the marginal revenue curve will be the same as the average revenue curve, since selling one more unit at a constant price (*AR*) merely adds that amount to total revenue. If an extra unit is sold at a constant price of £5, an extra £5 is earned.

Total revenue

Table 6.7 shows the effect on total revenue of different levels of sales with a constant price of £5 per unit. As price is constant, total revenue will rise at a constant rate as more is sold. The *TR* 'curve' will therefore be a straight line through the origin, as in Figure 6.16.

What would happen to the *TR* curve if the market price rose to £10? Try drawing it.

Revenue curves when price varies with output

The three curves (*TR*, *AR* and *MR*) look quite different when price does vary with the firm's output. If a firm has a relatively large share of the market, it will face a downward-sloping

demand curve. This means that if it is to sell more, it must lower the price. It could also choose to raise its price. If it does so, however, it will have to accept a fall in sales.

Average revenue

Remember that average revenue equals price. If, therefore, price has to be lowered to sell more output, average revenue will fall as output increases.

Table 6.8 gives an example of a firm facing a downward-sloping demand curve. The demand curve (which shows how much is sold at each price) is given by the first two columns.

Note that, as in the case of a price-taking firm, the demand curve and the *AR* curve lie along exactly the same line. The reason for this is simple: $AR = P$, and thus the curve relating price to quantity (the demand curve) must be the same as that relating average revenue to quantity (the *AR* curve).

Marginal revenue

When a firm faces a downward-sloping demand curve, marginal revenue will be less than average revenue, and may even be negative. But why?

If a firm is to sell more per time period, it must lower its price (assuming it does not advertise). This will mean lowering the price not just for the extra units it hopes to sell, but also for those units it would have sold had it not lowered the price.

Thus the marginal revenue is the price at which it sells the last unit, *minus* the loss in revenue it has incurred by reducing the price on those units it could otherwise have sold at the higher price. This can be illustrated with Table 6.8.

Assume that the price is currently £7. Two units are thus sold. The firm now wishes to sell an extra unit. It lowers the price to £6. It thus gains £6 from the sale of the third unit, but loses £2 by having to reduce the price by £1 on the two units it could otherwise have sold at £7. Its net gain is therefore $£6 - £2 = £4$. This is the marginal revenue: it is the extra revenue gained by the firm from selling one more unit. (Notice that in Table 6.8 the figures for *MR* are entered in the spaces between the figures for the other three columns.)

There is a simple relationship between marginal revenue and *price elasticity of demand*. Remember from Chapter 2 (page 59) that if demand is price elastic, a *decrease* in price

will lead to a proportionately larger increase in the quantity demanded and hence an *increase* in revenue. Marginal revenue will thus be positive. If, however, demand is inelastic, a decrease in price will lead to a proportionately smaller increase in sales. In this case, the price reduction will more than offset the increase in sales and as a result revenue will fall. Marginal revenue will be negative.

If, then, at a particular quantity sold marginal revenue is a positive figure (i.e. if sales per time period are 4 units or less in Figure 6.17), the demand curve will be elastic at that quantity, since a rise in quantity sold (as a result of a reduction in price) would lead to a rise in total revenue. If, on the other hand, marginal revenue is negative (i.e. at a level of sales of 5 or more units in Figure 6.17), the demand curve will be inelastic at that quantity, since a rise in quantity sold would lead to a *fall* in total revenue.

Figure 6.17 AR and MR curves for a firm facing a downward-sloping demand curve

* LOOKING AT THE MATHS

As with cost curves (see page 160), we can express revenue curves algebraically.

Price-taking firms

Let us take TR , AR and MR in turn. They will take the following forms:

$$TR = bQ \quad (1)$$

This equation will give an upward-sloping straight-line TR 'curve', with a slope of b . Note that the absence of a constant (a) term means that the line passes through the origin. This is obviously the case, given that if sales (Q) are zero, total revenue will be zero.

$$AR = \frac{TR}{Q} = b \quad (2)$$

This will give a horizontal AR curve at an AR (i.e. price) of b .

$$MR = \frac{d(TR)}{dQ} = b \quad (3)$$

Differentiating the TR function gives a value of b . As we have seen, $AR = MR$ when the firm is a price taker and faces a horizontal demand curve (at the market price).

Price-making firms: a straight-line demand 'curve'

'Price makers' face a downward-sloping demand curve. If this is a straight-line demand curve, the revenue equations will be as follows:

$$TR = bQ - cQ^2 \quad (4)$$

The negative cQ^2 term will give a revenue curve whose slope gets less until a peak is reached (see Figure 6.18). Thereafter, as the cQ^2 term becomes bigger than the bQ term, TR will fall.

$$AR = \frac{TR}{Q} = b - cQ \quad (5)$$

This gives a straight-line downward-sloping AR curve (demand curve) with a slope of $-c$, which crosses the horizontal axis when cQ becomes bigger than b .

$$MR = \frac{d(TR)}{dQ} = b - 2cQ \quad (6)$$

This again gives a straight downward-sloping line, this time with a slope of $-2c$. Note that this means that the slope of the MR curve is twice that of the AR curve.

But what if the demand curve is actually curved? What will the three revenue equations be then? We explore this in Maths Case 6.4 on the student website and relate the equations to the relevant diagrams.

The relationship between marginal revenue and price elasticity of demand

You can see from Figure 6.17 how price elasticity of demand and marginal revenue are related. We can express this relationship algebraically as follows:

$$MR = P(1 + (1/P\epsilon_D)) \quad (7)$$

or

$$P = \frac{MR}{1 + (1/P\epsilon_D)}$$

Proof of this relationship is given in Maths Case 6.2 on the student website, but for now we can see how equation (7) relates to Figure 6.17. The P term must be positive. If demand is elastic, then $P\epsilon_D$ must have a value less than -1 (i.e. the figure for elasticity, ignoring the negative sign, must be greater than 1). Thus the term $1/P\epsilon_D$ must have a negative value between 0 and -1 . This means, therefore, that the term $(1 + (1/P\epsilon_D))$ must be positive, and hence MR must be positive.

If, however, demand is inelastic, then $P\epsilon_D$ must have a value between -1 and zero. Thus the term $1/P\epsilon_D$ must have a negative value less than -1 (i.e. an absolute value, ignoring the negative sign, that is greater than 1). This means, therefore, that the term $(1 + (1/P\epsilon_D))$ must be negative, and hence MR must be negative.

Finally, if demand is unit elastic, then the term $1/P\epsilon_D$ must have a value of -1 and hence the term $(1 + (1/P\epsilon_D))$ must have a value of zero. MR must be zero.

Figure 6.18 Total revenue for a firm facing a downward-sloping demand curve

Thus the demand (AR) curve in Figure 6.17 is elastic to the left of point r and inelastic to the right.

Total revenue

Total revenue equals price times quantity. This is illustrated in Table 6.8. The TR column from Table 6.8 is plotted in Figure 6.18.

Unlike the case of a price-taking firm, the TR curve is not a straight line. It is a curve that rises at first and then falls.

But why? As long as marginal revenue is positive (and hence demand is price elastic), a rise in output will raise total revenue. However, once marginal revenue becomes negative (and hence demand is inelastic), total revenue will fall. The peak of the TR curve will be where $MR = 0$. At this point, the price elasticity of demand will be equal to 1.

Shifts in revenue curves

We saw in Chapter 2 that a change in *price* will cause a movement along a demand curve. It is similar with revenue curves, except that here the causal connection is in the other direction. Here we ask what happens to revenue when there is a change in the firm's *output*. Again the effect is shown by a movement along the curves.

A change in any *other* determinant of demand, such as tastes, income or the price of other goods, will shift the demand curve. By affecting the price at which each level of output can be sold, there will be a shift in all three revenue curves. An increase in revenue is shown by a shift upwards; a decrease by a shift downwards.

Copy Figures 6.17 and 6.18 (which are based on Table 6.8). Now assume that incomes have risen and that, as a result, two more units per time period can be sold at each price. Draw a new table and plot the resulting new AR , MR and TR curves on your diagrams. Are the new curves parallel to the old ones? Explain.

Section summary

1. Total revenue (TR) is the total amount a firm earns from its sales in a given time period. It is simply price times quantity: $TR = P \times Q$.
2. Average revenue (AR) is total revenue per unit: $AR = TR/Q$. In other words, $AR = P$.
3. Marginal revenue is the extra revenue earned from the sale of one more unit per time period.
4. The AR curve will be the same as the demand curve for the firm's product. In the case of a price taker, the demand curve and hence the AR curve will be a horizontal straight line and will also be the same as the MR curve. The TR curve will be an upward-sloping straight line from the origin.
5. A firm that faces a downward-sloping demand curve must obviously also face the same downward-sloping AR curve. The MR curve will also slope downwards, but will be below the AR curve and steeper than it. The TR curve will be an arch shape starting from the origin.
6. When demand is price elastic, marginal revenue will be positive and the TR curve will be upward sloping. When demand is price inelastic, marginal revenue will be negative and the TR curve will be downward sloping.
7. A change in output is represented by a movement along the revenue curves. A change in any other determinant of revenue will shift the curves up or down.

6.6 PROFIT MAXIMISATION

We are now in a position to put costs and revenue together to find the output at which profit is maximised, and also to find out how much that profit will be.

There are two ways of doing this. The first and simpler method is to use total cost and total revenue curves. The second method is to use marginal and average cost and marginal and average revenue curves. Although this method is a

little more complicated (but only a little!), it is more useful when we come to compare profit maximising under different market conditions.

We will look at each method in turn. In both cases, we will concentrate on the short run: namely, that period in which one or more factors are fixed in supply. In both cases, we take the instance of a firm facing a downward-sloping demand curve.

Figure 6.20 Finding the profit-maximising output using marginal curves

Figure 6.21 Measuring the maximum profit using average curves

Referring to Figure 6.20, at a level of output below 3, *MR* exceeds *MC*. This means that by producing more units there will be a bigger addition to revenue (*MR*) than to cost (*MC*). Total profit will *increase*. As long as *MR* exceeds *MC*, profit can be increased by increasing production.

At a level of output above 3, *MC* exceeds *MR*. All levels of output above 3 thus add more to cost than to revenue and hence *reduce* profit. As long as *MC* exceeds *MR*, profit can be increased by cutting back on production.

Profits are thus maximised where $MC = MR$: at an output of 3. This can be confirmed by reference to the *TPI* column in Table 6.10.

Students worry sometimes about the argument that profits are maximised when $MR = MC$. Surely, they say, if the last unit is making no profit, how can profit be at a *maximum*? The answer is very simple. If you cannot *add* anything more to a total, the total must be at the maximum. Take the simple analogy of going up a hill. When you cannot go any higher, you must be at the top.

Stage 2: Using average curves to measure the size of the profit

Once the profit-maximising output has been discovered, we use the average curves to measure the *amount* of profit at the maximum. Both marginal and average curves corresponding to the data in Table 6.10 are plotted in Figure 6.21.

First, average profit (*A*) is found. This is simply $AR - AC$. At the profit-maximising output of 3, this gives a figure for *API* of $£6 - £4^2/3 = £1^{1/3}$. Then total profit is obtained by multiplying average profit by output:

$$TPI = AP \times Q$$

This is shown as the shaded area. It equals $£1^{1/3} \times 3 = £4$. This can again be confirmed by reference to the *TPI* column in Table 6.10.

*** LOOKING AT THE MATHS**

As we have seen, the rule for profit maximisation is that firms should produce where $MC = MR$. This can be derived algebraically as follows. Profit is defined as

$$TPI = TR - TC \tag{1}$$

Profit is maximised at the point where an additional unit of output will add no more to profit – that is, where

$$\frac{\Delta TPI}{\Delta Q} = MPI = 0 \tag{2}$$

or, from (1), where

$$\frac{\Delta TR}{\Delta Q} = \frac{\Delta TC}{\Delta Q} = 0 \tag{3}$$

or

$$\frac{\Delta TR}{\Delta Q} = \frac{\Delta TC}{\Delta Q} \tag{4}$$

that is, where $MR = MC$.

Equation (2) can be related to Figure 6.19. Profits are maximised at the highest point of the *TPI* curve. At the top of any curve (or bottom for that matter), its slope is zero. Thus $\Delta TPI/Q = MPI = 0$. Put another way, the tangent to the top of the *TPI* curve is horizontal.

From the information for a firm given in the table below, construct a table like 6.10.

Q	0	1	2	3	4	5	6	7
P	12	11	10	9	8	7	6	5
TC	2	6	9	12	16	21	28	38

Use your table to draw diagrams like Figures 6.19 and 6.21. Use these two diagrams to show the profit-maximising output and the level of maximum profit. Confirm your findings by reference to the table you have constructed.

*BOX 6.10

USING CALCULUS TO FIND THE MAXIMUM PROFIT OUTPUT

EXPLORING ECONOMICS

Imagine that a firm's total revenue and total cost functions were

$$TR = 48Q - Q^2$$

$$TC = 12 + 16Q + 3Q^2$$

From these two equations the following table can be derived.

Q	TR	TC	π (= TR - TC)
0	0	12	-12
1	47	31	16
2	92	56	36
3	135	87	48
4	176	124	52
5	215	167	48
6	252	216	36
7	287	271	16

1. How much is total fixed cost?
2. Continue the table for $Q = 8$ and $Q = 9$.
3. Plot TR , TC and π on a diagram like Figure 6.19.

It can clearly be seen from the table that profit is maximised at an output of 4, where $\pi = 52$.

This profit-maximising output and the level of profit can be calculated without drawing up a table. The calculation involves calculus. There are two methods that can be used.

Finding where $MR = MC$

Marginal revenue can be found by differentiating the total revenue function.

$$MR = dTR/dQ$$

The reason is that marginal revenue is the rate of change of total revenue. Differentiating a function gives its rate of change.

Similarly, marginal cost can be found by differentiating the total cost function:

$$MC = dTC/dQ$$

Differentiating TR and TC gives

$$dTR/dQ = 48 - 2Q = MR$$

and

$$dTC/dQ = 16 + 6Q = MC$$

Profit is maximised where $MR = MC$, in other words, where

$$48 - 2Q = 16 + 6Q$$

Solving this for Q gives

$$32 = 8Q$$

$$\therefore Q = 4$$

The equation for total profit (π) is

$$\begin{aligned} \pi &= TR - TC \\ &= 48Q - Q^2 - (12 + 16Q + 3Q^2) \\ &= -12 + 32Q - 4Q^2 \end{aligned}$$

Substituting $Q = 4$ into this equation gives

$$\begin{aligned} \pi &= -12 + (32 \times 4) - (4 \times 4^2) \\ \therefore \pi &= 52 \end{aligned}$$

These figures can be confirmed from the table.

Maximising the total profit equation

To maximise an equation we want to find the point where the slope of the curve derived from it is zero. In other words, we want to find the top of the π curve.

The slope of a curve gives its rate of change and is found by differentiating the curve's equation. Thus to find maximum π we differentiate it (to find the slope) and set it equal to zero (to find the top).

$$\begin{aligned} \pi &= -12 + 32Q - 4Q^2 \text{ (see above)} \\ \therefore d\pi/dQ &= 32 - 8Q \end{aligned}$$

Setting this equal to zero gives

$$\begin{aligned} 32 - 8Q &= 0 \\ \therefore 8Q &= 32 \\ \therefore Q &= 4 \end{aligned}$$

This is the same result as was found by the first method. Again $Q = 4$ can be substituted into the π equation to give

$$\pi = 52$$

Given the following equations:

$$TR = 72Q - 2Q^2; TC = 10 + 12Q + 4Q^2$$

calculate the maximum profit output and the amount of profit at that output using both methods.

Some qualifications

Long-run profit maximisation

Assuming that the AR and MR curves are the same in the long run as in the short run, long-run profits will be maximised at the output where MR equals the long-run MC. The reasoning is the same as with the short-run case.

The meaning of 'profit'

One element of cost is the opportunity cost to the owners of the firm of being in business. This is the minimum return the owners must make on their capital in order to prevent them from eventually deciding to close down and perhaps move into some alternative business. It is a *cost* because, just as with wages, rent, etc., it has to be covered if the firm is to continue producing. This opportunity cost to the owners is sometimes known as **normal profit**, and is included in the cost curves.

What determines this normal rate of profit? It has two components. First, someone setting up in business invests capital in it. There is thus an opportunity cost. This is the interest that could have been earned by lending it in some riskless form (e.g. by putting it in a savings account in a bank). Nobody would set up a business unless they expected to earn at least this rate of profit. Running a business is far from riskless, however, and hence a second element is a return to compensate for risk. Thus:

$$\text{normal profit (\%)} = \text{rate of interest on a riskless loan} \\ + \text{a risk premium}$$

The risk premium varies according to the line of business. In those with fairly predictable patterns, such as food retailing, it is relatively low. Where outcomes are very uncertain, such as mineral exploration or the manufacture of fashion garments, it is relatively high.

Thus if owners of a business earn normal profit, they will (just) be content to remain in that industry. If they earn more than normal profit, they will also (obviously) prefer to stay in this business. If they earn less than normal profit, then after a time they will consider leaving and using their capital for some other purpose. We will see in Chapter 7 that the level of profits that a firm can make plays a pivotal role in the way markets are structured.

? How will the size of 'normal profit' vary with the general state of the economy?

Given that normal profits are included in costs, any profit that is shown diagrammatically (e.g. the shaded area in Figure 6.21) must therefore be over and above normal profit. It is known by several alternative names: **supernormal profit**, **pure profit**, **economic profit** or sometimes simply **profit**. They all mean the same thing: the excess of total profit over normal profit.

Figure 6.22 Loss-minimising output

Loss minimising

It may be that there is no output at which the firm can make a profit. Such a situation is illustrated in Figure 6.22: the AC curve is above the AR curve at all levels of output.

In this case, the output where $MR = MC$ will be the loss-minimising output. The amount of loss at the point where $MR = MC$ is shown by the shaded area in Figure 6.22. Even though the firm is making losses, there is no 'better' level of output at this point.

Whether or not to produce at all

The short run. Fixed costs have to be paid even if the firm is producing nothing at all. Rent and business rates have to be paid, etc. It was explained in Box 6.6 how some of these could sometimes be avoided if the firm temporarily shut down. However, to keep the following discussion as simple as possible it is assumed that all fixed costs are also sunk costs. This means that providing the firm is able to cover its *variable* costs, it is no worse off than it would be if it temporarily shut down. Therefore it should continue to produce because, if it shut down, its losses would be greater. Of course, if the firm's revenues are more than its variable costs, then it is able to go some way to covering the fixed costs and again it will continue to produce.

Definitions

Normal profit The opportunity cost of being in business: the profit that could have been earned in the next best alternative business. It is counted as a cost of production.

Supernormal profit (also known as pure profit, economic profit or simply profit) The excess of total profit above normal profit.

Figure 6.23 The short-run shut-down point

What happens if the firm's revenue is not enough to cover its variable costs: that is, if the *AVC* curve is above, or the *AR* curve below, the position illustrated in Figure 6.23? In that case the firm is worse off than if it only has fixed

costs and it will shut down production. This situation is known as the *short-run shut-down point*.

The long run. All costs are variable in the long run. If, therefore, the firm cannot cover its long-run average costs (which include normal profit), it will close down. The *long-run shut-down point* will be where the *AR* curve is tangential to the *LRAC* curve.

Definitions

Short-run shut-down point Where the *AR* curve is tangential to the *AVC* curve. The firm can only just cover its variable costs. Any fall in revenue below this level will cause a profit-maximising firm to shut down immediately.

Long-run shut-down point Where the *AR* curve is tangential to the *LRAC* curve. The firm can just make normal profits. Any fall in revenue below this level will cause a profit-maximising firm to shut down once all costs have become variable.

BOX 6.11 THE LOGIC OF LOGISTICS

CASE STUDIES AND APPLICATIONS

Driving up profits

One key to a company's success is the logistics of its operations. 'Logistics' refers to the management of the inflow of resources to a company and the outflow of finished goods from it; in other words, it refers to 'supply-chain management'. This includes the purchasing of raw materials, transporting them, production sequencing, stock control, delivery to wholesalers or retailers, and so on.

Logistics depends on the provision of high-quality and timely information. As IT systems have become increasingly sophisticated, they have enabled modern developments in logistics to transform the operation of many industries.

Driving down costs

With the widespread use of containerisation and development of giant distribution companies, such as UPS and DHL, transporting materials and goods around the world has become much faster and much cheaper. Instead of having to make parts in-house, companies can now use the logistics industry to obtain them at lower cost elsewhere, often from the other side of the world.

With improved systems for ordering materials, and deliveries becoming more and more reliable, firms no longer need to keep large stocks of parts; they simply buy them as they need them. The same opportunity to save costs lies with the finished product: a company can keep lower levels of stocks when its own delivery mechanisms are more efficient.

The globalisation of logistics, with increasing use of the Internet, has resulted in a hugely complex logistics industry. Firms that were once solely concerned with delivery are now employed to manage companies' supply chains and achieve substantial cost savings for them.

Driving up revenues

Efficient logistics has not just resulted in lower costs. The flexibility it has given firms has allowed many to increase their sales.

Carrying lower levels of stocks and switching from supplier to supplier, with the process often being managed by a logistics company, can allow companies to change the products they offer more rapidly. They can be more responsive to consumer demand and thereby increase their sales.

A well-known example of a company benefiting from this approach is Primark. This low-cost fashion retailer focuses much more on buying, logistics and supply-chain management than on branding or advertising.

1. What dangers are there in keeping stocks to a minimum and relying on complex supply chains?
2. Which industries do you think would benefit most from reduced transport times for their finished products? Think of an industry, other than low-cost fashion, which would benefit from the ability to switch rapidly the products offered.

*** LOOKING AT THE MATHS**

We can state the short- and long-run shut-down points algebraically. Remember that total profit (π) is defined as

$$\pi = TR - TC = TR - (TFC + TVC) \quad (1)$$

A negative value for π means that the firm makes a loss. This will occur when

$$TR - (TFC + TVC) < 0$$

or

$$TR < (TFC + TVC)$$

But when should the firm shut down?

Short-run shut-down point

If the firm shuts down, TR and TVC will be zero, but in the short run it will still incur total fixed costs (TFC) and thus

$$\pi = -TFC \quad (2)$$

In other words, it will make a loss equal to total fixed costs. From this it can be seen that the firm should close in the short run only if

$$\pi < -TFC$$

i.e.

$$(TR - TFC - TVC) < -TFC \quad (3)$$

In other words, the loss should not exceed fixed costs. Put another way (i.e. by rearranging (3)), it should continue in production as long as

$$TR \geq TVC \quad (4)$$

or, dividing both sides of (4) by quantity, where

$$AR \geq AVC \quad (5)$$

The firm, therefore, should shut down if

$$AR < AVC$$

This is shown in Figure 6.23.

Long-run shut-down point

In the long run, there are no fixed costs. Thus

$$\pi = TR - TVC = TR - TC \quad (6)$$

If the firm shuts down, it will earn no revenue, but incur no costs. Thus

$$\pi = TR - TC = 0 - 0 = 0$$

The firm should therefore continue in production as long as

$$(TR - TC) \geq 0$$

i.e.

$$TR \geq TC$$

or, dividing both sides by quantity, as long as

$$AR \geq AC$$

where AC in this case is long-run average cost. The firm, therefore, should shut down if

$$AR < AC$$

Section summary

- Total profit equals total revenue minus total cost. By definition, then, a firm's profits will be maximised at the point where there is the greatest gap between total revenue and total cost.
- Another way of finding the maximum profit point is to find the output where marginal revenue equals marginal cost. Having found this output, the level of maximum profit can be found by finding the average profit ($AR - AC$) and then multiplying it by the level of output.
- Normal profit is the minimum profit that must be made to persuade a firm to stay in business in the long run. It is counted as part of the firm's costs. Supernormal profit is any profit over and above normal profit.
- For a firm that cannot make a profit at any level of output, the point where $MR = MC$ represents the loss-minimising output.
- In the short run, a firm will close down if it cannot cover its variable costs. In the long run, it will close down if it cannot make normal profits.

END OF CHAPTER QUESTIONS

1. The following table shows the average cost and average revenue (price) for a firm at each level of output.

Output	1	2	3	4	5	6	7	8	9	10
AC (£)	7.00	5.00	4.00	3.30	3.00	3.10	3.50	4.20	5.00	6.00
AR (£)	10.00	9.50	9.00	8.50	8.00	7.50	7.00	6.50	6.00	5.50

- (a) Construct a table to show *TC*, *MC*, *TR* and *MR* at each level of output (put the figures for *MC* and *MR* midway between the output figures).
 - (b) Using *MC* and *MR* figures, find the profit-maximising output.
 - (c) Using *TC* and *TR* figures, check your answer to (b).
 - (d) Plot the *AC*, *MC*, *AR* and *MR* figures on a graph.
 - (e) Mark the profit-maximising output and the *AR* and *AC* at this output.
 - (f) Shade in an area to represent the level of profits at this output.
- *2. Draw the isoquant corresponding to the following table, which shows the alternative combinations of labour and capital required to produce 100 units of output per day of good X.

K	16	20	26 ² / ₃	40	60	80	100
L	200	160	120	80	53 ¹ / ₃	40	32

- (a) Assuming that capital costs are £20 per day and the wage rate is £10 per day, what is the least-cost method of producing 100 units? What will the daily total cost be? (Draw in a series of isocosts.)
 - (b) Now assume that the wage rate rises to £20 per day. Draw a new set of isocosts. What will be the least-cost method of producing 100 units now? How much labour and capital will be used?
- 3. Choose two industries that you believe are very different. Identify factors used in those industries that in the short run are (a) fixed; (b) variable.
 - 4. Taking the same industries, identify as many economies of scale as you can.
 - 5. 'Both short-run and long-run average cost curves may be U-shaped, but the explanations for their respective shapes are quite different.' Explain this statement.
 - 6. Why do marginal cost curves intersect both the average variable cost curve and the average cost curve at their lowest point?
 - 7. Draw a diagram like that in Figure 6.21. Now illustrate the effect of a rise in demand for the product. Mark the new profit-maximising price and output. Will the profit-maximising output, price, average cost and profit necessarily be higher than before?
 - 8. Why might it make sense for a firm which cannot sell its output at a profit to continue in production for the time being? For how long should the firm continue to produce at a loss?

Assessment of the theory	213
Contestable markets and the public interest	213

As we saw in Chapter 6, a firm's profits are maximised where its marginal cost equals its marginal revenue: $MC = MR$. But we will want to know more than this.

- What determines the amount of profit that a firm will make? Will profits be large, or just enough for the firm to survive, or so low that it will be forced out of business?
- Will the firm produce a high level of output or a low level?
- Will it be producing efficiently, making best use of resources?
- Will the price charged to the consumer be high or low?
- More generally, will the consumer and society as a whole benefit from the decisions a firm makes? This is, of course, a normative question (see section 1.3). Nevertheless, economists can still identify and analyse the wider effects of these decisions.

The answers to these questions largely depend on the amount of competition that a firm faces. A firm in a highly competitive environment will behave quite differently from a firm facing little or no competition. In particular, a firm facing competition from many other firms will be forced to keep its prices down and be as efficient as possible, simply to survive. If, however, the firm faces little or no competition (like a local water company or a major pharmaceutical company), it may have considerable power over prices, and we may end up paying considerably more as a result.

In this chapter and the next, we consider different types of market structure. Here we focus on the extremes: perfect competition (very many firms competing) and monopoly (only one firm in the industry).

7.1 ALTERNATIVE MARKET STRUCTURES

It is traditional to divide industries into categories according to the degree of competition that exists between the firms within the industry. There are four such categories.

At one extreme is **perfect competition**, where there are very many firms competing. Each firm is so small relative to the whole industry that it has no power to influence price. It is a price taker. At the other extreme is **monopoly**, where there is just one firm in the industry, and hence no competition from within the industry. In the middle come **monopolistic competition**, which involves quite a lot of firms competing and where there is freedom for new firms to enter the industry, and **oligopoly**, which involves only a few firms and where entry of new firms is restricted.

To distinguish more precisely between these four categories, the following must be considered:

- How freely firms can enter the industry. Is entry free or restricted? If it is restricted, just how great are the barriers to the entry of new firms?
- The nature of the product. Do all firms produce an identical product, or do firms produce their own particular brand or model or variety?
- The firm's degree of control over price. Is the firm a price taker or can it choose its price, and if so, how will changing its price affect its profits? What we are talking about here is the nature of the demand curve it faces. How elastic is it? If the firm puts up its price, will it lose (a) all its sales (a horizontal demand curve), or (b) a large proportion of its sales (a relatively elastic demand curve), or (c) just a small proportion of its sales (a relatively inelastic demand curve)?

it will also affect other firms' performance: *their* prices, profits, efficiency, etc. The collective conduct of all the firms in the industry will affect the whole industry's performance.

Economists thus see a causal chain running from market structure to the performance of that industry.

Structure → *Conduct* → *Performance*

First we shall look at the two extreme market structures: perfect competition and monopoly. Then in Chapter 8 we shall look at the two intermediate cases of monopolistic competition and oligopoly.

The two intermediate cases are sometimes referred to collectively as **imperfect competition**. The vast majority of firms in the real world operate under imperfect competition. It is still worth studying the two extreme cases, however, because they provide a framework within which to understand the real world. Some industries tend more to the competitive extreme, and thus the behaviour and performance of firms with these industries corresponds more closely to the predictions of perfect competition. Other industries tend more to the other extreme: for example, when there is one dominant firm and a few much smaller firms. In such cases, the behaviour and performance of firms corresponds more closely to the predictions of monopoly.

Chapters 7 and 8 assume that firms, under whatever market structure, are attempting to maximise profits. Chapter 9 questions this assumption. It looks at alternative theories of the firm: theories based on assumptions *other* than profit maximising.

Definitions

Perfect competition A market structure where there are many firms, none of which is large; where there is freedom of entry into the industry; where all firms produce an identical product; and where all firms are price takers.

Monopoly A market structure where there is only one firm in the industry. (Note that this is the economic definition of a pure monopoly. In UK competition law, the part that applies to the abuse of monopoly power covers firms that are in a position of 'market dominance'. Such firms will have a large share, but not necessarily a 100 per cent share of the market. See Chapter 14 for more on this.)

Monopolistic competition A market structure where, as with perfect competition, there are many firms and freedom of entry into the industry, but where each firm produces a differentiated product and thus has some control over its price.

Oligopoly A market structure where there are few enough firms to enable barriers to be erected against the entry of new firms.

Imperfect competition The collective name for monopolistic competition and oligopoly.

Market power. When firms have market power over prices, they can use this to raise prices and profits above the perfectly competitive level. Other things being equal, the firm will gain at the expense of the consumer. Similarly, if consumers or workers have market power, they can use this to their own benefit.

Table 7.1 shows the differences between the four categories.

1. Give two more examples in each category.
2. Would you expect builders and restaurateurs to have the same degree of control over price?

The market structure under which a firm operates will determine its behaviour. Firms under perfect competition will behave quite differently from firms which are monopolists, which will behave differently again from firms under oligopoly or monopolistic competition.

This behaviour (or 'conduct') will in turn affect the firm's performance: its prices, profits, efficiency, etc. In many cases,

Table 7.1 Features of the four market structures

Type of market	Number of firms	Freedom of entry	Nature of product	Examples	Implication for demand curve for firm
Perfect competition	Very many	Unrestricted	Homogeneous (undifferentiated)	Cabbages, carrots, foreign exchange (these approximate to perfect competition)	Horizontal. The firm is a price taker
Monopolistic competition	Many/several	Unrestricted	Differentiated	Builders, restaurants, hairdressers, garage mechanics	Downward sloping, but relatively elastic. The firm has some control over price
Oligopoly	Few	Restricted	1. Undifferentiated 2. Differentiated	1. Petrol, cement 2. Cars, electrical appliances, supermarkets, retail banking	Downward sloping, relatively inelastic but depends on reactions of rivals to a price change
Monopoly	One	Restricted or completely blocked	Unique	Prescription drugs produced under a patent, local water companies	Downward sloping, more inelastic than oligopoly. The firm has considerable control over price

7.2 PERFECT COMPETITION

Assumptions of perfect competition

The model of perfect competition is built on four assumptions:

- Firms are *price takers*. There are so many firms in the industry that each one produces an insignificantly small portion of total industry supply, and therefore has no power whatsoever to affect the price of the product. It faces a horizontal demand 'curve' at the market price: the price determined by the interaction of demand and supply in the whole market.
- There is complete *freedom of entry* into the industry for new firms. Existing firms are unable to stop new firms setting up in business. Setting up a business takes time, however. Freedom of entry, therefore, applies in the long run.
- All firms produce an *identical product*. (The product is 'homogeneous'.) There is therefore no branding and no advertising, since there would be no point in the firm incurring this cost.
- Producers and consumers have *perfect knowledge* of the market. Producers are fully aware of prices, costs and market opportunities. Consumers are fully aware of the price, quality and availability of the product.

These assumptions are very strict. Few, if any, industries in the real world meet these conditions. Certain agricultural markets are perhaps closest to perfect competition. The market for fresh vegetables is an example.

Nevertheless, despite the lack of real-world cases, the model of perfect competition plays a very important role in economic analysis and policy. Its major relevance is as an 'ideal type' for society. Many argue that achieving perfect competition would bring a number of important advantages, such as keeping prices down to marginal cost and preventing firms from making supernormal profit over the long run. The model can thus be used as a standard against which to judge the shortcomings of real-world industries. However, we will also see that it has disadvantages, when compared with other market structures.

1. *It is sometimes claimed that the market for various stocks and shares is perfectly competitive, or nearly so. Take the case of the market for shares in a large company like Apple. Go through each of the four assumptions above and see if they apply in this case. (Don't be misled by the first assumption. The 'firm' in this case is not Apple itself.)*
2. *Is the market for gold perfectly competitive?*

BOX 7.1

CONCENTRATION RATIOS

EXPLORING ECONOMICS

Measuring the degree of competition

We can get some indication of how competitive a market is by observing the number of firms: the more the firms, the more competitive the market would seem to be. However, this does not tell us anything about how *concentrated* the market might be. There may be *many* firms (suggesting a situation of perfect competition or monopolistic competition), but the largest two firms might produce 95 per cent of total output. This would make these two firms more like oligopolists.

Thus, even though a large number of producers may make the market *seem* highly competitive, this could be deceiving. Another approach, therefore, to measuring the degree of competition is to focus on the level of concentration of firms.

Firm concentration ratios for various industries (by output)

Industry	5-firm ratio	15-firm ratio
Sugar	99	99
Tobacco products	99	99
Oils and fats	88	95
Confectionery	81	91
Gas distribution	82	87
Soft drinks, mineral water	75	93
Postal/courier services	65	75
Telecommunications	61	75
Inorganic chemicals	57	80
Pharmaceuticals	57	74
Alcoholic beverages	50	78
Soap and toiletries	40	64
Accountancy services	36	47
Motor vehicles	34	54
Glass and glass products	26	49
Fishing	16	19
Advertising	10	20
Wholesale distribution	6	11
Furniture	5	13
Construction	5	9

Source: Based on data in *United Kingdom Input-Output Analyses*, 2006 edition (National Statistics, 2006), Table 8.31.

The simplest measure of industrial concentration involves adding together the market share of the largest so many firms: e.g. the largest 3, 5 or 15. This would give what is known as the '3-firm', '5-firm' or '15-firm' 'concentration ratio'. There are different ways of estimating market share: by revenue, by output, by profit, etc.

The table shows the 5-firm and 15-firm concentration ratios of selected industries in the UK by output. As you can see, there is an enormous variation in the degree of concentration from one industry to another.

One of the main reasons for this is differences in the percentage of total industry output at which economies of scale are exhausted. If this occurs at a low level of output, there will be room for several firms in the industry which are all benefiting from the maximum economies of scale.

The degree of concentration will also depend on the barriers to entry of other firms into the industry (see pages 201–4) and on various factors such as transport costs and historical accident. It will also depend on how varied the products are within any one industrial category. For example, in categories as large as furniture and construction there is room for many firms, each producing a specialised range of products.

So is the degree of concentration a good guide to the degree of competitiveness of the industry? The answer is that it is *some* guide, but on its own it can be misleading. In particular, it ignores the degree of competition from abroad.

1. What are the advantages and disadvantages of using a 5-firm concentration ratio rather than a 15-firm, a 3-firm or even a 1-firm ratio?
2. Why are some industries, such as bread baking and brewing, relatively concentrated, in that a few firms produce a large proportion of total output (see Box 7.2 and Case Study 7.4 on the student website), and yet there are also many small producers?

The short run and the long run

Before we can examine what price, output and profits will be, we must first distinguish between the short run and the long run as they apply to perfect competition.

In the *short run*, the number of firms is fixed. Depending on its costs and revenue, a firm might be making large profits, small profits, no profits or a loss; and in the short run, it may continue to do so.

In the *long run*, however, the level of profits affects entry and exit from the industry. If supernormal profits are made (see page 184), new firms will be attracted into the industry, whereas if losses are being made, firms will leave.

Note that although we shall be talking about the *level* of profit (since that makes our analysis of pricing and output decisions simpler to understand), in practice it is usually the

rate of profit that determines whether a firm stays in the industry or leaves. The *rate of profit* (r) is the level of profit (TI) as a proportion of the level of capital (K) employed: $r = TI/K$. If TI is measured as profit before tax and interest payments, r is

Definitions

Short run under perfect competition The period during which there is insufficient time for new firms to enter the industry.

Long run under perfect competition The period of time that is long enough for new firms to enter the industry.

Rate of profit Total profit (TI) as a proportion of the capital employed (K): $r = TI/K$. Often measured by using ROCE in the real world.

BOX 7.2

IS PERFECT BEST?

EXPLORING
ECONOMICS

Be careful of the word 'perfect'.

'Perfect competition' refers to competition that is complete. Perhaps 'complete competition' would be a better term. There is a complete absence of power, a complete absence of entry barriers, a complete absence of product differentiation between producers, and complete information for producers and consumers on the market. It is thus useful for understanding the effects of power, barriers, product differentiation and lack of information.

Perfect does not mean 'best', however.

Just because it is at the extreme end of the competition spectrum, it does not follow that perfect competition is desirable. After all, you could have a perfect killer virus – i.e. one that is totally immune to drugs, and against which

humans have no natural protection at all. Such a thing, though perfect, is hardly desirable.

To say that perfect competition is desirable and that it is a goal towards which government policy should be directed are normative statements. Economists, in their role as economists, cannot make such statements.

This does not mean, of course, that economists cannot identify the effects of perfect competition, but whether these effects are *desirable* or not is an ethical question.

The danger is that by using perfect competition as a yardstick, and by using the word 'perfect' rather than 'complete', economists may be surreptitiously persuading their audience that perfect competition is a goal we *ought* to be striving to achieve.

referred to as the return on capital employed (ROCE). As you would expect, larger firms will need to make a larger *total* profit to persuade them to stay in an industry. Total normal profit is thus larger for them than for a small firm. The *rate* of normal profit, however, will probably be similar.

1. Why do economists treat normal profit as a cost of production?
2. What determines (a) the level and (b) the rate of normal profit for a particular firm?

Thus whether the industry expands or contracts in the long run will depend on the rate of profit. Naturally, since the time a firm takes to set up in business varies from industry to industry, the length of time before the long run is reached also varies from industry to industry.

The short-run equilibrium of the firm

The determination of price, output and profit in the short run under perfect competition can best be shown in a diagram.

Figure 7.1 shows a short-run equilibrium for both an industry and a firm under perfect competition. Both parts of the diagram have the same scale for the vertical axis. The horizontal axes have totally different scales, however. For example, if the horizontal axis for the firm were measured in, say, thousands of units, the horizontal axis for the whole industry might be measured in millions or tens of millions of units, depending on the number of firms in the industry.

Let us examine the determination of price, output and profit in turn.

Figure 7.1 Short-run equilibrium of an industry and a firm under perfect competition

Price. The price is determined in the industry by the intersection of demand and supply. The firm faces a horizontal demand (or average revenue) 'curve' at this price. It can sell all it can produce at the market price (P_e), but nothing at a price above P_e .

Output. The firm will maximise profit where marginal cost equals marginal revenue ($MR = MC$), at an output of Q_e . Note that, since the price is not affected by the firm's output, marginal revenue will equal price (see pages 177–8 and Figure 6.15).

Profit. If the average cost (AC) curve (which includes normal profit) dips below the average revenue (AR) 'curve', the firm will earn supernormal profit. Supernormal profit per unit at Q_e is the vertical difference between AR and AC at Q_e . Total supernormal profit is the shaded rectangle in Figure 7.1.

What happens if the firm cannot make a profit at *any* level of output? This situation would occur if the AC curve were above the AR curve at all points. This is illustrated in Figure 7.2, where the market price is P_1 . In this case, the point where $MC = MR$ represents the *loss-minimising* point (where loss is defined as anything less than normal profit). The amount of the loss is represented by the shaded rectangle.

As we saw in section 6.6, whether the firm is prepared to continue making a loss in the short run or whether it will close down immediately depends on whether it can cover its *variable costs* – assuming all fixed costs are also sunk costs.

Provided price is above average variable cost (AVC), the firm will still continue producing in the short run: it can pay its variable costs and go some way to paying its fixed costs. It will shut down in the short run only if the market price falls below P_2 in Figure 7.2.

The firm's short-run supply curve

The *firm's* short-run supply curve will be a section of its (short-run) marginal cost curve.

A supply curve shows how much will be supplied at each price: it relates quantity to price. The marginal cost curve relates quantity to marginal cost. But under perfect competition, given that $P = MR$, and $MR = MC$, P must equal MC . Thus the supply curve and the MC curve will follow the same line.

For example, in Figure 7.3(b), if price were P_1 , profits would be maximised at Q_1 where $P_1 = MC$. Thus point *a* is one point on the supply curve. At a price of P_2 , Q_2 would be produced. Thus point *b* is another point on the supply curve, and so on.

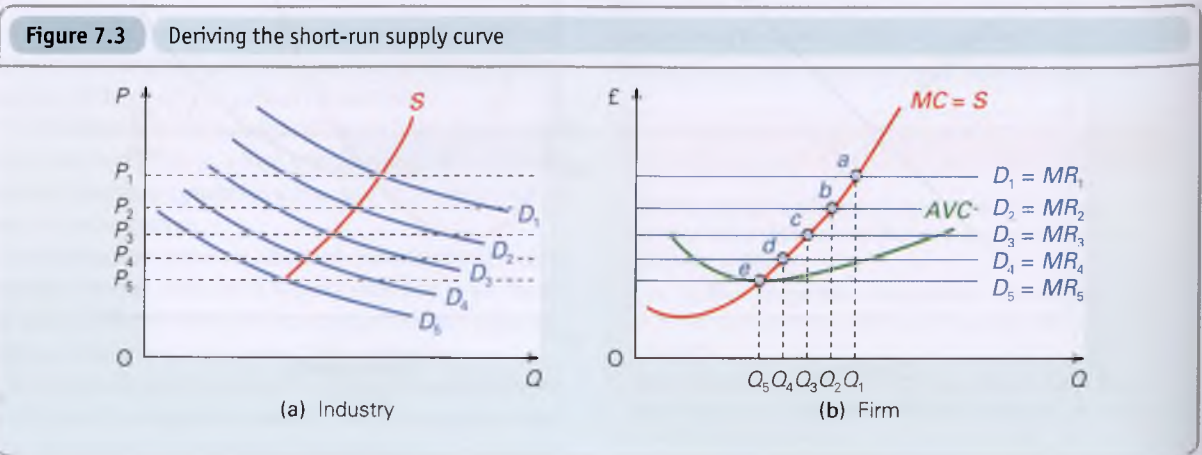

Figure 7.4 Long-run equilibrium under perfect competition

So, under perfect competition, the firm's supply curve is entirely dependent on costs of production. This demonstrates why the firm's supply curve is upward sloping. Given that marginal costs rise as output rises (due to diminishing marginal returns), a higher price will be necessary to induce the firm to increase its output.

Note that, assuming all fixed costs are also sunk costs, the firm will not produce at a price below AVC . Thus the supply curve is only that portion of the MC curve above point e .

The short-run industry supply curve

What is the short-run supply curve of the whole industry? This shows the total quantity supplied by all the firms already in the industry at each possible price. It does not include the output produced by any new entrants as this would only apply in the long run. To calculate short-run industry supply at any price we simply add up how much each individual firm wants to supply at that price. For example, if there were 100 firms in the market which all wanted to supply 10 units at a price of £5, then the market supply at £5 would be 1000. To derive the industry supply curve, therefore, we simply sum the short-run supply curves (and hence MC curves) of all the firms already in the industry. Graphically this will be a *horizontal sum*, since it is only the *quantities* that are added at each price.

? Will the industry supply be zero below a price of P_5 in Figure 7.3?

The long-run equilibrium of the firm

In the long run, if typical firms are making supernormal profits, new firms will be attracted into the industry. Likewise, if established firms can make supernormal profits by increasing the scale of their operations, they will do so, since all factors of production are variable in the long run.

The effect of the entry of new firms and/or the expansion of existing firms is to increase industry supply. This is

illustrated in Figure 7.4. At a price of P_1 supernormal profits are earned. This causes industry supply to expand (the short-run industry supply curve shifts to the right). This in turn leads to a fall in price. Supply will go on increasing and price falling until firms are making only normal profits. This will be when price has fallen to the point where the demand 'curve' for the firm just touches the bottom of its long-run average cost curve. Q_L is thus the long-run equilibrium output of the firm, with P_L the long-run equilibrium price.

? Illustrate on a diagram similar to Figure 7.4 what would happen in the long run if price were initially below P_L .

Since the $LRAC$ curve is tangential to all possible short-run AC curves (see section 5.4), the full long-run equilibrium will be as shown in Figure 7.5 where

$$LRAC = AC = MC = MR = AR$$

Figure 7.5 Long-run equilibrium of the firm under perfect competition

***LOOKING AT THE MATHS**

As we have seen, the long-run equilibrium output is where long-run average cost is minimised. If we know the equation for $LRAC$, we can simply use the techniques of minimisation (see pages A:9–13) to find the equilibrium output. Assume that the long-run average cost function is

$$LRAC = a - bQ + cQ^2$$

The technique is to differentiate this function and set it equal to zero, i.e.

$$\frac{d(LRAC)}{dQ} = -b + 2cQ = 0 \tag{1}$$

Solving equation (1) for Q gives the long-run equilibrium output. Once we have found the value of Q , we can substitute it back into equation (1) to find the value of $LRAC$ and hence the equilibrium price (since $P = LRAC$).

We can then use the second derivative test (see page A:12) to check that this indeed does represent a minimum, not a maximum, $LRAC$. An example of this is given in Maths Case 7.1 on the student website.

The firm's long-run supply curve

The firm's long-run supply curve is derived in a very similar way to the firm's short-run supply curve. The major difference is that, in the long run, the firm can adjust all of its inputs. This means that all of its costs are now variable and hence the long-run average cost curve is the same as long-run average variable cost curve. Therefore, the firm's long-run supply curve is the portion of its long-run marginal cost curve above the point where it is cut by the average cost curve. At prices below this level it would be loss minimising for the firm to produce zero.

The long-run industry supply curve

The long-run industry supply curve cannot be derived in the same way as the short-run industry supply curve: i.e. by

horizontally summing all the individual firms' supply curves. This is because, in the long run, the number of firms in the industry is no longer fixed and account has to be taken of the output produced by any new firms entering the industry. This has to be added to the quantity produced by existing firms.

The long-run industry supply curve can be derived by analysing the impact of an increase in demand on a market that is initially in long-run equilibrium. This initial equilibrium is shown at point a in Figure 7.6(a), where market demand (D_{M1}) is equal to both long-run and short-run market supply (LRS_M and SRS_{M1}). The market price and output are P_1 and Q_{M1} respectively.

Given this market price, the representative firm maximises profit at point x in Figure 7.6(b), where $MC = MR$. It produces Q_{F1} and, with $P_1 = AC_1$, makes normal profit.

Assume now that the market demand curve increases from D_{M1} to D_{M2} . Firms in the market respond to the higher prices by increasing production. The market equilibrium in the short run moves from point a to point b – a movement up along the short-run market supply curve (SRS_{M1}). The market price and quantity increase to P_2 and Q_{M2} .

Given this new higher market price of P_2 , the profit-maximising response of the representative firm is to move upwards along its supply or MC curve from point x to point y . Its output increases from Q_{F1} to Q_{F2} and, as the price is now greater than the firm's average cost, it makes supernormal profit.

In the long run, this supernormal profit will act as a signal to entrepreneurs and new firms will enter the market. The arrival of new entrants will cause the short-run market supply curve to shift to the right (to SRS_{M2}), putting downward pressure on the market price.

Not only will the new entrants affect the market for the final product, they will also have an impact on the various markets for different factors of production. For example, the demand for raw materials required to produce the good will increase as new entrants and existing firms try to purchase

Figure 7.6 Long-run industry supply curve (increasing cost industry)

them. This might put upward pressure on the prices of various input prices, such as raw materials, energy, labour and physical capital. If the price of factor inputs does rise, this will cause the firm's AC and MC curves in Figure 7.6(b) to shift upwards: e.g. from AC_1 to AC_2 and MC_1 to MC_2 .

Given this rise in the costs of production, new firms will stop entering the industry once the short-run industry supply curve has shifted to SRS_{M_2} . The new long-run market equilibrium is at point c with the price falling back to P_3 and industry output increasing to Q_{M_3} . At the new lower market price of P_3 the firm will maximise profits at point z . The market price is now equal to the firm's new higher AC curve (AC_2) – profits have returned to the normal level. There is thus no longer any incentive for other firms to enter the industry.

The long-run market supply curve (LRS_M) goes through points a and c : i.e. the two positions of long-run equilibrium.

Increasing cost industry – upward-sloping long-run supply curve. In the example in Figure 7.6, the long-run industry supply curve is upward sloping because the extra demand for factor inputs generated by new entrants puts upward pressure on their prices. This is referred to as an **increasing-cost industry** (i.e. where there are external diseconomies of scale – see page 164). It is likely to occur when the demand for factor inputs from firms within one industry make up a relatively large proportion of the total demand for those inputs. This is more likely when most of the factor inputs are industry specific: i.e. specialist capital equipment tailored to the production of a particular good. In these circumstances, any increase in demand from new entrants will have a significant impact on the total demand for the inputs, making an increase in their price more probable.

Constant-cost industry – horizontal long-run supply curve. In some industries the majority of factor inputs will be far less specialised. Take the example of an input such as electricity. The demand for electricity from firms in a particular industry will be small relative to the total demand for electricity across the whole economy. If the demand from new entrants in one industry increased, it is unlikely to affect the market price of electricity. If this was true for all factor inputs used by firms then it would be a **constant-cost industry**. As new firms entered, the average total cost curve of the individual firms would remain unchanged. A constant-cost industry would have a horizontal long-run industry supply curve.

Decreasing-cost industry – downward-sloping long-run supply curve. Another possibility is that increasing demand from new entrants within the industry causes the price of factor inputs to decrease. This is called a **decreasing-cost industry**. It can occur when the increased demand for inputs enables the suppliers of these inputs to exploit internal economies of scale. It can also occur when firms in the industry share

Definitions

Increasing-cost industry An industry where average costs increase as the size of the industry expands.

Constant-cost industry An industry where average costs stay constant as the size of the industry expands.

Decreasing-cost industry An industry where average costs decrease as the size of the industry expands.

common transport, training or other infrastructure. These external economies of scale (see page 164) cause the cost curves in Figure 7.6(b) to shift downwards. A decreasing-cost industry will therefore have a downward-sloping long-run industry supply curve.

Use a diagram similar to Figure 7.6 to derive a long-run market supply curve for (a) a constant-cost industry; (b) a decreasing-cost industry.

The incompatibility of perfect competition and substantial economies of scale

Why is perfect competition so rare in the real world – if it even exists at all? One important reason for this has to do with economies of scale.

In many industries, firms may have to be quite large if they are to experience the full potential economies of scale. But perfect competition requires there to be *many* firms and that each one is a price taker. Firms must therefore be small under perfect competition: too small in most cases for economies of scale.

Once a firm expands sufficiently to achieve economies of scale, it will usually gain market power. It will be able to undercut the prices of smaller firms, which will thus be driven out of business. Perfect competition is destroyed.

Perfect competition could only exist in any industry, therefore, if there were no (or virtually no) economies of scale.

1. What other reasons can you think of why perfect competition is so rare?
2. Why does the market for fresh vegetables approximate to perfect competition, whereas that for aircraft does not?

Perfect competition and the public interest

Benefits of perfect competition

There are a number of features of perfect competition which, it could be argued, benefit society:

- Price equals marginal cost. As we shall see in Chapter 12, this has important implications for the allocation of resources between alternative products. Given that price equals marginal utility (see Chapter 4), marginal utility will equal marginal cost. This is argued to be an *optimal* position.

BOX 7.3 E-COMMERCE AND MARKET STRUCTURE

Has technology shifted market power?

The relentless drive towards big business over the decades has seen many markets become more concentrated and dominated by large producers. And yet there are forces that undermine this dominance, bringing more competition to markets. One of these forces is *e-commerce*.

In this case study, we will consider the impact of e-commerce on the competitive environment and market power.

What do we mean by e-commerce?

E-commerce or e-shopping is a shorthand term for buying and selling products through electronic means, in most cases through the Internet. It has grown rapidly in the last 10 years and shows no sign of slowing down. The chart shows the rise in online retail sales as a proportion of all retail sales in the UK between 2007 and 2016. Note that the proportion of Internet sales rises each year in the run-up to Christmas as many people buy gifts online.

According to the EU's 2016 survey on *ICT usage and e-commerce in enterprises*,¹ approximately two-thirds of Internet users in the EU had purchased a good online in the previous 12 months. The figure was highest in the UK at 83 per cent. The most popular products purchased online were clothes/sports goods, tickets for events and books. Unsurprisingly, the fastest growth in the use of e-shopping has occurred amongst 16–24-year-olds.

Moving markets back towards perfect competition?

In an article published in the *Economist*² in 2000 it was stated that 'the internet cuts costs, increases competition and improves the functioning of the price mechanism. It thus moves the economy closer to the textbook model of perfect

competition, which assumes abundant information, zero transaction costs and no barriers to entry'.

To see if this is true, let's look at the assumptions of this market structure.

Large numbers of buyers and sellers. The growth of e-commerce has led to many new firms starting up in business. The majority of these are small companies that often sell directly to consumers via their own websites or use online marketplaces such as eBay or Amazon. In 2016, eBay had approximately 160 million active buyers and 25 million active sellers, while Amazon had approximately 310 million active customers and 2 million third-party sellers. Approximately 50 per cent of the units shipped by Amazon are goods sold by a third-party seller.

The global reach of the Internet increases the potential number of buyers and sellers that can trade with one another. For example, in 2016, 32 per cent of consumers in the EU who purchased online did so from sellers in other member states, while 20 per cent purchased from sellers outside of the EU.

Perfect knowledge. The Internet has significantly reduced some of the transaction costs of using a market. Consumers can easily compare the prices and other features of the goods they are interested in purchasing by using search engines, such as Google Shopping, NexTag and PriceGrabber. Indeed, it is common to see people in shops (physical shops in this case) browsing competitors' prices on their mobile phones. This places the high street retailer under intense competitive pressure. Interestingly, four of the top five online retailers in the UK in 2016 – Tesco, Argos, John Lewis, Next – also have physical shops. Success for some firms now means having both physical and online stores.

Value of Internet retail sales as a percentage of total retail sales

Source: Based on series J4MC from *Time Series Data* (National Statistics).

Although the competitive pressures seem to have increased in 'B2C' (business-to consumers) e-commerce the impact may be even greater in 'B2B' (business-to-business) e-commerce. Many firms are constantly searching for cheaper sources of supply, and the Internet provides a cheap and easy means of conducting such searches.

Freedom of entry Internet companies often have lower start-up costs than their conventional rivals. Their premises are generally much smaller, with no 'shop-front' costs and lower levels of stockholding; in fact many of these businesses are initially operated from their owners' homes and garages with little more required than a computer and good Wi-Fi connection. An e-commerce website for the business can be set up in a matter of hours. Marketing costs will also be lower if the new entrant's website can easily be located by a consumer using a search engine.

Internet companies are often smaller and more specialist, relying on Internet 'outsourcing' (buying parts, equipment and other supplies through the Internet), rather than making everything themselves. They are also more likely to use delivery firms rather than having their own transport fleet. All this can make it relatively cheap for new firms to set up and begin trading over the Internet.

One consequence of the rise in e-commerce is that the distinction between firms and consumers has become increasingly blurred. With the rise of online marketplaces such as eBay and Amazon, more and more people have found going into business incredibly easy. Some people sell products they produce at home, while others specialise in selling-on products using the marketing power of these online marketplaces.

Not only do these factors make markets more price competitive, they can also bring other benefits. Costs might be driven down as firms economise on stockholding, rely more on outsourcing and develop more efficient relationships with suppliers.

What are the limits to e-commerce?

In 20 years, will the majority of us be doing all our shopping on the Internet? Will the only shopping malls be virtual ones? Although e-commerce is revolutionising markets, it is unlikely that things will go that far.

One of the key benefits of shopping in physical shops is that you get to see the good, touch it and possibly try it out before buying. You can buy the good there and then and take instant possession: you don't have to wait. Although you can order things online and often get next-day delivery, it is not quite the same as instant possession.

Furthermore, shopping can be an enjoyable experience. Many people like wandering round the shops, meeting friends, trying on clothes, playing with the latest electronic gadgets, and so on. 'Retail therapy' can be a pleasurable leisure activity and one that some people are willing to pay for in the form of higher prices.

Rather than traditional and online shopping being seen as alternatives for one another, there is an increasing tendency for

people to see them as complementary. Many people go onto the High Street, try on clothes and try out electronic appliances before going home to order them on the Internet. This enables consumers to get the best possible prices, while also having more certainty about the characteristics of the product they are purchasing.

The extent to which people can use online shopping may be limited by current technology and infrastructure. Although the quality of Internet access has significantly improved as broadband has become widely available, online purchases might still be hampered by busy sites that cannot effectively handle the number of users.

Some consumers may also be deterred by fears that delivery of the product will be late or fail completely. Research by Citizens Advice³ found that, in 2015/16, people experienced problems with 4.8 million deliveries and spent 11.8 million hours trying to sort out any issues. Consumers had difficulty making contact with the relevant company to find out exactly where their missing parcel had gone and in many situations did not know who was responsible for sorting out any problems.

A final constraint on the spread of online shopping is that access to a credit or debit card is often required to make a purchase. This option might not be available to everyone, particularly younger consumers and those on lower incomes.

Increasing market power

There are some concerns that the rise of e-commerce could actually reduce competition and result in the growth of more firms with substantial market power. Greater price transparency could actually result in *less* competition. For example, sellers may have previously reduced their prices in the belief that they could make extra sales before their competitors responded. However, the greater price transparency provided by the Internet means that rivals are able to spot price changes and respond more quickly. This reduces the incentive for some firms to reduce their prices in the first place.

If firms can more easily monitor their rivals' pricing behaviour, it might also increase the likelihood of price-fixing agreements. The topic of collusion will be discussed in more detail in Chapter 8.

It was previously explained how the marketing costs for start-ups in e-commerce might be lower than those in more traditional retailing. However, simply creating a website is not enough to make online businesses successful – potential customers also have to visit them. New firms might have to spend considerable amounts of money on marketing to increase consumers' awareness of their brands and websites. The majority of this expenditure could be a sunk cost and so would act as a significant barrier to entry. Promotional costs might be reduced if the new entrant's website was listed on a search engine's results page. However, customers are most likely to visit the links that appear towards the top of the results page. These will be

those with the greatest number of hits, which are likely to be the more established firms.

Although comparison websites increase price transparency they could also result in consumers paying higher prices. Many of these websites make considerable profits. They earn revenue by charging a fee every time a customer is referred to a listed firm's website via the price comparison website. These fees add to costs and could result in firms charging higher prices. One important issue is the size of the fee. If consumers only use one price comparison website it would have considerable market power and the ability to charge listed firms high fees.

If users build up a familiarity and knowledge of using a particular website it might create switching costs. Consumers are then less likely to visit other rival websites and so this reduces competition.

There may also be significant economies of scale in logistics: i.e. the storage, packaging and shipping of the products to the consumer. Amazon has invested heavily in automating its distribution centres using Kiva robots. This type of capital investment will only reduce a firm's average costs if it sells a large volume of products. Interestingly, the

Head of Amazon UK stated in 2004 that 'one of the greatest myths in the 1990s was there are no barriers to entry in e-commerce'.

There is no doubt that e-commerce is here to stay in all sectors. Many large companies recognise that their retail outlets have effectively become display space for their online activities. It will be interesting to see if the continued growth of e-commerce results in either increasing competition or more market power.

1. Why may the Internet work better for replacement buys than for new purchases?
2. Give three examples of products that are particularly suitable for selling over the Internet and three that are not. Explain your answer.
3. As Amazon has grown in size it has acquired substantial monopoly power. What are the barriers to entry for other companies wishing to act as a marketplace for B2C and B2B business?

3 'Shoppers will spend two and a half hours sorting out a delivery problem this Christmas', *Citizens Advice Press Release*, 7 December 2016.

To demonstrate why, consider what would happen if they were not equal. If price were greater than marginal cost, this would mean that consumers were putting a higher value ($P = MU$) on the production of extra units than they cost to produce (MC). Therefore more ought to be produced. If price were less than marginal cost, consumers would be putting a lower value on extra units than they cost to produce. Therefore less ought to be produced. When they are equal, therefore, production levels are just right. But, as we shall see later, it is only under perfect competition that $MC = P$.

- Long-run equilibrium is at the bottom of the firm's long-run AC curve. That is, for any given technology, the firm, in the long run, will produce at the least-cost output.
- Perfect competition is a case of 'survival of the fittest'. Inefficient firms will be driven out of business, since they will not be able to make even normal profits. This encourages firms to be as efficient as possible.
- The combination of (long-run) production being at minimum average cost and the firm making only normal profit keeps prices at a minimum.
- If consumer tastes change, the resulting price change will lead firms to respond (purely out of self-interest). An increased consumer demand will result in extra supply with only a short-run increase in profit.

Because of these last two points, perfect competition is said to lead to **consumer sovereignty**. Consumers, through the market, determine what and how much is to be produced. Firms have no power to manipulate the market. They cannot control price. The only thing they can do to increase profit is to become more efficient, and that benefits the consumer too.

Definition

Consumer sovereignty A situation where firms respond to changes in consumer demand without being in a position in the long run to charge a price above average cost.

Possible disadvantages of perfect competition

Even under perfect competition, however, the free market has various limitations. For example, there is no guarantee that the goods produced will be distributed to the members of society in the *fairest* proportions. There may be considerable inequality of income. (We examine this issue in Chapter 10.) What is more, a redistribution of income would lead to a different pattern of consumption and hence production. Thus there is no guarantee that perfect competition will lead to the optimum combination of goods being produced when society's views on equity are taken into account.

Another limitation is that the production of certain goods may lead to various undesirable side effects, such as pollution. Perfect competition cannot safeguard against this either.

What is more, perfect competition may be less desirable than other market structures such as monopoly.

- Even though firms under perfect competition may seem to have an incentive to develop new technology (in order to gain supernormal profits, albeit temporarily), the long-run normal profits they make may not be sufficient to fund the necessary research and development. Also, with

complete information available, if they did develop new, more efficient methods of production, their rivals would merely copy them, in which case the investment would have been a waste of money.

- Perfectly competitive industries produce undifferentiated products. This lack of variety might be seen as a disadvantage to the consumer. Under monopolistic competition

and oligopoly there is often intense competition over the quality and design of the product. This can lead to innovation and improvements that would not exist under perfect competition. The issue of the efficiency or otherwise of perfect markets and the various failings of real-world markets is examined in more detail in Chapters 12–14.

Section summary

- The assumptions of perfect competition are: a very large number of firms, complete freedom of entry, a homogeneous product and perfect knowledge of the good and its market on the part of both producers and consumers.
- In the short run, there is not time for new firms to enter the market, and thus supernormal profits can persist. In the long run, however, any supernormal profits will be competed away by the entry of new firms.
- The short-run equilibrium for the firm will be where the price, as determined by demand and supply in the market, is equal to marginal cost. At this output, the firm will be maximising profit. The firm's short-run supply curve is the same as its marginal cost curve (that portion of it above the AVC curve).
- The long-run equilibrium will be where the market price is just equal to firms' long-run average cost. The long-run industry supply curve will thus depend on what happens to firms' $LRAC$ curves as industry output expands. If their $LRAC$ curves shift upwards due to increasing industry costs (external diseconomies of scale), the long-run industry supply curve will slope upwards. If their $LRAC$ curves shift downwards due to decreasing industry costs (external economies of scale), the long-run industry supply curve will slope downwards.
- There are no substantial (internal) economies of scale to be gained by perfectly competitive firms. If there were, the industry would cease to be perfectly competitive as the large, low-cost firms drove the small, high-cost ones out of business.
- Under perfect competition, production will be at the point where $P = MC$. This can be argued to be optimal. Perfect competition can act as a spur to efficiency and bring benefits to the consumer in terms of low costs and low prices.
- On the other hand, perfectly competitive firms may be unwilling to invest in research and development or may have insufficient funds to do so. They may also produce a lack of variety of goods. Finally, perfect competition does not necessarily lead to a fair distribution of income or guarantee an absence of harmful side effects of production.

7.3 MONOPOLY

What is a monopoly?

This may seem a strange question because the answer seems obvious. A monopoly exists when there is only one firm in the industry.

But whether an industry can be classed as a monopoly is not always clear. It depends how narrowly the industry is defined. For example, a confectionary company may have a monopoly on certain chocolate bars, but it does not have a monopoly on chocolate in general. A pharmaceutical company may have a monopoly of a certain drug, but there may be alternative drugs for treating a particular illness.

To some extent, the boundaries of an industry are arbitrary. What is more important for a firm is the amount of monopoly *power* it has, and that depends on the closeness of substitutes produced by rival industries. A train company may have a monopoly over railway journeys between two towns, but it faces competition in transport from cars, coaches and sometimes planes.

As an illustration of the difficulty in identifying monopolies, try to decide which of the following are monopolies: BT; a local evening newspaper; food sold in a university outlet; a village post office; Interflora®; the London Underground; ice creams in the cinema; Guinness; the board game 'Monopoly'. (As you will quickly realise in each case, it depends how you define the industry.)

Barriers to entry

For a firm to maintain its monopoly position, there must be **barriers to entry** that make it difficult for new firms to enter

Definition

Barrier to entry Anything that prevents or impedes the entry of firms into an industry and thereby limits the amount of competition faced by existing firms.

service. The switching costs increase as this knowledge becomes more specific to the brand/product supplied by a particular firm. For example, a consumer might have spent a considerable amount of time learning how to use applications with the iOS operating system on an iPhone®. This may deter them from switching to a smart-phone that uses Google's Android operating system.

- **Product uncertainty costs.** Consumers might not fully discover either the quality or how much they like a good until after they have purchased and used it for some time. This might make them reluctant to change supplier once they have found and experienced a particular brand or product they like.
- **Compatibility costs.** Some products have two elements to them. One part is more durable, while the other needs replacing more regularly. Once customers have purchased the more durable element from a supplier, they are 'locked in' to purchasing the non-durable part from the same supplier for compatibility reasons. Examples include razor handles and razor blades, coffee machines and coffee pods, printers and ink cartridges.

Some goods or services have very large switching costs because of the existence of network externalities. A **network externality** exists when consumers' valuation of a good is influenced by the number of other people who also use the same product. For example, the benefits of having a mobile phone increase with the number of other people who also have one. In some cases, a consumer's valuation will depend on the extent to which other people use one particular brand. For a specific social media website, such as Facebook, its success depends on lots of people using the same website. Buyers and sellers are willing to pay higher fees to use Amazon and eBay as an online marketplace because so many other buyers and sellers use the same websites.

When a good or service has significant network externalities it makes it difficult for a new entrant. Even if it produces a far superior and/or cheaper version of a product, it is difficult to get people to switch because they are unwilling to give up the network benefits associated with their current supplier. Other examples of products with network externalities include Microsoft's Windows (see Case Study 7.4 on the student website), Adobe's Acrobat (for PDF files) and airlines operating interconnecting routes (see Box 7.7).

Product differentiation and brand loyalty. If a firm produces a clearly differentiated product, where the consumer associates the product with the brand, it will be very difficult for a new firm to break into that market.

Definitions

Network externalities or network economies The benefits a consumer obtains from consuming a good/service increase with the number of other people who use the same good/service.

In 1908, James Spengler invented, and patented, the electric vacuum cleaner. Later that year he sold the patent to his cousin's husband, William Hoover, who set about putting mass production in place. Decades after their legal monopoly (see below) ran out, people still associate vacuum-cleaning with Hoover and many of us would say that we are going to 'Hoover the carpet', despite using a Dyson, or other machine. When looking for some information by using an Internet search engine people often say 'they googled it'.

Other examples of strong brand image include Guinness®, Kellogg's® Cornflakes, Coca-Cola®, Nescafé® and Sellotape®. In many cases, strong brand presence would not be enough to *block* entry, but it might well reinforce other barriers.

More favourable or complete control over access to customers. If a firm can gain more favourable access or control over the best outlets through which the product is sold, this can hinder the ability of new entrants to gain access to potential customers. For example, approximately 50 per cent of public houses (pubs) in the UK operate on tenancy contracts known as the 'tied lease model'. This is effectively an exclusive supply contract which means that landlords of such pubs have to purchase almost all of their beverages from the pub company (e.g. Enterprise Inns, Punch Taverns and J. D. Wetherspoon) that owns the pub.

Legal protection. The firm's monopoly position may be protected by patents on essential processes, by copyright, by various forms of licensing (allowing, say, only one firm to operate in a particular area) and by tariffs (i.e. customs duties) and other trade restrictions to keep out foreign competitors. Examples of monopolies protected by patents include most new medicines developed by pharmaceutical companies, Microsoft's Windows operating systems and agro-chemical companies, such as Monsanto, with various genetically modified plant varieties and pesticides.

Mergers and takeovers. The monopolist can put in a takeover bid for any new entrant. The mere threat of takeovers may discourage new entrants.

Aggressive tactics. An established monopolist can probably sustain losses for longer than a new entrant. Thus it can start a price war, mount massive advertising campaigns, offer an attractive after-sales service, introduce new brands to compete with new entrants, and so on.

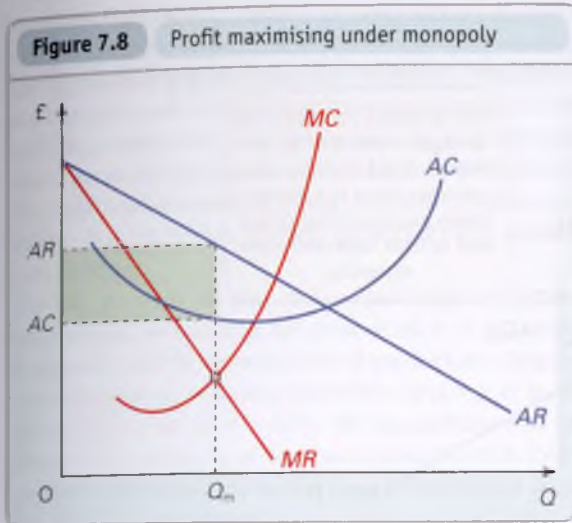

Intimidation. The monopolist may resort to various forms of harassment, legal or illegal, to drive a new entrant out of business.

Equilibrium price and output

Since there is, by definition, only one firm in the industry, the firm's demand curve is also the industry demand curve.

Compared with other market structures, demand under monopoly will be relatively inelastic at each price. The

Figure 7.8 Profit maximising under monopoly

monopolist can raise its price and consumers have no alternative firm in the industry to turn to. They either pay the higher price or go without the good altogether.

Unlike the firm under perfect competition, the monopoly firm is a 'price maker'. It can choose what price to charge. Nevertheless, it is still constrained by its demand curve. A rise in price will lower the quantity demanded. Be careful not to fall into the trap of thinking that a monopoly can control both price *and* output simultaneously.

As with firms in other market structures, a monopolist will maximise profit where $MR = MC$. In Figure 7.8, profit is maximised at Q_m . The supernormal profit obtained is shown by the shaded area.

These profits will tend to be larger the less elastic is the demand curve (and hence the steeper is the MR curve), and thus the bigger is the gap between MR and price (AR). The actual elasticity will depend on whether reasonably close substitutes are available in *other* industries. The demand for a rail service will be much less elastic (and the potential for profit greater) if there is no bus service to the same destination.

Since there are barriers to the entry of new firms, these supernormal profits will not be competed away in the long run. The only difference, therefore, between short-run and long-run equilibrium is that in the long run the firm will produce where $MR = \text{long-run } MC$.

? Try this brain teaser. A monopoly would be expected to face an inelastic demand. After all, there are no direct substitutes. And yet, if it produces where $MR = MC$, MR must be positive and demand must therefore be elastic. Therefore the monopolist must face an elastic demand! Can you solve this conundrum?

Limit pricing

If the barriers to the entry of new firms are not total, and if the monopolist is making very large supernormal profits, there may be a danger in the long run of potential rivals

* LOOKING AT THE MATHS

From Figure 7.8, it can be seen that the less elastic the demand at the output where $MC = MR$, the greater will be the gap between AR and MR , and hence the further above MR will the price be. The relationship between price, MR (or MC) and price elasticity of demand (P_{ϵ_D}) is given by the following formula:

$$P = \frac{MR}{1 + (1/P_{\epsilon_D})}$$

Thus if $MR = MC = £12$ and $P_{\epsilon_D} = -4$, the profit-maximising price would be

$$\frac{£12}{1 + (1/-4)} = \frac{£12}{1 - 1/4} = \frac{£12}{0.75} = £16$$

Proof of this rule is given in Maths Case 7.2 on the student website. You can see simply by examining the formula, however, that the lower the elasticity, the greater will be the price relative to MR or MC .¹

What is the profit-maximising price if $MR = MC = £12$ and $P_{\epsilon_D} = -2$?

¹ Note that this formula works only if demand is elastic, as it must be if MR is positive (which it will be, since MC must be positive).

breaking into the industry. In such cases, the monopolist may keep its price down and thereby deliberately restrict the size of its profits in the short run so as not to attract new entrants. This practice is known as **limit pricing**.

In Figure 7.9, three AC curves are drawn: one for the monopolist (firm M), one for a potential entrant (firm A) and one for another potential entrant (firm B). It is assumed that the monopolist has an absolute cost advantage over both potential entrants (e.g. more favourable access to factor inputs) so it has a lower AC curve over all levels of output. Any potential new entrant, if it is to compete successfully with the monopolist, must charge the same price or a lower one (assuming no product differentiation).

The short-run profit-maximising position for the monopolist is to produce where $MC = MR$. This is illustrated at point a in Figure 7.9. The firm will produce an output of Q_1 and charge a price of P_1 . If it faces potential competition from a new entrant such as firm A, it can charge this price without any fear of entry. Firm A's average costs are above this profit-maximising price and so it would not be profitable to enter the market at this price or any level below it. The barriers to entry for firm A are total.

Definition

Limit pricing Where a monopolist (or oligopolist) charges a price below the short-run profit-maximising level in order to deter new entrants.

Figure 7.9 Limit pricing

However, if a potential new entrant, such as firm B, had average costs below P_1 , it could make supernormal profits by entering at that price. In such a case, it is in the monopolist's interests to charge the lower price of P_L , and produce Q_2 , to deter firm B from entering the market. At a price of P_L , the best firm B could do would be to make just normal profit by producing Q_3 (point *b*). However, if it did enter the market and the monopolist continued to produce Q_2 , the market price would fall below P_L and the new entrant would make a loss at any output. Thus, P_L can be seen as a *limit price* – a price ceiling, at or below which potential new entrants will be deterred from entering the industry.

P_L may be below the monopolist's short-run profit-maximising price, but it may prefer to limit its price to P_L to protect its long-run profits from the damage caused by competition.

Fear of government intervention to curb the monopolist's practices may have a similar restraining effect on the price that the monopolist charges. In the UK, the Competition and Markets Authority may undertake an investigation, see section 14.1 for more on this.

1. What does this analysis assume about the price elasticity of demand for the new entrant (a) above P_L ; (b) below P_L ?
2. Can you think of any limitations with the limit price model?

Monopoly and the public interest

Disadvantages of monopoly

There are several reasons why monopolies may be against the public interest. As we shall see in Chapter 14, these have given rise to legislation to regulate monopoly power and/or behaviour.

Higher price and lower output than under perfect competition (short run). Figure 7.10 compares the profit-maximising position for an industry under monopoly with that under perfect competition. The monopolist will produce Q_1 at a price of P_1 . This is where $MC = MR$.

If the same industry operated under perfect competition, however, it would produce at Q_2 and P_2 – a higher output and a lower price. This is where industry supply under perfect competition equals industry demand. (Remember, we showed in section 7.2 that the firm's supply curve under perfect competition is its MC curve and thus the industry's supply curve is simply the *industry MC* curve: the MC curve shown in Figure 7.10.)

This analysis is based on the assumption that the industry has the *same AC and MC* curves whether under perfect competition or run as a monopoly. For example, suppose some potato farmers initially operate under perfect competition.

Figure 7.10 Equilibrium of the industry under perfect competition and monopoly: with the same MC curve

The market price is P_2 in Figure 7.10. Then they set up a marketing agency through which they all sell their potatoes. The agency therefore acts as a monopoly supplier to the market and charges a price of P_1 . Since it is the same farmers before and after, production costs are unlikely to have changed much. But as we shall see below, even if an industry has lower AC and MC curves under monopoly than under perfect competition, it is still likely to charge a higher price and produce a lower output.

When we were looking at the advantages of perfect competition, we said that the level where $P = MC$ could be argued to be the *optimum* level of production. Clearly, if a monopolist is producing below this level (e.g. at Q_1 in Figure 7.10 – where $P > MC$), the monopolist can be argued to be producing at *less* than optimal output. Consumers would be prepared to pay more for additional units than they cost to produce.

Higher price and lower output than under perfect competition (long run). Under perfect competition, freedom of entry eliminates supernormal profit and forces firms to produce at the bottom of their $LRAC$ curve. The effect, therefore, is to keep long-run prices down. Under monopoly, however, barriers to entry allow profits to remain supernormal in the long run. The monopolist is not forced to operate at the bottom of the AC curve. Thus, other things being equal, long-run prices will tend to be higher, and hence output lower, under monopoly.

Possibility of higher cost curves due to lack of competition. The sheer survival of a firm in the long run under perfect competition requires that it uses the most efficient known technique, and develops new techniques wherever possible. The monopolist, however, sheltered by barriers to entry, can still make large profits even if it is not using the most efficient technique. It has less incentive, therefore, to be efficient (see Box 7.4).

On the other hand, if it can lower its costs by using and developing more efficient techniques, it can gain extra supernormal profits which will not be competed away.

Unequal distribution of income. The high profits of monopolists may be considered as unfair, especially by competitive firms, or anyone on low incomes for that matter. The scale of this problem obviously depends on the size of the monopoly and the degree of its power. The monopoly profits of the village store may seem of little consequence when compared to the profits of a giant national or international company.

? *If the shares in a monopoly (such as a water company) were very widely distributed among the population, would the shareholders necessarily want the firm to use its monopoly power to make larger profits?*

In addition to these problems, monopolies may lack the incentive to introduce new product varieties, and large

monopolies may be able to exert political pressure and thereby get favourable treatment from governments.

Advantages of monopoly

Despite these arguments, monopolies can have some advantages.

Economies of scale. The monopoly may be able to achieve substantial economies of scale due to larger plant, centralised administration and the avoidance of unnecessary duplication (e.g. a monopoly water company would eliminate the need for several sets of rival water mains under each street). If this results in an MC curve substantially below that of the same industry under perfect competition, the monopoly will produce a *higher* output at a *lower* price. In Figure 7.11, the monopoly produces Q_1 at a price of P_1 , whereas the perfectly competitive industry produces Q_2 at the higher price P_2 .

Note that this result follows only if the monopoly MC curve is below point x in Figure 7.11. Note also that since an industry cannot exist under perfect competition if substantial economies of scale can be gained, it is somewhat hypothetical to make the comparison between a monopoly and an alternative situation that could not exist. What is more, were the monopolist to follow the $P = MC$ rule observed by perfectly competitive firms, it would charge an even lower price (P_3) and produce an even higher output (Q_3).

Possibility of lower cost curves due to more research and development and more investment. Although the monopolist's sheer survival does not depend on its finding ever more efficient methods of production, it can use part of its supernormal profits for research and development and investment. It thus has a greater ability to become efficient than has the small firm with limited funds.

Figure 7.11 Equilibrium of the industry under perfect competition and monopoly: with different MC curves

BOX 7.4

GOOGLE – A MONOPOLY ABUSING ITS MARKET POWER?

Searching for market dominance?

The early days of search engines and the rise of Google

Google is in a dominant position in the general Internet search engine market. In January 2017, it had a 80.47 per cent share of the global desktop search engine market and a 94.87 per cent share of the global mobile/tablet search engine market.

However, this has not always been the case. It is hard to imagine now but when the company began in 1997 it was a new entrant, doing battle with other established firms that dominated this new dynamic and growing market.

In 1994, Lycos® and Webcrawler® were the first businesses to introduce modern search engine services, where a user could input a general query and obtain a results page. AltaVista® entered the market in 1995 and soon became the dominant player as it provided a results page that users found the most useful. By the end of 1997, this search engine was receiving 80 million hits per day and was the sole provider of Internet search software for Yahoo.

Other companies such as Inktomi and HotBot entered the market successfully but Google began to rise to prominence at the turn of the century. Its global market share grew dramatically from less than 5 per cent at the beginning of 2000 to over 50 per cent by 2003. By 2007, it had reached the dominant position it has today.

Google appears to have obtained a dominant position in the market by using superior technology to search the web. Its initial success is largely credited to it providing a results page that its users found far more useful than those of its rivals. It has now remained in a dominant position for over 10 years.

Google's barriers to entry

Is there any evidence that Google has engaged in business activities whose sole purpose is to prevent or limit competition? Has it created any strategic barriers to entry?

Some switching costs may exist because of the existence of *network externalities*. As more people use the same search engine it enables the provider to collect more data about users' search behaviour. This information helps the firm to improve its search-engine results page making it more difficult for a new entrant to compete with a much smaller user base. This is an example of a structural barrier to entry because it is a result of the underlying characteristics of the industry. The size of these network externalities are smaller, however, in the Internet search market than for companies in other digital industries such as Facebook in the social media market.

Other switching costs appear to be trivial. Any search engine can be used irrespective of the device (desktop or mobile), the operating system or the web browser being used. The service is free so there are no contractual switching costs. The search costs are minimal – a search engine can be used to find its rivals. The learning costs are also small. Although there may be some variation in the presentation of the results, once users have become accustomed to one search engine they can easily use another.

It is hard to see how Google does anything to 'lock-in' its users: i.e. strategically increasing switching costs to such a level that consumers are prevented from switching to other search engines they would find more useful. If Google introduced a small fee for its search services, the majority of users would probably quickly switch to one of its rivals.

BOX 7.5

X INEFFICIENCY

The cost of a quiet life

The major criticism of monopoly has traditionally been that of the monopoly's power in selling the good. The firm charges a price above MC (see Figure 7.10). This is seen as *allocatively inefficient* because at the margin consumers are willing to pay more than it is costing to produce ($P > MC$); and yet the monopolist is deliberately holding back, so as to keep its profits up. Allocative inefficiency is examined in detail in section 12.1.

But monopolies may also be inefficient for another reason: they may have higher costs. Why is this?

Higher costs may be the result of *X inefficiency*¹ (sometimes known as *technical inefficiency*). Without

competitive pressure on profit margins, cost control may become lax. The firm may employ too many staff and spend on prestigious buildings and equipment. There may be less effort to keep technologically up to date, to research new products, or to develop new domestic and export markets.

The more comfortable the situation, the less may be the effort which is expended to improve it. The effect of this *X inefficiency* is to make the AC and MC curves higher than they would otherwise be. The outcome is that consumers pay higher prices and the firm moves even further away from the efficient, competitive, outcome.

EU investigation

However, after an investigation that began in 2010, the European Commission (EC) sent Google a 'Supplementary Statement of Objections' in July 2016. One of these objections relates to the way the general search page displays the results from a product search enquiry. The EC has accused Google of taking advantage of its dominant position in the general search engine market to suppress competition in another market where it faces much greater competition – the comparison shopping services market.

Comparison shopping websites collect product information together from participating retailers and display them on a single results page in response to a shopper's search enquiry. The EC argued that Google had systematically favoured its own comparison shopping service – Google Shopping. The shopping service appears as a very prominent box of images and links at the top of the general search results page. By doing this, Google is accused of potentially preventing consumers from seeing the comparison shopping websites they would find the most useful.

The EC noted that Google's first comparison shopping service 'Froogle' was not very successful. The subsequent services 'Google Product Search' and 'Google Shopping' have grown far more rapidly after changes to the presentation of results were introduced. Concerns have been expressed that Google's actions have significantly weakened its rivals in the comparison shopping market and deterred potential new entrants.

Google responded to the objections in November 2016 by complaining about the way the online shopping market was defined. In its report, the EC concluded that comparison

shopping services and merchant platforms such as eBay and Amazon were separate markets. Google argued that general search engines, comparison shopping sites, supplier websites and merchant platforms are all effectively in competition with each other. It referred to studies in the USA which found that 55 per cent of customers start their online shopping using Amazon, 28 per cent start on a search engine, while 16 per cent start by going straight to the individual suppliers' website. Although Google is becoming increasingly dominant in comparison shopping services, it argues that this is just one small part of a much bigger market.

The EC argues they are separate markets as companies such as Amazon pay comparison shopping service websites for referrals. Google's response is that it is quite possible for companies simultaneously to compete and co-operate with one another.

In June 2017, the EC imposed a record fine of €2.4 billion on Google for abusing its dominant market position. Google appealed against this fine to the General Court in September 2017. It will be interesting to see how this legal battle develops over the next few years.

1. Explain why network externalities are much smaller in the general Internet search market than they are for social media.
2. Provide a critique of Google's responses to the European Commission.

¹ 'Antitrust: Commission takes further steps in investigations alleging Google's comparison shopping and advertising-related practices breach EU rules', European Commission, Press release, 14 July 2016.

Following the financial crisis in 2007/8 and subsequent recession, there were significant reductions in X inefficiency in many countries. To cope with falling sales, and a fall in both sales and profits, many firms embarked on cost-cutting programmes. Much out-of-date plant was closed down, and employment was reduced. Those firms that survived the recession (and many did not) tended to emerge both more competitive and more efficient.

A further factor in the reduction in X inefficiency has been the growth in international competition. Even if a firm has monopoly power at home, the growth in global markets and e-commerce (see Box 7.3), and reductions in customs duties and other

barriers to trade (see section 24.2), provide fiercer competition from abroad.

1. How might you measure X inefficiency?
2. Another type of inefficiency is productive inefficiency. What do you think this is? (Clue: it has to do with the proportions in which factors are used.)
3. Explain why X inefficiency might be more common in state monopolies than those owned by shareholders.

¹ This term was coined by Harvey Leibenstein, 'Allocative efficiency or X efficiency', *American Economic Review*, June 1966.

BOX 7.6

CUT-THROAT COMPETITION

CASE STUDIES AND APPLICATIONS

The UK razor market

The market for wet razors and their blades is worth approximately £400 million in the UK. It was traditionally dominated by two producers, Gillette® and Procter & Gamble (P&G), with more than two thirds of sales between them. When they merged in 2007, the result was a new unified firm with substantial monopoly power. The Wilkinson Sword brand, owned by Edgewell Personal Care, was the next largest manufacturer in the UK, with around 18 per cent of sales. These two businesses also dominate the \$3 billion US market.

The industry displays many of the characteristics we would expect of a market dominated by one large firm – very high levels of advertising and strong branding that make it difficult for new entrants. There is also evidence of ongoing innovation: where once the twin-blade razor was a novelty, now five blades are the norm.

New entrants: the US market

Yet, despite all the potential barriers to entry, some new firms have successfully entered the market in recent years and changed the way that many customers purchase their razors. The most successful of all these businesses is the Dollar Shave Club. Founded in California in 2011, this company has had a significant impact on the US market. It introduced an innovative subscription service: customers sign up via the company's website for a year's supply of 60 standard twin-blade razor cartridges, which are delivered to their homes for \$1 per month.

Perhaps the most novel aspect of this business was its marketing strategy. As a new start-up, it did not have the multimillion-dollar advertising budget to compete with Gillette and Wilkinson Sword in traditional methods of marketing. It decided, instead, to launch its products using humorous YouTube videos featuring the company's CEO Michael Dublin. Its first video cost \$4500 and included advertising messages such as 'Do you think your razor needs a vibrating handle, a flashlight, a back scratcher and 10 blades? ... So stop paying for shave tech you don't need.'

The focus of the business is clearly on price rather than product differentiation.

Within two hours of posting its first video the company's website crashed and within six hours it had completely sold out of stock. The video has been viewed over 20 million times and has proved to be a very successful marketing tool. Sales increased from \$4 million in 2012 to \$200 million in 2016 and the company has a 15 per cent share of the US market for

razor cartridges. Its impact on the way many customers purchase razors has been dramatic. Online sales in the USA have increased rapidly and now account for 8 per cent of the razor market.

Other new start-ups, such as Harry's, Razor Co and Shave Mob, have also entered the growing online market. In the USA, P&G has responded to this competition by launching its own subscription service for its Gillette brand in 2014.

New entrants: the UK market

Similar changes have also occurred in the UK market. The King of Shaves razor was launched in 2008, with a view to building on the success of the brand's shaving gel and foams. The company worked on developing a lower-cost, lightweight alternative to the products offered by Gillette and Wilkinson Sword. It also tried to make greater use of online advertising, e-mail and social media to market its product.

However, the company has found it tough to compete successfully. It made losses of £959 000 in 2014 before making a profit in 2016 for the first time since 2009. Its recent improvement in performance appears to have come from switching more of its sales to its online subscription service.

Cornerstone also operates a subscription service in the UK where customers can have razor blades and skincare products delivered every 2, 6 or 18 weeks.

Perhaps the biggest threat to P&G's dominant position in this global industry will come from the decision of Unilever to enter the razor market. In July 2016, it purchased the Dollar Shave Club for \$1 billion. With the financial backing of the third largest consumer goods company in the world, this new entrant could now pose serious competition. It will be interesting to see if the Gillette brand name can maintain its dominant market position.

1. What are the characteristics of the razor market that present barriers to entry for new firms? How have companies, such as Dollar Shave Club, sought to overcome these barriers?
2. High levels of innovation have been a key characteristic of the market for wet razors for many years. Do these always benefit the consumer?
3. It has been estimated that Gillette makes a profit of 3000 per cent on each razor blade sold. Explain how this figure might have arisen.

Competition for corporate control. Although a monopoly faces no competition in the goods market, it may face an alternative form of competition in financial markets. A monopoly, with potentially low costs, which is currently run inefficiently, is likely to be subject to a takeover bid from another company. This **competition for corporate control** may thus force the monopoly to be efficient in order to avoid being taken over.

Innovation and new products. The promise of supernormal profits, protected perhaps by patents, may encourage the

Definition

Competition for corporate control The competition for the control of companies through takeovers.

development of new (monopoly) industries producing new products.

Monopoly and price discrimination

One further characteristic of monopoly is that it allows firms to price discriminate: to charge different prices either

to all customers or to different groups of customers. Firms undertake this as a way of further increasing profits. The ability to price discriminate rests on the firm having some monopoly power, although this need not be a complete monopoly. Price discrimination is discussed in more detail in section 8.4, pages 238–40.

Section summary

1. A monopoly is where there is only one firm in an industry. In practice, it is difficult to determine that a monopoly exists because it depends on how narrowly an industry is defined.
2. Barriers to the entry of new firms are usually necessary to protect a monopoly from competition. They may be either structural or strategic barriers.
3. Such barriers include cost advantages: these include economies of scale – perhaps with the firm being a natural monopoly – and absolute cost advantages, such as more favourable access or control over key inputs, the use of superior technology, more efficient production methods or economies of scope.
4. Barriers also include switching costs for customers, more favourable or complete control over access to customers, product differentiation, patents or copyright and tactics to eliminate competition (such as takeovers or aggressive advertising).
5. Profits for the monopolist (as for other firms) will be maximised where $MC = MR$. In the case of monopoly, this will probably be at a higher price relative to marginal cost than for other firms, due to the less elastic nature of its demand at any given price.
6. Monopolies may be against the public interest to the extent that they charge a higher price relative to cost than do competitive firms; if they cause a less desirable distribution of income; if a lack of competition removes the incentive to be efficient and innovative; and if they exert undesirable political pressures on governments.
7. On the other hand, any economies of scale will in part be passed on to consumers in lower prices, and the monopolist's high profits may be used for research and development and investment, which in turn may lead to better products at possibly lower prices.

7.4 THE THEORY OF CONTESTABLE MARKETS

Potential competition or monopoly?

In recent years, economists have developed the theory of contestable markets. This theory argues that what is crucial in determining price and output is not whether an industry is *actually* a monopoly or competitive, but whether there is the real *threat* of competition.

If a monopoly is protected by high barriers to entry – for example, it controls the supply of the key raw materials – then it will be able to make supernormal profits with no fear of competition.

If, however, another firm *could* potentially take away all of its customers with little difficulty, it will behave much more like a competitive firm. The threat of competition has a similar effect to actual competition.

As an example, consider a catering company engaged by a university to run its cafés and coffee bars. The catering company has a monopoly over the supply of food to the students at the university assuming there are no other eating places nearby. If, however, it starts charging high prices or providing a poor service, the university could offer the running of

the cafés to an alternative catering company. This threat may force the original catering company to charge 'reasonable' prices and offer a good service.

Perfectly contestable markets

A market is *perfectly contestable* when potential rivals (a) face no costs of entry and exit (b) can rapidly enter the market before the monopolist has time to respond. In such cases, the instant it becomes possible to earn supernormal profits, new firms will quickly enter the market and charge a price below the monopolist's price.

If the monopolist is unable to respond immediately, the new entrant sells to all of the customers in the market and makes supernormal profit. When the monopolist finally

Definition

Perfectly contestable market A market where there is free and costless entry and exit and the monopolist cannot immediately respond to entry.

Definition

Hit and run A strategy whereby a firm is willing to enter a market and make short-run profits and then leave again when the existing firm(s) cut prices. Costless exit makes hit-and-run behaviour more likely.

does respond by cutting its own prices, profits are driven back down towards their normal level. At that stage the new entrant is able to exit the market costlessly. This is known as 'hit and run'.

The sheer threat of this happening, so the theory goes, will ensure that the firm already in the market will (a) keep its prices down, so that it just makes normal profits, and (b) produce as efficiently as possible, taking advantage of any economies of scale and any new technology. If it did not do this, rivals would enter, and potential competition would become actual competition.

This is illustrated in Figure 7.12. Assume that there is only one firm in the industry, which faces a long-run average cost curve given by $LRAC$. Assume that profits are maximised at a price of P_1 , with supernormal profits being shown by the shaded area. If entry and exit costs are high, the price will remain at this level. If entry and exit costs are low, however, rival firms may be tempted to enter, charge a slightly lower price than the monopoly and take all of its customers.

To avert this, the existing firm will have to lower its price. In the case of zero entry and exit costs, the monopolist will have to lower its price to P_2 , where price equals $LRAC$, and where, therefore, profits are normal and would not attract rival firms to enter. At the same time, the monopolist will have to ensure that its $LRAC$ curve is as low as possible (i.e. that it avoids any X inefficiency (see Box 7.5)).

Contestable markets and natural monopolies

So why in such cases are the markets not *actually* perfectly competitive? Why do they remain monopolies?

The most likely reason has to do with economies of scale and the size of the market. To operate close to its minimum efficient scale, the firm may have to be so large relative to the market that there is only room for one such firm in the industry. If a new firm does come into the market, then one or other of the two firms will not survive the competition. The market is simply not big enough for both of them. This is the case in Figure 7.12. The industry is a natural monopoly, given that the $LRAC$ curve is downward sloping even at output c .

If, however, there are no entry or exit costs, new firms will be perfectly willing to enter even though there is only room for one firm – either because they believe that they are more

Figure 7.12 A contestable monopoly

efficient than the established firm or because they are willing to engage in hit-and-run competition. The established firm, knowing this, will be forced to produce as efficiently as possible and with only normal profit.

The importance of costless exit

There is always an element of risk whenever a firm is thinking of entering an industry. It is often difficult to forecast its costs and future demand accurately and there is no guarantee these forecasts will prove to be correct. For example, there could be an unanticipated fall in demand for the product caused by a negative shock such as a recession; the technology used by the entrant might quickly become obsolete, especially if it is entering an industry with high levels of innovation; the established firm may respond far more quickly to the new firm's entry than anticipated, leaving it unable to make any supernormal profit.

But does this risk matter? Cannot a new entrant engage in hit-and-run competition and quickly leave a market? This depends on the costs of exit – on the extent of *sunk costs* (see page 156). Setting up in a new business often involves large expenditures on physical capital (plant and machinery), advertising and complying with government regulations. Once this money is spent, it may not be possible to recover. For example, the losing firm may be left with capital equipment that it cannot use or sell. The firm may therefore be put off entering in the first place. The market is not perfectly contestable; the established firm can make supernormal profit.

If, however, the capital equipment does generate the same return in *alternative* uses, the exit costs will be zero (or at least very low), and new firms will be more willing to make the necessary investment and take the risks of entry. For example, a rival coach company may open up a service on a

route previously operated by only one company, and where there is still only room for one operator. If the new firm loses the resulting battle, it can still use the coaches it has purchased. It simply uses them for a different route. The cost of the coaches is not a sunk cost.

Costless exit, therefore, encourages firms to enter an industry, knowing that, if unsuccessful, they can always transfer their capital elsewhere.

The lower the exit costs, the more contestable the market. This implies that firms already established in other similar markets may provide more effective competition against monopolists, since they can simply transfer capital from one market to another. For example, studies of airlines in the USA show that entry to a particular route may be much easier for an established airline, which can simply transfer planes from one route to another (see Box 7.7).

In which of the following industries are exit costs likely to be low: (a) steel production; (b) market gardening; (c) nuclear power generation; (d) specialist financial advisory services; (e) production of a new drug; (f) street food; (g) car ferry operators? Do these exit costs depend on how narrowly the industry is defined?

Assessment of the theory

The theory of contestable markets is an improvement on simple monopoly theory, which merely focuses on the existing structure of the industry and makes no allowance for potential competition.

Perfectly contestable markets may exist only rarely. But, like perfect competition, they provide an *ideal type* against which to judge the real world. It can be argued that they provide a more useful ideal type than perfect competition, since they provide a better means of predicting firms' price and output behaviour than does the simple portion of the market currently supplied by the existing firm.

One criticism of the theory, however, is that it does not take sufficient account of the possible reactions of the established firm. There could be a contestable market, with no barriers to entry or exit, but the established firm may signal

very clearly that it will respond immediately if any firm dares to enter its market. The threat of facing an immediate price war might deter any potential entrant, allowing the established firm to continue charging high prices and making supernormal profits.

Perhaps the most important contribution of the theory is to help us focus on the importance of sunk costs when determining the threat of entry and performance of a market. Many of the factors that create barriers to entry, such as economics of scale and product differentiation/advertising, may only actually create a barrier to a new entrant if they involve expenditures that cannot be recovered if it later exits the market.

Contestable markets and the public interest

If a monopoly operates in a perfectly contestable market, it might bring the 'best of both worlds'. Not only will it be able to achieve low costs through economies of scale, but also the potential competition will keep profits and hence prices down.

For this reason, the theory has been seized on by politicians on the political right to justify a policy of laissez-faire (non-intervention) and deregulation (e.g. coach and air routes). They argue that the theory vindicates the free market. There are two points in reply to this:

- Few markets are *perfectly* contestable. If entry and exit are not costless, a monopoly can still make supernormal profits in the long run.
- There are other possible failings of the market beside monopoly power (e.g. inequality, pollution). These failings are examined in Chapters 11 and 12.

Nevertheless, the theory of contestable markets has highlighted the importance of sunk costs in determining monopoly behaviour. Monopolists may deliberately spend large amounts of money on advertising as they realise it increases the sunk costs of entry and hence deters new firms from entering its market. Many policy makers now focus on sunk costs when considering anti-monopoly policy.

BOX 7.7

AIRLINE DEREGULATION IN THE USA AND EUROPE

A case study of contestable markets

If a market is highly contestable, the mere threat of competition may successfully keep prices and profits down to near-competitive levels. Of course, established firms would be keen to erect barriers to entry and to make exit more costly for any firm that did enter.

Governments around the world are generally in favour of increased competition and frown on the erection of entry barriers (see section 14.1). This means that they generally prefer not to intervene if markets are competitive or highly contestable, but may attempt to regulate the prices, profits or behaviour of firms where competition or contestability is limited. Conversely, if markets have been regulated and yet are potentially competitive, many governments have then deregulated them (i.e. removed regulations).

A good case study of deregulation and contestability (or lack of it) is the airline industry. Here the reduction of regulations over decades has allowed low-cost airlines to build market share and challenge the large network carriers.

The USA

The airline industry in the United States was deregulated in 1978. Prior to that, air routes were allocated by the government, with the result that many airlines operated as monopolies or shared the route with just one other airline. Now there exists a policy of 'open skies'.

Initially the consequences were dramatic, with lower fares and, over many routes, a greater choice of airlines. The Brookings Institute calculated that, in the first 10 years of deregulation, the lower fares saved consumers some \$100 billion. One consequence of the increased competition was that many long-established US airlines went out of business.

Even where routes continued to be operated by just one or two airlines, fares still fell if the route was *contestable*: if the entry and exit costs remained low. In 1992, despite the bankruptcies, 23 new carriers were established in North America, and many routes were taken over by existing carriers.

But deregulation did not make all routes more contestable. In some cases the reverse happened. In a situation of rising costs and falling revenues, there were mergers and takeovers of the vulnerable airlines. By 2000, just 7 airlines accounted for over 90 per cent of American domestic air travel, compared with 15 in 1984. With this move towards greater monopolisation, some airlines managed to make their routes *less* contestable. The result was that air fares over the 1990s rose faster than prices in general.

A key ingredient in making routes less contestable was the development of a system of air routes radiating out from about 30 key or 'hub' airports. With waves of flights scheduled to arrive and depart within a short space of time, passengers can make easy connections at these hub airports.

The problem is that several of these hub airports became dominated by single airlines which, through economies of scale and the ownership or control of various airport facilities, such as boarding gates or check-in areas, could effectively keep out potential entrants. By 2002, at 15 of the hub airports, including some of the busiest, the dominant airline had a market share in excess of 70 per cent.

The airlines also used measures to increase contractual switching costs and thereby make entry barriers higher. These measures include frequent flier rewards, deals with travel agents and code sharing with 'partner' airlines.

The rise of the low-cost airlines. In the 2000s, however, the domestic US airlines market became more competitive again, thanks to the growth of low-cost carriers (LCCs), the largest being Southwest Airlines. These accounted for just 7 per cent of US domestic passengers in 1990; by 2009 this had risen to 34 per cent and in 2013, for the first time, LCCs had a greater market share than the network carriers. The response of the major airlines was to create their own low-cost carriers, such as Delta's 'Song' in 2004 and United's 'Ted' in 2004.

A danger here is that big airlines may use their LCCs to undercut the prices of small new entrants to drive them out of the market. Such 'predatory pricing' (see pages 246 and 422) is illegal, and the Department of Justice investigated several cases. However, predatory pricing is very difficult to distinguish from price competition between firms. Thus cases have been consistently dismissed by juries, who have concluded that there was insufficient proof that the big airlines were breaking the law. This issue re-emerged in 2011, when Delta Airlines was criticised for adopting predatory practices in order to maintain a monopoly position at Minneapolis St Paul Airport.

With the rise in fuel prices in 2006–8 and lower passenger numbers from 2007, resulting from the global recession, some of these new LCCs went out of business. Delta shut its Song division in 2006 and United shut Ted in 2008.

The whole industry has gone through a period of major consolidation with five big mergers reducing the number of large airlines from nine to four. For example, in 2011 Southwest acquired AirTran, another major low-cost carrier. This deal enabled it to remove one of its leading rivals. American, United, Delta and Southwest now control 80 per cent of the US market and some observers have expressed concerns about the lack of competition on prices. At 40 of the largest US airports, one airline now has the majority of the market. This was the case at 34 airports 10 years ago.

The US airline market is more competitive than it was before the industry deregulated in 1978. However, the level of competition has fallen dramatically in the past 10 years. It will be interesting to see if the threat of potential competition

constrains the pricing behaviour of the four big airlines in the future.

Europe

Until the early 1990s, the European air transport industry was highly regulated, with governments controlling routes. National routes were often licensed to the national airline and international routes to the two respective national airlines. Since 1993, the industry has been progressively deregulated and competition has increased, with a growing availability of discount fares. Now, within the EU, airlines are free to charge whatever they like, and any EU airline can fly on any route it wants, providing it can get the slots at the airports at either end.

As in the USA, however, whilst increased competition has benefited passengers, many of the airlines have tried to make their routes less contestable by erecting entry barriers. Predatory pricing occurred, as the established airlines tried to drive out new competitors. The proliferation of fare categories made it hard for consumers to compare prices, and established carriers' highly publicised fares often had many restrictions, with most people having to pay considerably higher fares. As in the USA, code sharing and airline alliances have reduced competition. Finally, at busy airports, such as Heathrow, the shortage of check-in and boarding gates, runways and airspace provided a major barrier to new entrants.

Nevertheless, new low-cost airlines, such as easyJet, Ryanair and Flybe, provided effective competition for the established national and short-haul international carriers, which were forced to cut fares on routes where they directly competed. British Airways went as far as re-badging their loss-making subsidiary regional airline as BA Connect in 2006, adopting a low-cost model and pledging to 'cut one third from standard domestic fares'. However, the company accrued further losses that year and was sold to Flybe in early 2007.

Low-cost airlines have been able to enter the market by using other airports, such as Stansted and Luton in the case of London, and various regional airports throughout Europe. Many passengers showed themselves willing to travel further at the beginning and end of their journey if the overall cost remained much lower. Ryanair, in particular, has made use of smaller airports located some way from major cities.

Lower costs

How do the LCCs compete? The airline industry does not on the face of it seem to be a highly contestable one. Apart from anything else, aircraft would appear to be a high-cost input.

The answer lies in a variety of cost-saving opportunities. The LCCs are able to lease planes rather than buy them; even when they own their own planes, the aircraft are generally older and more basic, offering a standard accommodation rather than different classes. The result is reduced exit costs, increasing

contestability. In addition, by charging extra for each item of luggage, they reduce the amount they carry, thus saving fuel.

There is also evidence of lower staff costs. Initially, LCCs paid less than the traditional airlines; however, this is no longer the case. Peter Belobaba, of MIT, has reported that since 2006 salaries and benefits for LCC employees have equalled those available to employees of the larger carriers. Yet productivity is measurably higher, with 15 per cent more available seat miles per employee.

The large hub-and-spoke carriers have also found that the very nature of their operations constricts their ability to compete with the LCCs on city-to-city routes. Not only are the hubs themselves expensive, but the movement of passengers in and out of the terminals takes longer than with smaller airports. Thus the LCCs, with operating costs some 25 to 50 per cent lower than the traditional carriers, have become a highly effective competitive force on these routes between various city pairs and have forced down prices.

Despite these successes, a period of increasing fuel prices and falling consumer demand from 2008 led some commentators to suggest that the LCCs were unlikely to survive. However, although they experienced some tough years, the LCCs have proved to be very resilient. They now account for about 40 per cent of the European aviation market and this share is forecast to grow in the future.

Ryanair and easyJet have also tried to make improvements to customer service. For example, Ryanair made changes to its website to make it easier and quicker to book tickets. Both companies have also tried to target more business customers. Ryanair introduced 'business plus' tickets, which give extra baggage allowance and premium seats at the front of the plane while remaining very price competitive.

Four of the biggest airlines in Europe are LCCs and it seems that the market will remain highly contestable for the foreseeable future.

1. Make a list of those factors that determine the contestability of a particular air route.
2. In the UK, train operators compete for franchises to run services on a particular route. The franchises are normally for 7, 10, 12 or 15 years. The franchise specifies prices and minimum levels of services (frequency, timing and quality). Would this be a good system to adopt in the airline market over particular routes? How is the airline market similar to/different from the rail market in this regard?
3. In a period of rising fuel prices, and thus higher airfares, do you think that the low-cost carriers are more or less vulnerable than the traditional carriers in the short term? Would your answer differ when we look at the longer-term decisions of passengers?
4. In a recession, do you think that the low-cost carriers are more or less vulnerable than the traditional carriers? And in a boom?

Section summary

- Potential competition may be as important as actual competition in determining a firm's price and output strategy.
- The threat of this competition increases as entry and exit costs to and from the industry diminish. If the entry and exit costs are zero, the market is said to be perfectly contestable. Under such circumstances, an existing monopolist will be forced to keep its profits down to the normal level if it is to resist entry by new firms. Exit costs will be lower, the lower are the sunk costs of the firm.
- The theory of contestable markets provides a more realistic analysis of firms' behaviour than theories based simply on the existing number of firms in the industry.

END OF CHAPTER QUESTIONS

- A perfectly competitive firm faces a price of £14 per unit. It has the following short-run cost schedule:

Output	0	1	2	3	4	5	6	7	8
TC (£)	10	18	24	30	38	50	66	91	120

- Copy the table and put in additional rows for average cost and marginal cost at each level of output. (Enter the figures for marginal cost in the space between each column.)
 - Plot AC , MC and MR on a diagram.
 - Mark the profit-maximising output.
 - How much (supernormal) profit is made at this output? t
 - What would happen to the price in the long run if this firm were typical of others in the industry? Why would we need to know information about long-run average cost in order to give a precise answer to this question?
- If the industry under perfect competition faces a downward-sloping demand curve, why does an individual firm face a horizontal demand curve?
 - If supernormal profits are competed away under perfect competition, why will firms have an incentive to become more efficient?
 - Is it a valid criticism of perfect competition to argue that it is incompatible with economies of scale?
 - On a diagram similar to Figure 7.4, show the long-run equilibrium for both firm and industry under perfect competition. Now assume that the demand for the product falls. Show the short-run and long-run effects.
 - Why is the profit-maximising price under monopoly greater than marginal cost? In what way can this be seen as inefficient?
 - On three diagrams like Figure 7.8, illustrate the effect on price, quantity and profit of each of the following: (a) a rise in demand; (b) a rise in fixed costs; (c) a rise in variable costs. In each case, show only the AR , MR , AC and MC curves.
 - Think of three examples of monopolies (local or national) and consider how contestable their markets are.

Very few markets in practice can be classified as perfectly competitive or as a pure monopoly. The vast majority of firms do compete with other firms, often quite aggressively, and yet they are not price takers: they do have some degree of market power. Most markets, therefore, lie between the two extremes of monopoly and perfect competition, in the realm of 'imperfect competition'.

There are two types of imperfect competition: monopolistic competition and oligopoly.

Under monopolistic competition, there will normally be quite a large number of relatively small firms. Think of the number of car repair garages, builders, hairdressers, restaurants and other small traders that you get in any large town or city. They are in fierce competition with each other, and yet competition is not perfect. They are all trying to produce a product that is different from their rivals.

Under oligopoly, there will be only a few firms competing. Most of the best-known companies, such as Ford, Coca-Cola, Nike, BP and Apple, are oligopolists. Sometimes oligopolists will attempt to collude with each other to keep prices up. On other occasions, competition will be intense, with rival firms trying to undercut each other's prices, or developing new or better products in order to gain a larger share of the market. We will examine both collusion and competition between oligopolists and show when each is more likely to occur.

8.1 MONOPOLISTIC COMPETITION

We will start by looking at monopolistic competition. This was a theory developed in the 1930s by the American economist Edward Chamberlin. Monopolistic competition is nearer to the competitive end of the spectrum. It can best be understood as a situation where there are a lot of firms competing, but where each firm does nevertheless have some degree of market power (hence the term 'monopolistic' competition): each firm has some choice over what price to charge for its products.

Assumptions of monopolistic competition

- There are *quite a large number of firms*. As a result, each firm has an insignificantly small share of the market, and therefore its actions are unlikely to affect its rivals to any great extent. This means that when each firm makes its decisions it does not have to worry how its rivals will react. It assumes that what its rivals choose to do will *not* be influenced by what it does.

This is known as the assumption of *independence*. (As we shall see later, this is not the case under oligopoly. There we assume that firms believe that their decisions *do* affect their rivals, and that their rivals' decisions will affect them. Under oligopoly, we assume that firms are *interdependent*.)

- There is *freedom of entry* of new firms into the industry. If any firm wants to set up in business in this market, it is free to do so.

In these two respects, therefore, monopolistic competition is like perfect competition.

- The situation differs from perfect competition, however, in that each firm produces a product or provides a service in some way different from those of its rivals. As a result, it can raise its price without losing all its customers. Thus its demand curve is downward sloping, although it will be relatively elastic given the large number of competitors to which customers can turn. This is known as the assumption of *product differentiation*.

Restaurants, hairdressers and builders are all examples of monopolistic competition.

-  Give some other examples of monopolistic competition. (Try looking at www.yell.com if you are stuck.)

Definitions

Independence (of firms in a market) Where the decisions of one firm in a market will not have any significant effect on the demand curves of its rivals.

Product differentiation Where one firm's product is sufficiently different from its rivals' to allow it to raise the price of the product without customers all switching to the rivals' products. A situation where a firm faces a downward-sloping demand curve.

Equilibrium of the firm

Short run

As with other market structures, profits are maximised at the output where $MC = MR$. The diagram will be the same as for the monopolist, except that the AR and MR curves will be more elastic. This is illustrated in Figure 8.1(a). As with perfect competition, it is possible for the monopolistically competitive firm to make supernormal profit in the short run. This is shown as the shaded area.

Just how much profit the firm will make in the short run depends on the strength of demand: the position and elasticity of the demand curve. The further to the right the demand curve is relative to the average cost curve, and the less elastic the demand curve is, the greater will be the firm's short-run profit. Thus a firm facing little competition and whose product is considerably differentiated from that of its rivals may be able to earn considerable short-run profits.

- Why may a food shop charge higher prices than supermarkets for 'essential items' and yet very similar prices for delicatessen items?
- Which of these two items is a petrol station more likely to sell at a discount: (a) oil; (b) sweets? Why?

Long run

If typical firms are earning supernormal profit, new firms will enter the industry in the long run. As they do, they will take some of the customers away from established firms. The demand for the established firms will therefore fall. Their demand (AR) curve will shift to the left, and will continue doing so as long as supernormal profits remain and thus new firms continue entering.

Long-run equilibrium is reached when only normal profits remain: when there is no further incentive for new firms to enter. This is illustrated in Figure 8.1(b). The firm's demand curve settles at D_L , where it is tangential to the firm's $LRAC$ curve. Output will be Q_L : where $AR_L = LRAC$. (At any other output, $LRAC$ is greater than AR and thus less than normal profit would be made.)

- Why does the $LRMC$ curve cross the MR_L curve directly below the tangency point of the $LRAC$ and AR_L curves?
- Assuming that supernormal profits can be made in the short run, will there be any difference in the long-run and short-run elasticity of demand? Explain.

Limitations of the model

There are various problems in applying the model of monopolistic competition to the real world:

- Information may be imperfect. Firms will not enter an industry if they are unaware of what supernormal profits are being made, or if they underestimate the demand for the particular product they are considering selling.

Figure 8.1 Equilibrium of the firm under monopolistic competition

- Given that the firms in the industry produce different products, it is difficult if not impossible to derive a demand curve for the industry as a whole. Thus the analysis has to be confined to the level of the firm.
- Firms are likely to differ from each other not only in the product they produce or the service they offer, but also in their size and cost structure. What is more, entry may not be *completely* unrestricted. Two petrol stations could not set up in exactly the same place – on a busy crossroads, say. Thus although the typical or ‘representative’ firm may earn only normal profit in the long run, other firms may be able to earn long-run supernormal profit. They may have some cost advantage or produce something that is impossible to duplicate perfectly.
- One of the biggest problems with the simple model shown in Figure 8.1 is that it concentrates on price and

output decisions. In practice, the profit-maximising firm under monopolistic competition also has to decide the exact variety of product to produce and how much to spend on advertising it. This will lead the firm to take part in non-price competition.

Non-price competition

Non-price competition involves two major elements: product development and advertising.

The major aims of *product development* are to produce a product that will sell well (i.e. one in high or potentially high demand) and that is different from rivals’ products (i.e. has a relatively inelastic demand due to lack of close substitutes). For shops or other firms providing a service, ‘product development’ takes the form of attempting to provide a

BOX 8.1 SELLING ICE CREAM AS A STUDENT

CASE STUDIES AND APPLICATIONS

John’s experience of monopolistic competition

When I was a student, my parents lived in Exeter in Devon, and at that time the city’s bypass became completely jammed on a summer Saturday as holidaymakers made their way to the coast. Traffic queues were several miles long.

For a summer job, I drove a small ice-cream van. Early on, I had the idea of selling ice cream from a tray to the people queuing in their cars. I made more money on a Saturday than the rest of the week put together. I thought I was on to a good thing.

But news of this lucrative market soon spread, and each week new ice-cream sellers appeared – each one reducing my earnings! By the middle of August there were over thirty ice-cream sellers from five different ice-cream companies. Most tried to get to the beginning of the queue, to get ahead of their rivals.

Imagine the scene. A family driving to the coast rounds a bend and is suddenly met by a traffic jam and several ice-cream sellers all jostling to sell them an ice cream. It was quite surreal. Not surprisingly, many of the potential customers refused to buy, feeling somewhat intimidated by the spectacle. It was not long before most of us realised that it was best to disperse and find a section of the road where there were no other sellers.

But with so many ice-cream sellers, no one made much money. My supernormal earnings had been reduced to a normal level. I made about the same on Saturday to people stuck in queues as I would have done if I had driven my van around the streets.

- Was there totally free entry to this market?
- What forms of product differentiation were there?

Definitions

Non-price competition Competition in terms of product promotion (advertising, packaging, etc.) or product development.

Excess capacity (under monopolistic competition) In the long run, firms under monopolistic competition will produce at an output below their minimum-cost point.

service which is better than, or at least different from, that of rivals: personal service, late opening, certain lines stocked, and so on.

The major aim of *advertising* is to sell the product. This can be achieved not only by informing the consumer of the product's existence and availability, but also by deliberately trying to persuade consumers to purchase the good. Like product development, successful advertising will not only increase demand, but also make the firm's demand curve less elastic since it stresses the specific qualities of this firm's product over its rivals' (see Box 2.4 on page 61).

Product development and advertising not only increase a firm's demand and hence revenue, they also involve increased costs. So how much should a firm advertise to maximise profits?

For any given price and product, the optimal amount of advertising is where the revenue from *additional* advertising (MR_A) is equal to its cost (MC_A). As long as $MR_A > MC_A$, additional advertising will add to profit. But extra amounts spent on advertising are likely to lead to smaller and smaller increases in sales. Thus MR_A falls, until $MR_A = MC_A$. At that point, no further profit can be made. It is at a maximum.

? Why will additional advertising lead to smaller and smaller increases in sales?

Two problems arise with this analysis:

- The effect of product development and advertising on demand will be difficult for a firm to forecast.
- Product development and advertising are likely to have different effects at different prices. Profit maximisation, therefore, will involve the more complex choice of the optimum combination of price, type of product, and level and variety of advertising.

Monopolistic competition and the public interest

Comparison with perfect competition

It is often argued that monopolistic competition leads to a less efficient allocation of resources than perfect competition.

Figure 8.2 compares the long-run equilibrium positions for two firms. One firm is under perfect competition and thus faces a horizontal demand curve. It will produce an output of Q_1 at a price of P_1 . The other is under monopolistic

competition and thus faces a downward-sloping demand curve. It will produce the lower output of Q_2 at the higher price of P_2 . A crucial assumption here is that a firm would have the *same* long-run average cost ($LRAC$) curve in both cases. Given this assumption, monopolistic competition has the following disadvantages:

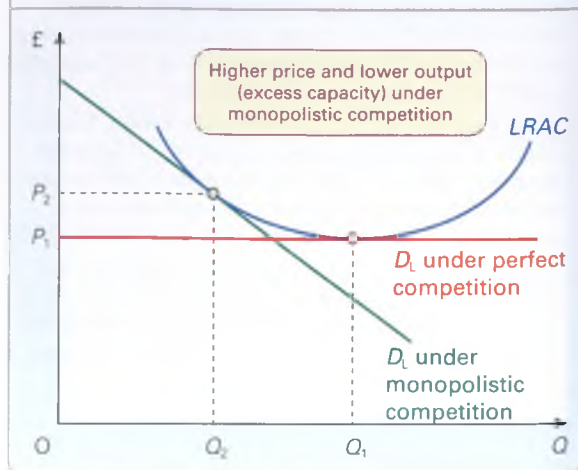

- Less will be sold and at a higher price.
- Firms will not be producing at the least-cost point.

By producing more, firms would move to a lower point on their $LRAC$ curve. Thus firms under monopolistic competition are said to have *excess capacity*. In Figure 8.2 this excess capacity is shown as $Q_1 - Q_2$. In other words, monopolistic competition is typified by quite a large number of firms (e.g. petrol stations), all operating at an output less than that necessary to achieve minimum cost, and thus being forced to charge a price above that which they could charge if they had a bigger turnover. How often have you been to a petrol station and had to queue for the pumps.

? Does this imply that if, say, half of the petrol stations were closed down, the consumer would benefit? (Clue: what would happen to the demand curves of the remaining stations?)

On the other hand, it is often argued that these wastes of monopolistic competition may be insignificant. In the first place, although the firm's demand curve is downward sloping, it is still likely to be highly elastic due to the large number of substitutes. In the second place, although the firm under monopolistic competition will not be operating quite at the bottom of its $LRAC$ curve, the nature of the industry may allow some economies of scale to be gained. The $LRAC$ curve would thus be lower than in the case of the larger

Figure 8.2 Long-run equilibrium of the firm under perfect and monopolistic competition

number of smaller firms that would be necessary to keep the industry perfectly competitive. The size of the economies of scale, if any, will obviously vary from industry to industry.

Perhaps more importantly, consumers are likely to benefit from monopolistic competition by having a greater variety of products to choose from. Given that we all have individual tastes and preferences, our utility will be higher with choice.

Which would you rather have: five restaurants to choose from, each with very different menus and each having spare tables so that you could always guarantee getting one; or just two restaurants to choose from, charging less but with

less choice and making it necessary to book well in advance?

Comparison with monopoly

The arguments here are very similar to those comparing perfect competition and monopoly.

On the one hand, freedom of entry for new firms and hence the lack of long-run supernormal profits under monopolistic competition are likely to help keep prices down for the consumer and encourage cost saving. On the other hand, monopolies are likely to achieve greater economies of scale and have more funds for investment and research and development.

Section summary

1. Monopolistic competition occurs where there is free entry to the industry and quite a large number of firms operating independently of each other, but where each firm has some market power as a result of producing differentiated products or services.
2. In the short run, firms can make supernormal profits. In the long run, however, freedom of entry will drive profits down to the normal level. The long-run equilibrium of the firm is where the (downward-sloping) demand curve is tangential to the long-run average cost curve.
3. The long-run equilibrium is one of excess capacity. Given that the demand curve is downward sloping, its tangency point with the *LRAC* curve will not be at the bottom of the *LRAC* curve. Increased production would thus be possible at *lower* average cost.
4. In practice, supernormal profits may persist into the long run: firms have imperfect information; entry may not be completely unrestricted; firms may use non-price competition to maintain an advantage over their rivals.
5. Non-price competition may take the form of product development or product promotion (advertising, etc.).
6. Monopolistically competitive firms, because of excess capacity, may have higher costs than perfectly competitive firms, but consumers may gain from a greater diversity of products.
7. Monopolistically competitive firms may have fewer economies of scale than monopolies and conduct less research and development, but the competition may keep prices lower than under monopoly.

8.2 OLIGOPOLY

Oligopoly occurs when just a few firms between them share a large proportion of the industry.

There are, however, significant differences in the structure of industries under oligopoly and similarly significant differences in the behaviour of firms. The firms may produce a virtually identical product (e.g. metals, chemicals, sugar, petrol). Most oligopolists, however, produce differentiated products (e.g. cars, soap powder, soft drinks, electrical appliances). Much of the competition between such oligopolists is in terms of the marketing of their particular brand. Marketing practices may differ considerably from one industry to another.

The two key features of oligopoly

Despite the differences between oligopolies, two crucial features distinguish oligopoly from other market structures.

Barriers to entry

In contrast to the situation under monopolistic competition, there are various barriers to the entry of new firms. These are similar to those under monopoly (see pages 201–4). The size of the barriers, however, varies from industry to industry. In some cases entry is relatively easy, whereas in others it is virtually impossible.

Interdependence of the firms

Because there are only a few firms under oligopoly, each has to take account of the others. This means that they are mutually dependent: they are *interdependent*. Each firm is affected by its rivals' actions. If a firm changes the price or specification of its product, for example, or the amount of its advertising, the sales of its rivals will be affected. The rivals may then respond by changing their price,

specification or advertising. No firm can afford to ignore the actions and reactions of other firms in the industry.

KEY
IDEA
23

People often think and behave strategically. How you think others will respond to your actions is likely to influence your own behaviour. Firms, for example, when considering a price or product change will often take into account the likely reactions of their rivals.

Definition

Interdependence (under oligopoly) One of the two key features of oligopoly. Each firm will be affected by its rivals' decisions. Likewise its decisions will affect its rivals. Firms recognise this interdependence. This recognition will affect their decisions.

BOX 8.2 INCREASING CONCENTRATION

CASE STUDIES AND APPLICATIONS

Losing innocence

We have identified barriers to entry under oligopoly as a factor in keeping the number of firms low. But why does market power grow in some oligopolies, with the number of firms decreasing? The answer can be found in mergers and acquisitions, tough economic conditions and increasing brand loyalty, all of which can reduce competition.

As we saw in Box 7.1, one of the simplest ways of assessing the extent of market power is to look at concentration ratios – the market share of the leading firms. The table below gives some extracts of the table in that box.

Five-firm concentration ratios for various industries (by output)

Industry	Five-firm ratio	Industry	Five-firm ratio
Sugar	99	Fishing	16
Tobacco products	99	Advertising	10
Confectionary	81	Wholesale distribution	6
Soft drinks, mineral water	75	Furniture	5
Motor vehicles	34	Construction	5

Source: Based on data in *United Kingdom Input-Output Analyses*, Table 8.31 (Office of National Statistics, 2006).

1. Can you identify which firms make up the majority of the soft drinks industry?
2. What are the characteristics that make fishing so 'unconcentrated'?
3. Does the relatively low concentration in the car industry surprise you? Explain your answer.

Unsurprisingly, the industries with the highest concentration ratios display a number of varying characteristics. They often involve high capital costs, allowing firms to benefit from economies of scale. Alternatively, a small number of firms have control of the required resources; sugar is a good example here.

In industries with differentiated products, such as confectionary, there are high levels of branding and advertising. On the other hand, the industries with the lowest

ratios tend to have lower costs of entry. In many cases their advertising spend is likely to be local, if it exists at all.

Innocent

But why do concentration ratios change over time? One factor is mergers and takeovers. Take the case of Innocent. In 1999 three friends set up the Innocent® Drinks Company. Specialising in smoothies, it was a new entrant to the soft drinks industry, one which is dominated by Coca-Cola®, Pepsi™ and Cadbury Schweppes (now the Dr Pepper Snapple® Group).

Over the next decade the company grew, from three employees to more than 250, achieving a market share of over 77 per cent by 2007. (By 'market' here we are referring to smoothies and yoghurt drinks rather than all soft drinks.) Making good profits and with a reputation for outstanding corporate social responsibility, life seemed good for the three entrepreneurs.

However, even the most successful of firms is vulnerable to takeover and in 2009 it was announced that Coca-Cola had acquired an 18 per cent stake in Innocent. By 2013, this had increased to 90 per cent, with Coca-Cola taking full control. The outcome was uproar from those who had 'bought-in' to the Innocent mission, and of course an increase in the concentration ratio of the soft drinks industry. However, one of the three entrepreneurs who established Innocent Drinks, Richard Reed, has argued that without the backing of Coca-Cola the firm would have been unable to achieve its global success.

Innocent drinks has approximately 60 per cent of the UK market. However, this once new entrant is itself now under increasing competition from a number of new start-ups including Savse®, Plenish®, Radiance, Moju, Love Smoothies, Blend & Press and Juice Warrior.

1. Are there any advantages to consumers in a highly concentrated industry?
2. Explain why the measurement of the concentration ratio will be dependent on the definition of the market, referring to the Innocent story.
3. Do small independent burger companies have any market advantages over the global firms such as McDonald's® and Burger King®?

It is impossible, therefore, to predict the effect on a firm's sales of, say, a change in its price without first making some assumption about the reactions of other firms. Different assumptions yield different predictions. For this reason there is no one single theory of oligopoly. Firms may react differently and unpredictably.

K10
p70

Competition and collusion

The interdependence of firms in an oligopolistic market pulls them in two very different directions:

- Each firm, by carefully studying the market and its rivals' strategy may believe that, by competing, it can gain a greater share of industry profits.
- On the other hand, firms may conclude that competition will be destructive and lead to lower profits: i.e. through retaliatory price-cutting. So instead, they may prefer to collude with each other by making agreements about price, output, product design, etc. By acting together as if they were a monopoly, the firms could take actions that jointly maximise industry profits and share these profits between them.

These two policies are incompatible. The more fiercely firms compete to gain a bigger share of industry profits, the smaller these industry profits will become. For example, price competition will drive down the average industry price, while competition through advertising will raise industry costs. Either way, industry profits will fall.

Sometimes firms collude, sometimes not. The following sections examine first *collusive oligopoly* (both open and tacit), and then *non-collusive oligopoly*.

Industry equilibrium under collusive oligopoly

When firms under oligopoly engage in collusion, they may agree on output, prices, market share, advertising expenditure, etc. Such collusion reduces the uncertainty they face. It reduces the fear of engaging in competitive price cutting or retaliatory advertising, both of which could reduce total industry profits.

A formal collusive agreement is called a *cartel*. The cartel will maximise profits if it acts like a monopoly: if the members behave as if they were a single firm. This is illustrated in Figure 8.3.

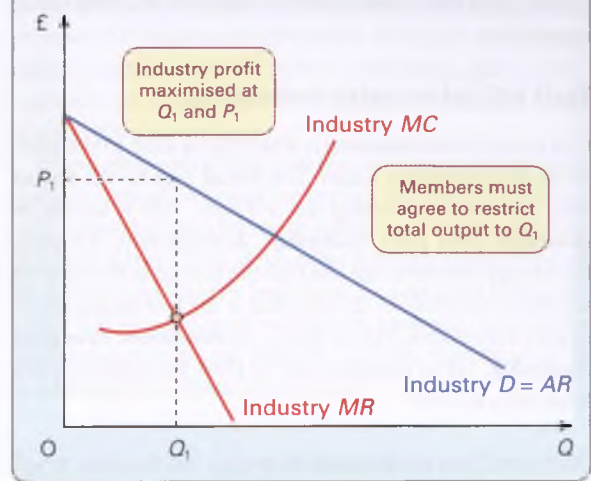

The total market demand curve is shown with the corresponding market *MR* curve. The cartel's *MC* curve is the horizontal sum of the *MC* curves of its members (since we are adding the *output* of each of the cartel members at each level of marginal cost). Profits are maximised at Q_1 where $MC = MR$. The cartel must therefore set a price of P_1 (at which Q_1 will be demanded).

Having agreed on the cartel price, the members may then compete against each other using *non-price competition*, to gain as big a share of resulting sales (Q_1) as they can.

TCR
p109

K12
p100

Figure 8.3 Profit-maximising cartel

? How will advertising affect the cartel's *MC* and *AR* curves? How will this affect the profit-maximising output? Is there any problem here for the cartel in fixing the price?

Alternatively, the cartel members may somehow agree to divide the market between them. Each member would be given a *quota*. The sum of all the quotas must add up to Q_1 . If the quotas exceeded Q_1 , either there would be output unsold if price remained fixed at P_1 , or the price would fall.

But if quotas are to be set by the cartel, how will it decide the level of each individual member's quota? The most likely method is for the cartel to divide the market between the members according to their current market share. This is the solution most likely to be accepted as 'fair'.

? If this 'fair' solution were adopted, what effect would it have on the industry *MC* curve in Figure 8.3?

In many countries, cartels are illegal – being seen by the government as a means of driving up prices and profits, and thereby as being against the public interest (see section 14.1). Where open collusion is illegal, however, firms may simply break the law, or get round it. Alternatively, firms may stay

Definitions

Collusive oligopoly Where oligopolists agree (formally or informally) to limit competition between themselves. They may set output quotas, fix prices, limit product promotion or development, or agree not to 'poach' each other's markets.

Non-collusive oligopoly Where oligopolists have no agreement between themselves, formal, informal or tacit.

Cartel A formal collusive agreement.

Quota (set by a cartel) The output that a given member of a cartel is allowed to produce (production quota) or sell (sales quota).

specification or advertising. No firm can afford to ignore the actions and reactions of other firms in the industry.

Sometimes firms collude, sometimes not. The following sections examine first *collusive oligopoly* (both open and tacit), and then *non-collusive oligopoly*.

Industry equilibrium under collusive oligopoly

When firms under oligopoly engage in collusion, they may agree on output, prices, market share, advertising expenditure, etc. Such collusion reduces the uncertainty they face. It reduces the fear of engaging in competitive price cutting or retaliatory advertising, both of which could reduce total industry profits.

A formal collusive agreement is called a *cartel*. The cartel will maximise profits if it acts like a monopoly: if the members behave as if they were a single firm. This is illustrated in Figure 8.3.

The total market demand curve is shown with the corresponding market *MR* curve. The cartel's *MC* curve is the horizontal sum of the *MC* curves of its members (since we are adding the *output* of each of the cartel members at each level of marginal cost). Profits are maximised at Q_1 where $MC = MR$. The cartel must therefore set a price of P_1 (at which Q_1 will be demanded).

Having agreed on the cartel price, the members may then compete against each other using *non-price competition*, to gain as big a share of resulting sales (Q_1) as they can.

Figure 8.3 Profit-maximising cartel

? How will advertising affect the cartel's *MC* and *AR* curves? How will this affect the profit-maximising output? Is there any problem here for the cartel in fixing the price?

Alternatively, the cartel members may somehow agree to divide the market between them. Each member would be given a *quota*. The sum of all the quotas must add up to Q_1 . If the quotas exceeded Q_1 , either there would be output unsold if price remained fixed at P_1 , or the price would fall.

But if quotas are to be set by the cartel, how will it decide the level of each individual member's quota? The most likely method is for the cartel to divide the market between the members according to their current market share. This is the solution most likely to be accepted as 'fair'.

? If this 'fair' solution were adopted, what effect would it have on the industry *MC* curve in Figure 8.3?

In many countries, cartels are illegal – being seen by the government as a means of driving up prices and profits, and thereby as being against the public interest (see section 14.1). Where open collusion is illegal, however, firms may simply break the law, or get round it. Alternatively, firms may stay

Definitions

Collusive oligopoly Where oligopolists agree (formally or informally) to limit competition between themselves. They may set output quotas, fix prices, limit product promotion or development, or agree not to 'poach' each other's markets.

Non-collusive oligopoly Where oligopolists have no agreement between themselves, formal, informal or tacit.

Cartel A formal collusive agreement.

Quota (set by a cartel) The output that a given member of a cartel is allowed to produce (production quota) or sell (sales quota).

within the law, but still *tacitly* collude by watching each other's prices and keeping theirs similar. Firms may tacitly 'agree' to avoid price wars or aggressive advertising campaigns.

Tacit collusion: price leadership

One form of *tacit collusion* is where firms keep to the price set by an established leader. The leader may be the largest firm: the one dominating the industry. This is known as *dominant firm price leadership*. Alternatively, the price leader may simply be the one that has proved to be the most reliable one to follow: the one that is the best barometer of market conditions. This is known as *barometric firm price leadership*. Let us examine each of these two types of price leadership in turn.

Dominant firm price leadership

How in theory does the leader set the price? The leader will maximise profits where its marginal revenue is equal to its marginal cost. Figure 8.4(a) shows the total market demand curve and the supply curve of all followers. These firms, like

perfectly competitive firms, accept the price as given, only in this case it is the price set by the leader, and thus their joint supply curve is simply the sum of their MC curves – the same as under perfect competition.

The leader's demand curve can be seen as that portion of market demand unfilled by the other firms. In other words, it is market demand minus other firms' supply. At P_1 the whole of market demand is satisfied by the other firms, and so the demand for the leader is zero (point *a*). At P_2 the other firms' supply is zero, and so the leader faces the full market demand (point *b*). The leader's demand curve thus connects points *a* and *b*.

The leader's profit will be maximised where its marginal cost equals its marginal revenue. This is shown in Figure 8.4(b). The diagram is the same as Figure 8.4(a) but with the addition of MC and MR curves for the leader. The leader's marginal cost equals its marginal revenue at an output of Q_L (giving a point *l* on its demand curve). The leader thus sets a price of P_L , which the other firms then duly follow. They supply Q_F (i.e. at point *f* on their supply curve). Total market demand at P_L is Q_T (i.e. point *t* on the market demand curve), which must add up to the output of both leader and followers (i.e. $Q_L + Q_F$).

Definitions

Tacit collusion Where oligopolists take care not to engage in price cutting, excessive advertising or other forms of competition. There may be unwritten 'rules' of collusive behaviour such as price leadership.

Dominant firm price leadership Where firms (the followers) choose the same price as that set by a dominant firm in the industry (the leader).

Barometric firm price leadership Where the price leader is the one whose prices are believed to reflect market conditions in the most satisfactory way.

Draw a pair of diagrams like those in Figure 8.4. Illustrate what would happen if market demand rose but the costs of neither leader nor followers rose. Would there be an equal percentage increase in the output of both leader and followers?

In practice, however, it is very difficult for the leader to apply this theory. The leader's demand and MR curves depend on the followers' supply curve – something the leader will find virtually impossible to estimate with any degree of accuracy. The leader will thus have to make a rough estimate of what its profit-maximising price and output will be, and simply choose that. That is the best it can do.

Figure 8.4 Dominant firm price leadership

* LOOKING AT THE MATHS

In Figure 8.4, the various curves can be represented by equations and this would allow us to solve for P_L , Q_L , Q_F and Q_T . An example of this is given in Maths Case 8.1 on the student website.

Note that we derived all the curves in Figure 8.4 from just three: the market demand curve, the followers' supply curve and the leader's MC curve. It follows that, if we know the functions for these three curves, we can derive the functions for the remainder.

A simpler model is where the leader assumes that it will maintain a constant *market share* (say, 50 per cent). It makes this assumption because it also assumes that all other firms will follow its price up and down. This is illustrated in Figure 8.5. It knows its current position on its demand curve (say, point a). It then estimates how responsive its demand will be to industry-wide price changes and thus constructs its demand and MR curves accordingly. It then chooses to produce Q_L at a price of P_L : at point l on its demand curve (where $MC = MR$). Other firms then follow that price. Total market demand will be Q_T , with followers supplying that portion of the market not supplied by the leader, namely $Q_T - Q_L$.

There is one problem with this model: the assumption that the followers will want to maintain a constant market share. If the leader raises its price, the followers may want to supply more, given that the new price ($=MR$ for a price-taking follower) may well be above their marginal cost. On the other hand, the followers may decide merely to maintain their market share for fear of retaliation from the leader, in the form of price cuts or an aggressive advertising campaign.

Figure 8.5 Price leader aiming to maximise profits for a given market share

Barometric firm price leadership

A similar exercise can be conducted by a barometric firm. Although such a firm does not dominate the industry, its price will be followed by the others. It merely tries to estimate its demand and MR curves – assuming, again, a constant market share – and then produces where $MR = MC$ and sets price accordingly.

In practice, which firm is taken as the barometer may frequently change. Whether we are talking about oil companies, car producers or banks, any firm may take the initiative in raising prices. Then, if the other firms are merely waiting for someone to take the lead – say, because costs have risen – they will all quickly follow suit. For example, if one of the banks raises its mortgage rates by 1 per cent, then this is likely to stimulate the others to follow suit.

Tacit collusion: rules of thumb

An alternative to following an established leader is to follow an established set of simple 'rules of thumb'. These rules do not involve setting MC equal to MR , and thus may involve an immediate loss of profit. They do, however, help to prevent an outbreak of competition, and thus help to maintain profits into the longer term.

One example of a rule of thumb is *average cost pricing*. Here, producers simply add a certain percentage for profit on top of average costs. Thus, if average costs rise by 10 per cent, prices will automatically be raised by 10 per cent. This is a particularly useful rule of thumb in times of inflation, when all firms will be experiencing similar cost increases.

? *If a firm has a typically shaped average cost curve and sets prices 10 per cent above average cost, what will its supply curve look like?*

Another rule of thumb is to have certain *price benchmarks*. Thus clothes may sell for £19.95, £24.95 or £49.95 (but not £18.31 or £36.42). If costs rise, then firms simply raise their price to the next benchmark, knowing that other firms will do the same.

Rules of thumb can also be applied to advertising (e.g. you do not criticise other firms' products, only praise your own); or to the design of the product (e.g. lighting manufacturers tacitly agreeing not to bring out an everlasting light bulb).

Definitions

Average cost pricing Where a firm sets its price by adding a certain percentage for (average) profit on top of average cost.

Price benchmark A price that is typically used. Firms, when raising a price, will usually raise it from one benchmark to another.

BOX 8.3 OPEC

The history of the world's most famous cartel

OPEC, the Organization of the Petroleum Exporting Countries, is probably the best known of all cartels. It was set up in 1960 by the five major oil-exporting countries: Saudi Arabia, Iran, Iraq, Kuwait and Venezuela. Today it has 13 members, including Nigeria, Angola, Libya and Ecuador. Its stated objectives were as follows:

- The co-ordination and unification of the petroleum policies of member countries.
- The organisation of means to ensure the stabilisation of prices, eliminating harmful and unnecessary fluctuations.

The years leading up to 1960 had seen the oil-producing countries increasingly in conflict with the international oil companies, which extracted oil under 'concessionary agreement'. The oil-producing countries had little say over output and price levels.

The early years

Despite the formation of OPEC in 1960, it was not until 1973 that control of oil production was effectively transferred from the oil companies to the oil countries, with OPEC making the decisions on how much oil to produce and thereby determining its oil revenue. By this time OPEC consisted of 13 members.

OPEC's pricing policy over the 1970s consisted of setting a market price for Saudi Arabian crude (the market leader), and leaving other OPEC members to set their prices in line with this. This was a form of dominant 'firm' price leadership.

As long as demand remained buoyant, and was price inelastic, this policy allowed large price increases with consequent large revenue increases. In 1973/4, after the Arab-Israeli war, OPEC raised the price of oil from around \$3 per barrel to over \$12. The price was kept at roughly this level until 1979. And yet the sales of oil did not fall significantly.

? *Illustrate what was happening here on a demand and supply diagram. Remember that demand was highly inelastic and was increasing over time.*

After 1979, however, following a further increase in the price of oil from around \$15 to \$40 per barrel, demand did fall. This was largely due to the recession of the early 1980s which, in turn, was largely caused by governments' responses to the oil price increases.

The use of quotas

Faced by declining demand, OPEC after 1982 agreed to limit output and allocate production quotas in an attempt to keep

Oil prices

Source: Nominal oil price data from *Global Economic Monitor (GEM), Commodities* (World Bank); Price Index from *Data Extracts* (OECD).

the price up. However, the cartel was beginning to break down. Reasons included:

- The world recession and the resulting fall in the demand for oil.
- Growing output from non-OPEC members.
- 'Cheating' by some OPEC members who exceeded their quota limits.

With a glut of oil, OPEC could no longer maintain the price. As the chart shows, the oil price fell.

The trend of lower oil prices was reversed in the late 1980s. With the world economy booming, the demand for oil rose and along with it the price. Then in 1990, Iraq invaded Kuwait and the first Gulf War ensued. With the cutting off of supplies from Kuwait and Iraq, the supply of oil fell and there was a sharp rise in its price.

But with the ending of the war and the recession of the early 1990s, the price rapidly fell again and only recovered slowly as the world economy started expanding once more.

On the demand side, the development of energy-saving technology plus increases in fuel taxes led to a relatively slow growth in consumption. On the supply side, the growing proportion of output supplied by non-OPEC members, plus the adoption in 1994 of a relatively high OPEC production ceiling of 24.5 million barrels per day, meant that supply more than kept pace with demand.

The situation for OPEC deteriorated further in the late 1990s, following the recession in the Far East. Oil demand fell by some 2 million barrels per day. By early 1999, the price had fallen to around \$10 per barrel – a mere \$2.70 in 1973 prices! In response, OPEC members agreed to cut production by 4.3 million barrels per day. The objective was to push the price back up to around \$18–20 per barrel.

But, with the Asian economy recovering and the world generally experiencing more rapid economic growth, the price rose rapidly and soon overshot the \$20 mark. By early 2000 it had reached \$30: a tripling in price in just 12 months. With the world economy then slowing down, however, the price rapidly fell back, reaching \$18 in November 2001.

However, in late 2001 the relationship between OPEC and non-OPEC oil producers changed. The 10 members of the OPEC cartel decided to cut production by 1.5 million barrels a day. This followed an agreement with five of the major oil producers outside of the cartel to reduce their output too, the aim being to push oil prices upwards and then stabilise them at around \$25 per barrel. The alliance between OPEC and non-OPEC oil producers is the first such instance of its kind in the oil industry. As a result, it seemed that OPEC might now once again be able to control the market for oil.

The price surge of 2003–8

But how successfully could this alliance cope with crisis? With worries over an impending war with Iraq and a strike in Venezuela, the oil price rose again in late 2002, passing the \$30 mark in early 2003. In 2004, the situation worsened with supply

concerns related to the situation in Iraq, Saudi Arabia, Russia and Nigeria, and the oil price rose to over \$50 in October 2004. OPEC tried to relax the quotas, but found it difficult to adjust supply sufficiently quickly to make any real difference to the price.

From 2006, oil prices increased more sharply than they ever had before and, for the first time in years, the real price of oil exceeded that seen in the 1970s. The major cause of the increases was very substantial increases in demand, particularly from India and China, coupled with continuing concerns about supply. The implications of the sharp price increases were substantial: inflationary pressures built up across the world, while the income of OPEC nations doubled in the first half of 2008.

By July 2008 the price reached \$147. Some analysts were predicting a price of over \$200 per barrel by the end of the year.

... and then a fall but rise again

But then, with the growing banking turmoil and fears of a recession, the price began to fall, and rapidly so, reaching \$34 by the end of the year – less than a quarter of the price just five months previously. While this was good news for the consumer, it was potentially damaging for investment in oil exploration and development and also for investment in alternative energy supplies.

OPEC responded to the falling price by announcing cuts in production, totalling some 14 per cent between August 2008 and January 2009. But with OPEC producing less than a third of global oil output, this represented less than 5 per cent of global production. Nevertheless, as global demand recovered, so oil prices rose again from 2009, peaking in March 2012 at \$118.

A new threat to OPEC

Prices remained relatively stable from 2012 to mid-2014. However, OPEC was facing increased competition from a big new entrant into the market – US shale oil production. US shale oil production doubled between 2011 and 2014, contributing to a fall in the oil price from \$112 a barrel in June 2014 to just \$30 a barrel in February 2016.

OPEC responded to this fall in prices, not by cutting output, but by announcing that it would retain output. This strategy was relying on the fact that although production from shale oil wells has low marginal costs, it often only lasts two or three years. Investment in new shale oil wells, by contrast, tends to be relatively expensive. By OPEC maintaining production, it was hoping to use its remaining market power to reduce supply of competitors over the medium to long term.

However, with revenues from oil falling so dramatically, OPEC and non-OPEC producers (such as Russia) reached an agreement in December 2016 to cut production. This is the first time such an agreement had occurred since 2001 and it was estimated that the countries involved were responsible

BOX 8.3 OPEC (continued)

for producing about 55 per cent of global output. The oil price immediately started to increase again.

Early reports suggest record adherence to the agreement. The problem for OPEC is that the increase in oil price has made US shale production profitable once again. A number of rigs that temporarily shut down have become operational again and production has increased by 9 million barrels a day. It will be interesting to see what influence OPEC can have on the price of oil in the future given the increase in non-conventional extraction, such as in shale formations.

1. What conditions facilitate the formation of a cartel? Which of these conditions were to be found in the oil market in (a) the early 1970s; (b) the mid-1980s; (c) the mid-2000s; (d) 2016?
2. Could OPEC have done anything to prevent the long-term decline in real oil prices seen from 1981 to 2002?
3. Does the increased demand seen from China and India imply that the era of cheap energy is over? What impact could technology have in the long run on (a) demand; (b) supply?

Factors favouring collusion

Collusion between firms, whether formal or tacit, is more likely when firms can clearly identify with each other or some leader and when they trust each other not to break agreements. It will be easier for firms to collude if the following conditions apply:

- There are only very few firms all well known to each other.
- They are not secretive with each other about costs and production methods.
- They have similar production methods and average costs, and are thus likely to want to change prices at the same time and by the same percentage.
- They produce similar products and can thus more easily reach agreements on price.
- There is a dominant firm.
- There are significant barriers to entry and therefore little fear of disruption by new firms.
- The market is stable. If industry demand or production costs fluctuate wildly, it will be difficult to make agreements, partly due to difficulties in predicting and partly

because agreements may frequently have to be amended. There is a particular problem in a declining market where firms may be tempted to undercut each other's prices in order to maintain their sales.

- There are no government measures to curb collusion.

In which of the following industries is collusion likely to occur: bricks, beer, margarine, cement, crisps, washing powder, blank DVDs, carpets?

Non-collusive oligopoly: the breakdown of collusion

In some oligopolies, there may only be a few (if any) factors favouring collusion. In such cases, the likelihood of price competition is greater.

Even if there is collusion, there will always be the temptation for individual oligopolists to 'cheat', by cutting prices or by selling more than their allotted quota.

Let us take the case of a cartel consisting of five equal-sized firms. The whole cartel is illustrated in Figure 8.6(a). Assume that the cartel sets the industry profit-maximising

Figure 8.6 The incentive for a firm to produce more than its quota, or undercut the cartel's price

price of £10. This will give an industry output of 1000 units, which the cartel divides equally between its five members: i.e. each member is assigned a quota of 200 units.

Now consider Figure 8.6(b). This shows the position for one of the members of the cartel, firm A. Provided the cartel's price remains fixed at £10, then £10 would also be the marginal revenue for the individual firm. This will create an incentive for cartel members to cheat: to sell more than their allotted quota. Firm A would maximise its own profits by selling 600 units, where $MC = P (= MR)$, provided it could do this by taking market share off the other members, and thus leaving total industry output (and hence price) unaffected.

Alternatively, individual members might be tempted to undercut the cartel's price. Again, provided the rest of the cartel maintained its price at £10, firm A would face a relatively elastic demand curve (shown by AR in Figure 8.6(b)). A modest cut in its price would attract considerable custom away from the other members of the cartel. Firm A would maximise its profit by cutting its price to £8 and thereby increasing its sales to 400 units.

The danger, of course, with either selling above quota or cutting price is that this would invite retaliation from the other members of the cartel, with a resulting price war. Price would then fall and the cartel could well break up in disarray.

Non-collusive oligopoly: assumptions about rivals' behaviour

Even though oligopolists might not collude, they will still need to take account of rivals' likely behaviour when deciding their own strategy. In doing so, they will probably look at rivals' past behaviour and make assumptions based on it. There are three well-known models, each based on a different set of assumptions.

The Cournot model: firms choose quantity and the market determines the price

One of the earliest models of oligopoly was developed by the French economist Augustin Cournot in 1838. The simplest version of the **Cournot model** has the following assumptions.

- Each firm has to choose an output level for a given period without knowing its rivals' production plans (although, except in the case of new firms, they will know how much their rivals have produced in the past). In other words, firms have to make decisions about production simultaneously.
- Production has long lead times and is relatively inflexible. For example, imagine a business investing in a factory or unit that has a specific production capacity. Once the building work begins and the specialised machinery has been ordered and installed, it is difficult for the firm to alter its planned output.

- Whereas output has long lead times, the market price adjusts instantly so that each firm is able to sell all the output it produces.
- The good is homogenous and each firm has the same costs. This means that all the firms in the market sell their output for the same price.

This combination of flexible prices and inflexible output creates an interesting strategic environment. The price the firm receives for its output, in any given period, depends on the production decisions of other firms as well as its own. To calculate its profit-maximising output it has to estimate the most likely output its rivals will produce. The Cournot model assumes that each firm expects its rival(s) to produce the same amount in the current period as it did in the previous period.

To make the analysis as simple as possible we will assume that the industry is a **duopoly** and that the two firms, A and B, each have the same costs.

Figure 8.7(a) illustrates the profit-maximising price and output for firm A. The total market demand curve is shown as D_M . Assume that firm B produced Q_{B1} units last year. Firm A, according to the model's assumption, therefore believes that firm B will continue to produce Q_{B1} units this year.

To calculate firm A's profit-maximising output we need to identify its **residual demand curve**: i.e. the curve showing how much of the total demand is left for firm A, after B has supplied the market with its output. With firm B's output assumed to be Q_{B1} , firm A perceives its own residual demand curve to be D_{A1} . This is the market demand curve, D_M , minus Q_{B1} units: i.e. the horizontal gap between D_M and D_{A1} in Figure 8.7(a).

The marginal revenue curve corresponding to D_{A1} is MR_{A1} and the profit-maximising output is Q_{A1} , where $MR_{A1} = MC_A$. The market will adjust instantly so that firm A can sell Q_{A1} units and firm B can sell Q_{B1} units of this homogenous product for a price of P_1 .

If firm A believed that firm B would produce *more* than Q_{B1} , its residual demand and MR curves would be further to the left and the profit-maximising quantity and price would both be lower. This illustrates that the outputs are strategic substitutes – as firm A believes that firm B will produce more, its best response is to produce less.

Definitions

Cournot model A model of duopoly where each firm makes its price and output decisions on the assumption that its rival will produce a particular quantity.

Duopoly An oligopoly where there are just two firms in the market.

Residual demand curve A firm's residual demand curve illustrates the relationship between the output it produces and the market price for the product, holding constant the output produced by other firms.

Figure 8.7 The Cournot model of duopoly

One limitation of the analysis so far is that it only illustrates firm A's profit-maximising best response to one predicted level of output: i.e. that firm B produce Q_{B1} units. Firm A's **reaction function**, illustrated by curve R_A in Figure 8.7(b), shows its profit-maximising best responses to *all* the different outputs its rival could produce. It has a negative slope because outputs are strategic substitutes: the more firm B produces, the less will firm A produce. Thus if it perceived that firm B would produce Q_{B2} units, it would produce Q_{A2} units (point y).

Figure 8.7(b) also illustrates firm B's reaction function, assuming that firm B behaves similarly to firm A and assumes that its rival will produce a particular level of output. Firm B's reaction function is given by the curve R_B . Thus if firm B perceived that A would produce Q_{A1} units, firm B would produce Q_{B1} units (point z).

What is the **Cournot equilibrium**? This will occur at point e in Figure 8.7(b). Only at this point will neither firm choose to adjust its output once it has discovered the production level of its rival. How is this point reached if neither firm currently produces that level of output?

Assume that production is at point x . Firm A predicts that firm B will produce Q_{B1} . Although firm A is on its reaction

curve, firm B is not. If firm B predicts that firm A will produce Q_{A1} , its best move is *not* to produce Q_{B1} . It will instead produce at a point on its reaction curve vertically above this (i.e. an output *greater* than Q_{B1}). Firm A will discover that firm B has produced a greater output than it predicted. It will respond by reducing its own production level – it will move up along its reaction curve. This process will continue until point e is reached. Only at this point will the levels of production chosen by each firm (in the light of what the other one chooses) add up to the total amount demanded.

Profits in the Cournot model. Industry profits will be *less* than under a monopoly or a cartel. The reason is that price will be lower than the monopoly price. This can be seen from Figure 8.7(a). If this were a monopoly, then to find the profit-maximising output, we would need to construct an MR curve corresponding to the market demand curve (D_M). This would intersect with the MC curve at a higher output than Q_{A1} , and a *higher* price (given by D_M).

Nevertheless, profits in the Cournot model will be higher than under perfect competition, since price is still above marginal cost. However, as the number of firms in the industry increases the price would move closer to the level in a competitive market and industry profits would fall.

Maths Case 8.2 on the student website shows how the Cournot equilibrium can be derived algebraically from the market demand function and the cost functions of the two firms.

The Bertrand model: firms set prices and the market determines the quantity sold

Another famous model of oligopoly was developed by the French economist, Joseph Bertrand, in 1883. He criticised the Cournot model as he argued that firms are more likely

Definitions

Reaction function (or curve) This shows how a firm's optimal output varies according to the output chosen by its rival (or rivals).

Cournot equilibrium Where each of two firm's actual output is the same as what the other firm predicted it would produce: where the two firms' reaction curves cross.

to set prices and let the market determine the quantity sold. Bertrand again took the simple case of a duopoly where both firms have the same costs of production. However, the conclusions of the model apply equally to oligopolies with three or more firms. It is based on the following assumptions:

- Each firm has to choose its price without knowing the price set by the other firm. It assumes its rival will charge the same price in the current period as it did in the previous period.
- Firms have to set prices in advance and decisions cannot be easily changed: i.e. prices are inflexible.
- The good is homogenous – the only thing that customers care about when they purchase the product is its price.
- Each firm can adjust its output instantly and has no capacity constraints. Therefore, if a firm charges a lower price than its rival it can immediately supply the entire market.

The model predicts that each firm will keep reducing its price until all supernormal profits are competed away. The reason for this result is simple. If firm A assumes that its rival, firm B, will hold price constant, then firm A predicts that by undercutting this price by a small amount it will gain the whole market, which it can instantly supply. By following the same line of reasoning firm B will be forced to respond by cutting its price. The model, therefore, predicts a price war with prices being reduced until they equal average total cost, with only normal profits remaining.

This outcome is very different from the one predicted by the Cournot model. It is referred to as the *Bertrand Paradox* because the result seems counterintuitive: i.e. a duopoly results in an outcome very similar to that of perfect competition. The prediction changes significantly if product differentiation and/or limits in the ability of the firm to supply the entire market (i.e. capacity constraints) are introduced into the model. Firms may also seek to collude long before profits have been reduced to a normal level. Alternatively, firms may put in a *takeover bid* for their rival(s).

Nash equilibrium. The equilibrium outcome in either the Cournot or Bertrand models is not in the *joint* interests of the firms. In each case, total profits are less than under a monopoly or cartel. But, in the absence of collusion, the outcome is the result of each firm doing the best it can, given the assumptions it makes about what its rivals are doing. The resulting equilibrium is known as a **Nash equilibrium**, after John Nash, a US mathematician (and subject of the film *A Beautiful Mind*) who introduced the concept in 1951. This concept will be discussed in more detail in section 8.3.

 Can you think of any reasons why the predictions of the Cournot and Bertrand models of oligopoly are so different?

The kinked demand curve assumption

In 1939, a theory of non-collusive oligopoly was developed simultaneously on both sides of the Atlantic: in the USA by Paul Sweezy and in Britain by R. L. Hall and C. J. Hitch. This **kinked demand theory** has since become perhaps the most famous of all theories of oligopoly. The model seeks to explain how it is that, even when there is no collusion at all between oligopolists, prices can nevertheless remain stable.

The theory is based on two asymmetrical assumptions:

- If an oligopolist cuts its price, its rivals will feel forced to follow suit and cut theirs, to prevent losing customers to the first firm.
- If an oligopolist raises its price, however, its rivals will *not* follow suit since, by keeping their prices the same, they will gain customers from the first firm.

The logic that follows from these assumptions, is that each oligopolist will face a demand curve that is *kinked* at the current price and output (see Figure 8.8). A rise in price will lead to a large fall in sales as customers switch to the now

Definitions

Takeover bid Where one firm attempts to purchase another by offering to buy the shares of that company from its shareholders.

Nash equilibrium The position resulting from everyone making their optimal decision based on their assumptions about their rivals' decisions. Without collusion, there is no incentive for any firm to move from this position.

Kinked demand theory The theory that oligopolists face a demand curve that is kinked at the current price, demand being significantly more elastic above the current price than below. The effect of this is to create a situation of price stability.

Figure 8.8 Kinked demand for a firm under oligopoly

Figure 8.9 Stable price under conditions of a kinked demand curve

relatively lower-priced rivals. The firm will thus be reluctant to raise its price. Demand is relatively elastic above the kink. On the other hand, a fall in price will bring only a modest increase in sales, since rivals lower their prices too and therefore customers do not switch. The firm will thus also be reluctant to lower its price. Demand is relatively inelastic below the kink. Therefore oligopolists will be reluctant to change prices at all.

This price stability can be shown formally by drawing in the firm's marginal revenue curve, as in Figure 8.9.

To see how this is done, imagine dividing the diagram into two parts, one on either side of Q_1 . At quantities less than Q_1 (the left-hand part of the diagram), the MR curve will correspond to the shallow part of the AR curve. At quantities greater than Q_1 (the right-hand part), the MR curve will correspond to the steep part of the AR curve. To see how this part of the MR curve is constructed, imagine extending the steep part of the AR curve back to the vertical axis. This and the corresponding MR curve are shown by the dotted lines in Figure 8.9.

As you can see, there will be a gap between points a and b . In other words, there is a vertical section of the MR curve between these two points.

Profits are maximised where $MC = MR$. Thus, if the MC curve lies anywhere between MC_1 and MC_2 (i.e. between points a and b), the profit-maximising price and output will be P_1 and Q_1 . Thus prices will remain stable *even with a considerable change in costs*.

Despite its simple demonstration of the real-world phenomenon of price stability, the model does have two major limitations:

- Price stability may be due to *other* factors. Firms may not want to change prices too frequently as this involves modifying price lists, working out new revenue

predictions and revaluing stocks of finished goods, and it may upset customers. Price stability, therefore, is not proof of the accuracy of the model.

- Although the model can help to explain price stability, it does not explain how prices are set in the first place. To do this, some other model would be required. This is a serious limitation in times of inflation, when oligopolists, like other firms, raise prices in response to higher costs and higher demand. What the model does predict, however, is that the price will be raised only after marginal cost has risen above MC_2 in Figure 8.9, and that once it has been raised, a new kink will form at that price. Price will then remain fixed at that level until higher costs once more force a further price rise.

Oligopoly and the public interest

If oligopolists act collusively and jointly maximise industry profits, they will in effect be acting together as a monopoly. In such cases, the disadvantages to society experienced under monopoly will also be experienced under oligopoly (see section 7.3).

Furthermore, in two respects, oligopoly may be more disadvantageous than monopoly:

- Depending on the size of the individual oligopolists, there may be less scope for economies of scale to mitigate the effects of market power.
- Oligopolists are likely to engage in much more extensive advertising than a monopolist (see Case Study 8.10 on the student website).

These problems will be less, however, if oligopolists do not collude, if there is some degree of price competition and if barriers to entry are weak.

Also, the power of oligopolists in certain markets may to some extent be offset if they sell their product to other powerful firms. Thus oligopolistic producers of baked beans sell a large proportion of their output to giant supermarket chains, which can use their market power to keep down the price at which they purchase the beans. This phenomenon is known as *countervailing power*.

? Which of the following are examples of effective countervailing power?

- Tour operators purchasing seats on charter flights.
- A large office hiring a photocopier from Xerox®.
- Marks & Spencer buying clothes from a garment manufacturer.
- A small village store (but the only one for miles around) buying food from a wholesaler.

Definition

Countervailing power Where the power of a monopolistic/oligopolistic seller is offset by powerful buyers who can prevent the price from being pushed up.

BOX 8.4

BUYING POWER

EXPLORING ECONOMICS

The UK grocery sector

Over the past few years there has been increasing concern about the power of large supermarket chains in the UK. This has resulted in a number of Competition Commission investigations. Many of these have focused on anti-competitive practices such as rival chains agreeing not to set up in the same town and price collusion on some staple products. (For more on government competition policy, see Chapter 14, pages 429–30).

However, more recently, focus has turned to the supermarkets' power not as sellers, but as buyers. If a wholesale manufacturer of ready-meals, or a supplier of sausages, wants to reach a wide customer base, it will need to deal with the four largest supermarket chains, which control over 75 per cent of the market. A market like this, where there are a few large purchasers of goods and services, is known as an *oligopsony*. (A single large buyer of goods, services or factors of production is known as a *monopsony* and we look at this in Chapter 10, pages 287–90).

Market power

Over the years a number of unfair practices by the supermarkets towards their suppliers have been identified. These include retrospectively changing contracts and forcing suppliers to fund special offers such as 'buy one, get one free'. Furthermore, there is evidence that firms were regularly asked for very substantial payments, in order to be included on 'preferred supplier' lists.

After a lengthy investigation, the Competition Commission (one of the predecessors to the Competition and Markets Authority) concluded that the supermarkets were passing on excessive risks and unexpected costs to their suppliers. As a consequence, a stronger Grocery Supplies Code of Practice

(GSCP) was introduced in 2009. This recognised the power that large grocery retailers wield over their smaller suppliers and outlawed the practices detailed above.

In January 2013, the government appointed a 'Groceries Code Adjudicator' (GCA) to make sure the supermarkets were complying with the GSCP. In January 2016, the GCA concluded that Tesco had not been complying with the code. In particular, she concluded that the company had 'knowingly delayed paying money to suppliers in order to improve its own financial position'. In June 2016, Morrisons was also judged to have broken the code by requiring suppliers to make lump-sum payments even though they were not required according to the supply contracts.

Who benefits?

It would be easy to conclude that the power of supermarkets, both as purchasers and as retailers, is so great that they are a 'bad thing'. However, that would be overly simplistic. There is evidence that they compete on price and as a consequence have held down the cost of food bills in the UK. They have also introduced a variety of products and offer very convenient shopping for many people, particularly those who work full-time. The grocery market is a good example of a sector where growth and market power can be identified as both beneficial and harmful to other economic agents.

1. Explain why manufacturers of food products continue to supply supermarkets, despite concerns that they are not always treated fairly.
2. Is the supermarket sector an oligopoly or monopolistically competitive, in your opinion? Justify your answer.

The power of oligopolists will also be reduced if the market in which they operate is contestable (see section 7.4). The lower the entry and exit costs for new firms, the more difficult it will be for oligopolists to collude and make super-normal profits.

Which of the following markets do you think are contestable: (a) credit cards; (b) brewing; (c) petrol retailing; (d) insurance services; (e) compact discs?

In some respects, oligopoly may have *advantages* to society over other market structures:

- Oligopolists, like monopolists, can use part of their super-normal profit for research and development. Unlike monopolists, however, oligopolists will have a considerable *incentive* to do so. If the product design is improved, this may allow the firm to capture a larger share of the market, and it may be some time before rivals can respond with a similarly improved product. If, in addition, costs

Definition

Oligopsony A goods market with just a few buyers (or employers in the case of labour markets).

are lowered by technological improvement, the resulting higher profits will improve the firm's capacity to withstand any price war.

- Non-price competition through product differentiation may result in greater choice for the consumer. Take the case of stereo equipment. Non-price competition has led to a huge range of different products of many different specifications, each meeting the specific requirements of different consumers.

It is difficult, however, to draw any general conclusions, since oligopolies differ so much in their performance.

Section summary

1. An oligopoly is where there are just a few firms in the industry with barriers to the entry of new firms. Firms recognise their mutual dependence.
2. Oligopolists will want to maximise their joint profits. This will tend to make them collude to keep prices high. On the other hand, they will want the biggest share of industry profits for themselves. This will tend to make them compete.
3. They are more likely to collude if there are few of them; if they are open with each other; if they have similar products and cost structures; if there is a dominant firm; if there are significant entry barriers; if the market is stable; and if there is no government legislation to prevent collusion.
4. Collusion can be open or tacit.
5. A formal collusive agreement is called a 'cartel'. A cartel aims to act as a monopoly. It can set price and leave the members to compete for market share, or it can assign quotas. There is always a temptation for cartel members to 'cheat' by undercutting the cartel price if they think they can get away with it and not trigger a price war.
6. Tacit collusion can take the form of price leadership. This is where firms follow the price set by either a dominant firm in the industry or a firm seen as a reliable 'barometer' of market conditions. Alternatively, tacit collusion can simply involve following various rules of thumb, such as average cost pricing and benchmark pricing.
7. Even when firms do not collude, they will still have to take into account their rivals' behaviour. In the Cournot model, firms assume that their rivals' output is given and then choose the profit-maximising price and output in the light of this assumption. The resulting price and profit are lower than under monopoly, but still higher than under perfect competition.
8. In the Bertrand model, firms assume that their rivals' price is given. This will result in prices being competed down until only normal profits remain.
9. In the kinked demand curve model, firms are likely to keep their prices stable unless there is a large shift in costs or demand.
10. Whether oligopoly behaviour is in the public interest depends on the particular oligopoly and how competitive it is; whether there is any countervailing power; whether the firms engage in extensive advertising and of what type; whether product differentiation results in a wide range of choice for the consumer; how much of the profits are ploughed back into research and development; and how contestable the market is. Since these conditions vary substantially from oligopoly to oligopoly, it is impossible to state just how well or how badly oligopoly in general serves the public interest.

8.3 GAME THEORY

When firms operate in a competitive environment and recognise their interdependence, what is the most probable outcome? If each firm aims to maximise its profits it needs to think strategically: it needs to work out its optimal response to the actual or most likely actions of its rivals.

At first sight, this might seem like an almost impossible task given the complexity of the reasoning involved. However, economists have developed *game theory* as a useful framework and set of tools for thinking about these situations. By helping to identify the best strategy that each firm can adopt for each assumption about its rivals' behaviour, game theory can help economists to predict the most likely outcome in markets with strategic interdependence.

This section will show how game theory can provide useful insights into firms' behaviour in oligopolistic markets. It is important to remember that it can also be applied to a broad range of issues, including the negotiations over the UK's exit from the European Union. For some types of games, however, game theory offers few insights. For example, where the outcomes are determined purely by chance: e.g. lotteries, bingo, etc. or where there is only one player: e.g. solitaire. Nevertheless, there are many economic situations where game theory can provide considerable insights.

Simultaneous single-move games

As we have seen, the firm's profit-maximising strategy in a competitive oligopoly market depends, in part, on how it thinks its rivals will react to its decisions on prices, output, product development, advertising, etc. If this competition is a one-off event (such as firms competing for a specific contract) then it can be modelled as a *simultaneous single-move game*. This type of game is also called a single-period or one-shot game.

Definitions

Game theory A mathematical method of decision making in which alternative strategies are analysed to determine the optimal course of action for the interested party, depending on assumptions about rivals' behaviour. Widely used in economics, game theory is also used as a tool in biology, psychology and politics.

Simultaneous single-move game A game where each player has just one move, where each player plays at the same time and acts without knowledge of the actions chosen by other players.

A 'complete-information' simultaneous single-move game has the following characteristics. Each firm:

- is aware of all the choices available to its rival: i.e. all the decisions it could possibly make about pricing, output, advertising, product development, etc.
- is able to calculate the impact of each of these potential decisions on its own profits;
- makes its own decision without knowing the choice of its rival.

These assumptions are very similar to those found in the Bertrand and Cournot models of oligopoly discussed in section 8.2. Economists have actually reinterpreted both of these models as examples of simultaneous single-move games. Another example is the Rock–Paper–Scissors game. Each player knows the three choices available to both participants and has to decide without knowing the choice made by the other player. A sealed bid auction is another example, where each bidder submits a price without knowing any of the bids submitted by their competitors.

This type of environment poses a significant challenge for a firm. As a first step it can work out the impact of each of its rivals' actions on its own profit. However, to determine its best response it would usually need to know which of these actions its rival has actually taken. In a simultaneous single-move game it does not have this information. How can a firm work out its best response to a rival's decision that it cannot observe.

TC 9
p129

Simultaneous single-move games with dominant strategies

In some strategic environments the firm does not have to worry about trying to work out the most likely actions of its rivals. Its best response remains the same, no matter what assumptions it makes about its rivals' behaviour. In the terminology of game theory, the firm has a *dominant strategy*.

One of the best ways of illustrating this idea is to represent the strategic environment facing the firms as a *normal-form game*. A normal (or strategic) representation of a game is presented as a matrix. This matrix illustrates the pay-offs (e.g. profits) from each of the different available decisions. A simple example of a pay-off is shown in Table 8.1.

This example illustrates the various profits two firms (X, and Y) could earn from charging two different prices – £2 and £1.80. To keep the example simple, we assume the firms have identical costs, products and demand and can only choose one or other of the two prices.

Let us initially consider firm Y's position. Should it set its price at £2 or £1.80? Which decision would make it the most profit? To answer this question we need to look at the impact of firm X's different pricing decisions on the profits of firm Y and work out its best response. If firm Y assumes that firm X chooses a price of £2, it needs to focus on the left-hand column of the pay-off matrix. Firm Y's best response is clearly to charge £1.80, earning it £12 million in profits, as illustrated in cell C. If firm Y sets its price at £2, it makes a lower profit of £10 million, as illustrated in cell A.

What happens if firm Y now assumes that firm X chooses a price of £1.80? All the relevant information is now in the right-hand column of the pay-off matrix. Firm Y's best response once again is to charge £1.80, earning it profits of £10 million, as illustrated in cell D. If firm Y sets its price at £2, it makes a lower profit of £5 million, as illustrated in cell B.

Therefore, no matter which of the two prices firm Y assumes that firm X will charge, firm Y's best response is always to charge £1.80 as this will yield the highest possible profits. Charging £1.80 is a dominant strategy for firm Y.

If we now look at the game from firm X's viewpoint we get exactly the same result. No matter what price firm X assumes that firm Y will charge, its best response is always to charge £1.80. Therefore charging £1.80 is also a dominant strategy for firm X.

Because both firms have a dominant strategy, the outcome of the game is easy to predict. Both firms charge £1.80 and earn £8 million in profit, as illustrated in cell D. This is the dominant strategy equilibrium of the game.

This game is an example of the *prisoners' dilemma*. The original scenario with two prisoners is discussed in more detail in Box 8.5. What exactly is the dilemma in the game above? By pursuing a strategy to maximise its own individual profit, each firm makes less money than it could have if it had acted collectively. If they both co-operated with one another (i.e. colluded) and agreed to charge the higher price

Table 8.1 Profits for firms X and Y at different prices

		X's price	
		£2.00	£1.80
Y's price	£2.00	A £10m, £10m	B £5m, £12m
	£1.80	C £12m, £5m	D £8m, £8m

Definitions

Dominant-strategy game Where the firm's optimal strategy remains the same, irrespective of what it assumes its rivals are going to do.

Normal-form game Where the possible pay-offs from different strategies or decisions are presented as a matrix.

Prisoners' dilemma Where two or more firms (or people), by attempting independently to choose the best strategy, think about what their rivals are likely to do, end up in a worse position than if they had co-operated in the first place.

of £2 they would each have made a profit of £10 million (cell A) instead of £8 million (cell D). The game clearly illustrates the incentive each firm has to cheat on a collusive arrangement in the absence of any binding agreements.

Is the incentive structure in the single-move prisoners' dilemma game in the interests of society?

More complex simultaneous single-move games

In many instances, one or both firms will not have a dominant strategy. In these cases, a firm's best response will vary depending on what it thinks its rival will do. Take the example shown in Table 8.2. This is very similar to the example in Table 8.1, but has a different profit structure.

Let us once again consider firm Y's position. If firm Y assumes that firm X chooses a price of £2, its best response is to charge £1.80, earning £20 million in profits as shown in cell C. However, if it assumes that firm X chooses a price of £1.80, its best response is to charge £2, earning £15 million in profits as shown in cell B. Hence, its best response changes depending on what price it thinks firm X will charge.

Accurately predicting firm X's decision is important for firm Y if it wants to maximise its profits. If its belief turns out to be wrong, it will make less profit. What is the most effective way of anticipating what your rival will do? The answer is for firm Y to try to examine the decision from the perspective of firm X. Can it successfully put itself in its rival's shoes and analyse the competition from their viewpoint?

If firm Y looks at the pricing decision from firm X's point of view it will see that firm X actually has a dominant strategy. If firm Y charges £2 it can see that firm X's best response is to charge £1.80 (making a profit of £6m rather than £5m). If firm Y charges £1.80, firm X's best response is also to charge £1.80 (making a profit of £4m rather than £3m). Therefore, firm X will charge £1.80 – its dominant strategy. Firm Y's best response, therefore, is to charge £2.00 and make a profit of £15m rather than £12m. This combination of prices in cell B is the equilibrium in the game.

Some games can be much more complicated than the one shown in Table 8.2. For example, neither firm could have a dominant strategy; there could be more than two firms and more than two choices. How can we predict the most likely

outcome in these circumstances? At what point will every firm have no incentive to change its strategy?

Nash equilibrium and expected behaviour

In section 8.2 (page 231), we looked at the concept of the Nash equilibrium. This is the position that results from everyone making their optimal decision based on their assumptions about their rivals' decisions. The dominant strategy equilibrium in the prisoners' dilemma and the equilibrium in Table 8.2 are both examples of a Nash equilibrium. In each case, neither firm has an incentive to change its decision as it is choosing its best price in response to the price chosen by its rival.

In fact, all dominant strategy equilibria (i.e. where both firms have a dominant strategy) are examples of Nash equilibria. Identifying any dominant strategies, if they exist, makes it easier to find the Nash equilibrium.

In many games, there is more than one Nash equilibrium. In these cases, it is more difficult to predict the most likely outcome.

If a firm's actual behaviour was *different* from its expected behaviour, then the decisions of its rivals do not represent a Nash equilibrium. In these circumstances, what the firm perceives to be its best response, based on the expected behaviour of its rival, proves not to be the case when the actual behaviour of the other firm is observed. The firm will have an incentive to change its behaviour.

Repeated simultaneous-move games

The previous analysis of simultaneous single-move games gives some useful insights but instances of one-off interactions are relatively unusual. In most real-world settings, firms in oligopolistic markets compete against one another on a repeated basis. Decisions about pricing, advertising, product development, etc., are made continually over the months and years that firms are in business. For example, Apple and Samsung launch new versions of their smartphone handsets on an annual basis. Do the predicted outcomes of single-move games remain the same when the game is repeated?

We previously examined a single-move prisoners' dilemma game in which the most likely outcome was for both firms to charge the lower price of £1.80 (see Table 8.1 on page 235). There was a strong incentive for both firms to cheat on any collusive agreement to fix prices at £2.00. Does repeated interaction between the same firms change the predicted outcome of the game? For example, if firms X and Y make the same simultaneous pricing decisions repeatedly, could their optimal strategy change so that they both start charging £2.00?

The big difference between a single-move game and a repeated game is that each firm can now see what its rivals did in previous periods. This creates the possibility that whatever firms choose to do in one period might have an impact on the behaviour of their rivals, and hence their own profits, in later periods. In particular, decisions that generate

BOX 8.5

THE PRISONERS' DILEMMA

CASE STUDIES AND APPLICATIONS

Game theory is not just relevant to economics. A famous non-economic example is the prisoners' dilemma.

Nigel and Amanda have been arrested for a joint crime of serious fraud. Each is interviewed separately and given the following alternatives:

- First, if they say nothing, the court has enough evidence to sentence both to a year's imprisonment.
- Second, if either Nigel or Amanda *alone* confesses, he or she is likely to get only a three-month sentence but the partner could get up to ten years.
- Third, if both confess, they are likely to get three years each.

What should Nigel and Amanda do?

		Amanda's alternatives	
		Not confess	Confess
Nigel's alternatives	Not confess	A Each gets 1 year	C Nigel gets 10 years Amanda gets 3 months
	Confess	B Nigel gets 3 months Amanda gets 10 years	D Each gets 3 years

Let us consider Nigel's dilemma. Should he confess in order to get the short sentence? This is better than the year he would get for not confessing. There is, however, an even better reason for confessing. Suppose Nigel doesn't confess but, unknown to him, Amanda does confess. Then Nigel ends up with the long sentence. Better than this is to confess and to get no more than three years. Nigel's best response is always to confess.

Amanda is in exactly the same dilemma, so the result is simple. When both prisoners act in their own self-interest by confessing, they both end up with relatively long prison terms. Only when they collude will they end up with relatively short prison terms, the best combined solution.

Of course, the police know this and will do their best to prevent any collusion. They will keep Nigel and Amanda in separate prison cells and try to persuade each of them that the other is bound to confess.

Thus the choice of strategy depends on:

- Nigel's and Amanda's risk attitudes: i.e. are they 'risk lovers' or 'risk averse'?
- Nigel's and Amanda's estimates of how likely the other is to own up.

1. Why is this a dominant-strategy 'game'?
2. How would Nigel's choice of strategy be affected if he had instead been involved in a joint crime with Rikki, Kate, Amrita and Dave, and they had all been caught?

The prisoners' dilemma is a good illustration of the *fallacy of composition* that we examined in Box 3.5 (see page 97). What applies at the level of the individual does not apply to the group as a whole. It might be in the individual's interests to confess. It is clearly not in the interests of both, however, for both to confess.

Let us now look at two real-world examples of the prisoners' dilemma.

Standing at football

When people go to some public event, such as a football match, they often stand in order to get a better view. But once people start standing, everyone is likely to do so: after all, if they stayed sitting, they would not see at all. If everyone stands, no one has an incentive to sit down, since they would then see nothing. In this Nash equilibrium, most people are worse off, since, except for tall people, their view is likely to be worse and they lose the comfort of sitting down.

Too much advertising

Why do firms spend so much on advertising? If they are aggressive, they do so to get ahead of their rivals. If they are cautious, they do so in case their rivals increase their advertising. Although in both cases it may be in the individual firm's best interests to increase advertising, the resulting Nash equilibrium is likely to be one of excessive advertising: the total spent on advertising (by all firms) is not recouped in additional sales.

1. Give some other non-economic examples of the prisoners' dilemma.
2. Can collusion by firms overcome the prisoners' dilemma?

higher profits today could lead to lower profits in the future. The potential impact of this trade-off can be illustrated by using the prisoners' dilemma example in Table 8.1.

Assume that firm X and Y have an agreement to charge £2.00 (or simply follow each other's lead in doing so). Each firm will thus continue charging £2 as long as the other firm

does too. If, however, firm Y ever cut its price to £1.80 in one period, then firm X would do the same in all future periods. Once this has happened, no matter what firm Y then does, firm X is unlikely to charge a price of £2 ever again. In game theory, this new strategy employed by firm Y is known as the *trigger strategy*.

Figure 8.10 Profits for firm Y in a repeated game

The profit profile for firm Y of following two different pricing strategies is illustrated in Figure 8.10. By following the same dominant strategy as in the single-move game and charging a price of £1.80 (i.e. breaking the agreement), firm Y can increase its profit in the first period from £10 million to £12 million. The downside of this strategy is that its profits in all future periods will fall to £8 million as firm X responds by also charging £1.80. This is illustrated by the profit profile of $a \rightarrow b \rightarrow c \rightarrow d$ in Figure 8.10.

Alternatively, firm Y could stick to the agreement and charge £2.00 in the first period. Its profit of £10 million is £2 million lower than it would have earned by charging £1.80. However, as long as it maintains its price at this level, firm X will also charge £2.00. Firm Y's profits in all future period will thus be £10 million as opposed to £8 million. This is shown by the profit profile $e \rightarrow f \rightarrow g$.

After a while, both Y and X will realise that the Nash equilibrium (£1.80) is not to the advantage of either. This may persuade them to set up a stronger collusive agreement to restore prices to £2. This outcome is most likely to occur when:

- firms value future profits quite highly;
- firms compete against each other very frequently – there are more future time periods to benefit from the higher profits of charging £2 and area $fgdc$ is larger;
- the higher profits from charging £1.80 in the first period are relatively small. This reduces the size of area $abfe$;
- a firm can quickly observe that its rival is charging the lower price. This reduces the length of time over which a firm will benefit from the higher profits of charging £1.80, again reducing the size of area $abfe$;
- both firms adopt the trigger strategy, putting them in a similar position.

Backwards induction and movement to the Nash equilibrium. Another issue is whether both firms know just how long the current product designs and costs will last – in other words, when the current round of repeated price

Definitions

Trigger strategy Once a firm observes that its rival has broken some agreed behaviour it will never co-operate with them ever again.

Backwards induction A process by which firms think through the most likely outcome in the last period of competition and then work backwards step by step thinking through the most likely outcomes in earlier periods of competition.

settings will end. If they do, then the chances of the firm co-operating and charging higher prices is much lower. The most likely outcome is the same as for a single-move game, with the dominant strategy being to cut price.

To understand why this is the case both firms need to think about the most likely outcome in the last period of competition (i.e. the last time prices are set before any changes in product design, costs, etc.) and then work backwards to think about the most likely outcome in earlier periods. This is called *backwards induction*.

The incentive for each firm to charge £2 in any period is to influence the behaviour of its rivals in future periods. However, in the last period of competition there is no future to affect, as the firms will never compete against one another again with the same product. Therefore, the last period is effectively the same as a simultaneous single-move game and both firms are highly likely to follow their dominant strategies of charging £1.80.

If both firms realise in the last-but-one period of competition that they cannot influence what their rival will do in the last period of competition then their best strategy is also to charge £1.80. If they keep following the same line of reasoning they will both charge £1.80 in every period of competition.

Therefore, the chances of the firms charging a higher price is much greater when they both believe that competition between them will carry on indefinitely: i.e. neither of them knows the precise date when the current type of interaction between them will come to an end.

? Another type of strategy firms can follow in a repeated game is the 'tit-for-tat' strategy. What is the 'tit-for-tat' strategy? What impact will it have on the most likely outcome in a repeated game?

Sequential-move games

So far we have looked at simultaneous games: where firms take decisions at the same time without seeing the decision of the other firm(s). However, in many real-world competitive environments, one firm (the first mover) makes and implements a decision (i.e. it produces a certain output, sets a particular price or introduces a new product) *before* its rivals (the second movers). The second movers are then able to observe the actions of the first mover before deciding on their best

response. These strategic environments can be studied by using *sequential-move games*.

Take the case of a new generation of large passenger aircraft that can fly further without refuelling. Assume that there is a market for a 500-seater version of this type of aircraft and a 400-seater version, but that the market for each size of aircraft is not big enough for the two manufacturers, Boeing and Airbus, to share it profitably. Let us also assume that the 400-seater market would give an annual profit of £50 million to a single manufacturer and the 500-seater would give an annual profit of £30 million, but that if both manufacturers produced the same version, they would each make an annual loss of £10 million.

Assume that Boeing is the first mover and announces which plane it will build: the 400-seater or the 500-seater. Airbus then has to respond to the decision and decide which plane it will build.

This scenario can be illustrated as a sequential-move game and is shown in Figure 8.11. Sequential-move games are typically illustrated in 'extensive form' by use of a *decision tree*, which identifies the possible sequence of events. The small square on the left of the decision tree shown in Figure 8.11 is Boeing's decision point (point A). If it decides to build the 500-seater plane, we move up the top branch. Airbus would now have to make a decision (point B₁). If it too decides to build the 500-seater plane, we would move to outcome 1: a loss of £10 million for both manufacturers.

Clearly, with Boeing building a 500-seater plane, the best response for Airbus would be to choose the 400-seater plane: we would move to outcome 2, with Boeing making a profit of £30 million and Airbus a profit of £50 million. Airbus would be very pleased!

Boeing's best strategy at point A, however, would be to build the 400-seater plane. We would then move to Airbus's decision point B₂. In this case, Airbus's best response is to build the 500-seater plane. Its profit would be only £30 million (outcome 3), but this is better than a £10 million loss if it too built

the 400-seater plane (outcome 4). With Boeing deciding first, the Nash equilibrium will thus be outcome 3.

There is clearly a *first-mover advantage* here. Once Boeing has decided to build the more profitable version of the plane, the best response for Airbus is to build the less profitable one. Naturally, Airbus would like to build the more profitable one and be the first mover. Which company succeeds in going first depends on how advanced they are in their research and development and in their production capacity.

The importance of threats and promises

In a sequential-move game, a second mover could threaten or promise to behave in a certain way in an attempt to influence the behaviour of the first mover. For example, in the above game Airbus could announce that it was going to build a 400-seater plane irrespective of what Boeing decides to do. Why would Airbus do this? If Boeing believed Airbus' announcement then its best move is to build a 500-seater plane, making a profit of £30 million as opposed to a loss of £10 million. Hence, the announcement influences Boeing's behaviour in a manner that is favourable to Airbus – it earns greater profits.

However, there is a problem with Airbus' announcement – Boeing will probably not believe it! If Boeing

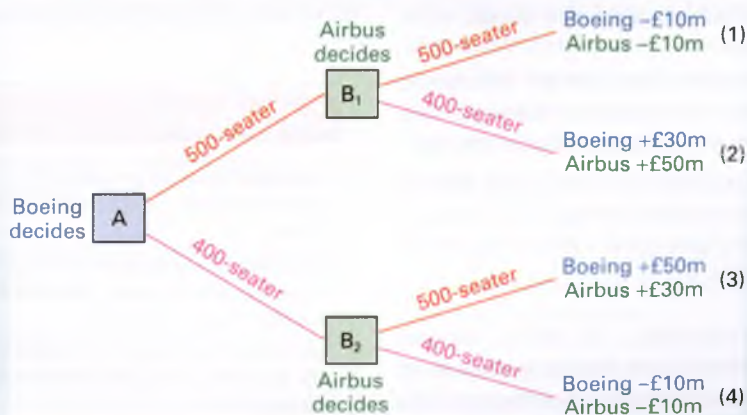

Definitions

Sequential-move game One firm (the first mover) makes and implements a decision. Rival firms (second movers) can observe the actions taken by the first mover before making their own decisions.

Decision tree (or game tree) A diagram showing the sequence of possible decisions by competitor firms and the outcome of each combination of decisions.

First-mover advantage When a firm gains from being the first one to take action.

Figure 8.11 A decision tree

actually built a 400-seater plane, Airbus' best move would be to build a 500-seater plane. Boeing can clearly see that it is not in Airbus' own self-interest to do what it said it was going to do. Therefore the strategy is not **credible** and Boeing will build the 400-seater plane.

Could Airbus take some irreversible actions so it is committed in advance to building the 400-seater plane? The key to the success of this policy is that Boeing must believe it: it must be credible. If this was possible, then by limiting its own options, Airbus could actually make greater profits. In some circumstances, inflexibility can actually improve the competitive position of the firm by altering its rivals' expectations about how it will behave.

More complex sequential-move games

The aircraft example is the simplest version of a sequential-move game, with just two companies and each one making only one key decision. In many business situations, much more complex trees could be constructed. The 'game' would be more like one of chess, with many moves and several options on each move. If there were more than two companies, the decision tree would be more complex still.

Assessing the simple theory of games

Game theory provides a very useful framework for helping us to think about competitive environments where there is strategic interdependence. It highlights the importance of each firm trying to think through situations from their rival's viewpoint in order to work out their own profit-maximising decision.

In this section, we have considered a number of quite simple games, with just two firms having to choose between just two different options. In reality, many oligopolistic markets will consist of a number of firms that each have to choose from multiple options on pricing, product design, advertising, etc. Therefore it would be very difficult if not impossible for them to obtain precise information on (a) the pay-offs to all their rivals from all the possible actions they could take and (b) the impact of all the possible actions of their rivals on their own pay-offs. The approach is useful, therefore, only in relatively simple cases, and even then the estimates of profit from each outcome may amount to no more than a rough guess.

Even if we assume that both firms have full information on all the relevant pay-offs, the outcome of real-world competition may still be different from that predicted by standard game theory. At a Nash equilibrium each firm assumes that its rivals behave in a rational manner: that they can consider all the pay-offs and successfully make decisions that maximise their own profits.

Decision making under uncertainty. In reality, decision makers may make systematic errors, especially when faced with complicated problems. How sure can a firm be when working out its best response that its rival is in fact behaving

in a rational manner? Could it mistakenly choose a suboptimal strategy?

If firms believe there is a strong chance that their rivals will behave in an irrational manner, then the outcome of competition is much harder to predict. In response to this uncertainty they might play it safe by choosing the strategy that minimises their losses from the worst-case scenario from the unpredictable behaviour of their rival. Such a strategy is known as **maximin**. Alternatively, if they were more risk loving, they could gamble and choose the outcome that maximises their pay-off from the best-case scenario. Such a strategy is known as **maximax**.

Changing behaviour patterns over time. Behaviour may also change over time as firms learn about the consequences of their actions and the competitive environment changes. For example, firms may compete hard for a time (in price or non-price terms) and then realise that it is making them all worse off. Firms may then start to collude and jointly raise prices and reduce advertising. Later, after a period of tacit collusion, competition may break out again. This may be sparked off by the entry of a new firm, by the development of a new product design, by a change in market demand, or simply by one or more firms no longer being able to resist the temptation to 'cheat'. In short, the behaviour of particular oligopolists may change quite radically over time as they find out new information.

The objectives of firms. Finally, we have been assuming that firms behave selfishly – that they make decisions with the sole purpose of maximising profits. In reality, people's actions are likely to be influenced by their moral values. Businesspeople may be unwilling to behave ruthlessly or dishonestly, or to undertake profitable activities that they regard as unfair. In Chapter 9, we examine some of the consequences of pursuing goals other than ruthless profit maximisation.

Given the lack of perfect information, uncertainty about the rationality of rivals and varying objectives of firms, simple game theory cannot predict with any accuracy what price, output and level of advertising firms will choose in the real world.

Definitions

Credible threat (or promise) One that is believable to rivals because it is in the threatener's interests to carry it out.

Maximin The strategy of choosing the policy whose worst possible outcome is the least bad. Maximin is usually a low-risk strategy.

Maximax The strategy of choosing the policy that has the best possible outcome. Maximax is usually a high-risk strategy.

Section summary

1. Game theory is a way of modelling behaviour in strategic situations where the outcome for an individual or firm depends on the choices made by others. Thus game theory examines various strategies that firms can adopt when the outcome of each is not certain.
2. One of the simplest types of 'game' is a simultaneous single-move or single-period game. They are often presented in normal form: i.e. as a pay-off matrix. Some simultaneous single-move games have predictable outcomes, no matter what assumptions each firm makes about its rivals' behaviour. Such games are known as dominant-strategy games. Many other simultaneous games are more complicated and either one or both firms do not have a dominant strategy. The Nash equilibrium is a useful way to predict the most likely outcome in any of these games.
3. If a simultaneous game is repeated, the equilibrium can change. The final result depends on a number of factors such as whether the end date of the game is known.
4. In sequential-move games play passes from one 'player' to the other sequentially. Firms will respond not only to what firms do, but what they say they will do. To this end, a firm's threats or promises must be credible if they are to influence rivals' decisions.
5. A firm may gain a strategic advantage over its rivals by being the first one to take action (e.g. to launch a new product). The second mover may gain an advantage if it can commit in advance to behave in a certain manner. A decision tree can be constructed to show the possible sequence of moves in a multiple-move game.

8.4 PRICE DISCRIMINATION

Up to now we have assumed that firms sell each unit of output for the same price. This is known as *uniform pricing*. However, if a firm is able to charge *more* than one price, it might be able to increase profits. It could do this if it can charge a higher price to those customers who are willing to pay more and a lower price to those consumers who would only buy it at a lower price. A strategy of charging more than one price is known as *price discrimination*. However, care needs to be taken when explaining the precise meaning of this concept, as vague definitions can sometimes lead to it being incorrectly applied.

If the costs to the firm of supplying different customers does not vary then price discrimination is defined as the practice of selling the same or similar products to different customers for different prices. If the costs of supplying different customers *does* vary then the definition is slightly more complicated. It is defined as the practice of selling the same or similar product at different prices and the difference in price cannot be fully accounted for by any difference in the cost of supply.

If customers were all charged the same price for a product could this ever be classed as an example of price discrimination? Explain your answer.

Economists traditionally distinguish between three different types of price discrimination.

First-degree price discrimination is where the seller of the product charges each consumer the maximum price he or she is prepared to pay for each unit. It is sometimes called 'perfect price discrimination' or 'personalised pricing'.

Definitions

Price discrimination Where a firm sells the same product at different prices.

First-degree price discrimination Where the seller of the product charges each consumer the maximum price they are prepared to pay for each unit.

Second-degree price discrimination Where a firm offers consumers a range of different pricing options for the same or similar product. Consumers are then free to choose whichever option they wish, but the price is often dependent on some factor such as the quantity purchased.

In reality, first-degree price discrimination is more of a theoretical benchmark than a viable business strategy because it is very unlikely that sellers could obtain reliable information on the maximum amount people are willing to pay. However, there may be some real-world cases where sellers can implement a person-specific pricing strategy that approaches one of first-degree price discrimination. For example, stallholders in a street market and second-hand car dealers will attempt to do this when haggling with their customers.

Second-degree price discrimination is where a firm offers consumers a range of different pricing options for the same or similar product. Consumers are then free to choose whichever option they wish but the lower prices are conditional on factors such as:

- The quantity of the product purchased. In order to obtain the good at a lower price the customer has to purchase a certain quantity of the good or service.

- The use of coupons/vouchers. To be eligible to purchase the product for a lower price customers have to produce a voucher or coupon that they have collected: e.g. from a flyer inside a local newspaper or from the Internet.
- When the product is purchased. For example, some goods are priced at a higher level when they are first released onto the market. Rail fares are higher at peak times than at off-peak times.
- The version of the product purchased. Firms can produce different versions of the same core product that have different levels of actual or perceived quality: e.g. value ranges of own-label products sold in supermarkets. This is called 'versioning'. One example of versioning is the 'damaged goods strategy' where firms create a lower quality version of its good by deliberately damaging the product. It does this by removing some features or reducing its performance characteristics. Note that versioning is not *pure* price discrimination because the product is slightly different.

Third-degree price discrimination is where a firm divides consumers into different groups based on some characteristic that is (a) relatively easy to observe; (b) informative about consumers' willingness to pay; (c) legal; and (d) acceptable to the consumer. The firm then charges a different price to consumers in different groups, but the same

Definition

Third-degree price discrimination Where a firm divides consumers into different groups based on some characteristic that is relatively easy to observe and informative about how much consumers are willing to pay. The firm then charges a different price to consumers in different groups, but the same price to all the consumers within a group.

Table 8.3 Examples of third-degree price discrimination

Characteristic	Example
Age	16–25 or senior rail card; half-price children's tickets in the cinema.
Gender	'Ladies' night' in a bar or club where men pay the full price for drinks while women can get the same drinks at a discounted price.
Nationality	In several countries, foreign visitors are charged higher entrance fees than locals to various tourist sites.
Location	Pharmaceutical companies often charge different prices for the same medicine/drug in different countries. Consumers in the USA are often charged more than those from other countries.
Occupation	Apple, Microsoft and Orange™ provide price discounts to employees of educational institutions.
Business or individual	Publishers of academic journals charge much lower subscription rates to individuals than university libraries.
Past buying behaviour	Firms often charge new customers a lower price than existing customers for the same product or service as an 'introductory offer'.

price to all consumers in the same group. Some examples include charging different prices based on age, occupation, geographical location and past buying behaviour. See Table 8.3 for some specific examples.

Conditions necessary for price discrimination to operate

As we shall see, a firm will be able to increase its profits if it can engage in price discrimination. But under what

BOX 8.6

WHAT'S THE TRAIN FARE TO LONDON?

CASE STUDIES AND APPLICATIONS

Price discrimination on the trains

Ask the question 'What's the fare to London?' at ticket enquiries, and you may receive any of the following replies:

- Do you want 1st or standard class?
- Do you want single or return?
- How old are you?
- Do you have a railcard (Family & Friends, 16–25, Disabled Person, Senior, Two Together)?
- Will you be travelling on a weekday?
- Will you be travelling out before 9:30am?
- Will you be leaving London between 4pm and 6:30pm?
- Are you able to book your ticket in advance?
- Do you need to be flexible about the time and date of your journeys, or are you willing to pre-commit to a specific train?

1. Look at each of the above questions. In each case, decide whether price discrimination is being practised. If it is, is it sensible for train operators to practise it? How are the train operators able to identify travellers with different price elasticities of demand?
2. Are these various forms of price discrimination in the traveller's interest?

You can check out the range of ticket types and prices by going to the National Rail website at www.nationalrail.co.uk and selecting a journey.

BOX 8.7 PEAK-LOAD PRICING

EXPLORING
ECONOMICS

Charging more when it costs more to produce

A common form of price discrimination is **peak-load pricing**. This is where people are charged more at times of peak demand and less at off-peak times. Take the case of a holiday. If you look through the brochures or online, you will see that high-season prices are often considerably higher than low-season prices. Similarly, call charges for telephones are often much higher during weekdays than in the evenings and at weekends. Other examples of peak-load (or 'peak-period') pricing are rail and airfares, prices in cinemas and restaurants (higher in the evenings) and charges made by health and sports clubs (higher at weekends and in the evenings).

The reason for the higher prices charged at peak times has partly to do with elasticity of demand. Demand is less elastic at peak times. For example, many commuters have little option but to pay higher rail fares at peak times. This is genuine price discrimination.

But often the higher charges also have to do with higher marginal costs incurred at peak times and, as such, are not true price discrimination. With various fixed factors (such as plant and equipment), marginal costs are likely to rise as output expands to meet higher demand. This could be due to diminishing returns to the variable factors; or it could be due to having to use additional equipment with higher operating costs.

Take the case of electricity. At off-peak times, the power stations with the lowest operating costs will be used. These are normally the wind, nuclear and coal-fired stations. At periods of peak demand, however, stations with higher

operating costs, such as oil-fired and gas-fired stations, will have to be brought online. (Both oil- and gas-fired stations are relatively cheap to build, but have higher running costs, largely because of the more expensive fuel.) As a result, the marginal cost of generating electricity is higher at peak times than at off-peak times.

But what are the profit-maximising peak and off-peak prices? These are illustrated in the diagram, which shows units per hour (e.g. of electricity). There are two demand (AR) curves – peak and off-peak – and their corresponding marginal revenue (MR) curves. Profit is maximised in either period at the output where $MR = MC$ (points a and b respectively). In the peak period, this will be at the higher price P_{peak} . There are two reasons why the price is higher. First, demand is less elastic. This is demonstrated by the fact that price is a higher percentage above MR in the peak period than in the off-peak period. Second, marginal cost is higher in the peak period.

1. How likely is it that domestic customers will be able to switch consumption of electricity to off-peak periods? How likely is it that businesses will be able to do so?
2. If, over time, consumers are encouraged to switch their consumption to off-peak periods, what will happen to peak and off-peak prices?
3. To what extent is peak-load pricing in the interests of consumers?
4. Is total consumption likely to be higher or lower with a system of peak and off-peak prices as opposed to a uniform price at all times?

Definition

Peak-load pricing Price discrimination (second or third degree) where a higher price is charged in peak periods and a lower price in off-peak periods.

circumstances will it be able to charge discriminatory prices? There are three conditions that must be met:

- The firm must be able to set its price. Thus price discrimination will be impossible under perfect competition, where firms are price takers. In other words, firms practising price discrimination must have some market power.

- The markets must be separable. Consumers in the low-priced market must not be able to resell the product in the high-priced market. For example, children must not be able to resell a half-priced child's cinema ticket for use by an adult.
- Demand elasticity must differ in each market. The firm will charge the higher price in the market where demand is less elastic, and thus less sensitive to a price rise.

Advantages to the firm

Price discrimination allows the firm to earn a higher revenue from any given level of sales. Let us examine the case of third-degree price discrimination.

Figure 8.12 represents a firm's demand curve. If it is to sell 200 units without price discrimination, it must charge a price of P_1 . The total revenue it earns is shown by the green area. If, however, it can practise third-degree price discrimination by selling 150 of those 200 units at the higher price of P_2 , it will gain the pink area in addition to the green area in Figure 8.12.

? Explain why, if the firm can practise first-degree price discrimination by selling every unit at the maximum price each consumer is prepared to pay, its revenue from selling 200 units will be the green area plus the pink area in Figure 8.13.

Another advantage to the firm of price discrimination is that it may be able to use it to drive competitors out of business. If a firm has a monopoly in one market (e.g. the home market), it may be able to charge a high price due to relatively inelastic demand, and thus make high profits. If it is under oligopoly in another market (e.g. the export market), it may use the high profits in the first market to subsidise a very low price in the oligopolistic market, thus forcing its competitors out of business.

Profit-maximising prices and output

Assuming that the firm wishes to maximise profits, what discriminatory prices should it charge and how much should it produce? Let us first consider the case of first-degree price discrimination.

First-degree price discrimination

Since an increase in sales does not involve lowering the price for any unit save the *extra* one sold, the extra revenue gained from the last unit (*MR*) will be its price. Thus profit is maximised at Q_1 in Figure 8.14, where $MC = MR (= P$ of the *last* unit).

Third-degree price discrimination

Assume that a firm sells a given product (such as window cleaning services) and can split its customers into two groups, based on location, where people in market H have a

Figure 8.12 Third-degree price discrimination

Figure 8.13 First-degree price discrimination

Figure 8.14 Profit-maximising output under first-degree price discrimination

higher average income than people in market L. This is illustrated in Figure 8.15.

It is highly probable that most consumers with the higher incomes would be willing to pay more for the product than those on low incomes. Panel (a) in Figure 8.15 illustrates the demand curve for the firm's product in the high-income

Figure 8.15 Profit-maximising output under third-degree price discrimination

market, market H, while panel (b) illustrates the demand curve for those in the low-income market, market L.

Equilibrium for a single-price firm. If the firm were unable to split its customers into these two groups, then a market demand curve could be derived. This is illustrated in panel (c) and is obtained by horizontally aggregating the demand curves in panel (a) and (b). The market demand curve between points g and h is the same as the demand curve in market H between points a and b. This is because no consumer in market L is willing to pay a price above d . As the price falls below d , consumers in both market H and market L are willing to buy the good, so horizontal aggregation of both demand curves must take place from this point onwards. This creates a kink in the market demand curve at point h . This kink also creates a discontinuity in the MR curve between points j and k . To simplify the explanation it is also assumed that the firm's marginal cost is constant and it has no fixed costs. Thus $AC = MC$.

To understand how a firm would behave if it could only set one price for all of its customers we need to focus on the market demand curve in panel (c). If it was a profit-maximising firm then it would produce where the market MR (i.e. MR_M) = MC . This occurs at point l in panel (c) of Figure 8.15. It would therefore produce an output of Q^* and sell all of this output at the same price of P^* .

Equilibrium under third-degree price discrimination. What happens if the firm could now charge a different price to the customers in market H from those in market L? At the single price of P^* the price elasticity of demand in market H is lower than it is in market L. (Note that demand is nevertheless elastic in both markets at this price as MR is positive). Therefore the firm could increase its profits by charging a price above P^* in market H and below P^* in market L. Once again this can be illustrated in Figure 8.15.

In market H the profit-maximising firm should produce where $MR_H = MC$. Therefore it should sell an output of Q_H for a price of P_H .

In market L the profit-maximising firm should produce where $MR_L = MC$ at point f . Therefore it should sell an output of Q_L for a price of P_L .

Note that P_L is below P^* , while P_H is above P^* . Also, because the demand curves are linear, the total output sold is the same under third-degree price discrimination as it is under uniform pricing: i.e. $Q^* = Q_H + Q_L$. We will see later in the chapter that this is a key point when considering whether or not price discrimination is in the public interest.

How easy do you think it would be for a firm to split customers into different groups based on their incomes?

*LOOKING AT THE MATHS

We can use calculus to work out the profit-maximising prices and outputs in each of the two markets H and L in Figure 8.15. If we know the demand functions in each of the two markets, H and L , we can derive the total revenue functions in each market (TR_H and TR_L) and hence in the two markets together ($TR = TR_H + TR_L$). Total profit is given by

$$T\Pi = TR_H + TR_L - TC$$

To find the maximum-profit output in each market, we (partially) differentiate the total profit equation with respect to output in each of H and L and set each equal to zero and solve for Q_H and Q_L (see pages A:9–13 for how calculus is used to find a maximum value). We can then substitute these values of Q_H and Q_L in the respective demand functions to work out P_H and P_L .

Maths Case 8.3 on the student website shows how this is done by using a worked example.

Price discrimination and the public interest

It is tempting to think that anything that increases firms' profits must be at the expense of consumers' welfare. However, this is not necessarily the case and no clear-cut decision can be made over the social desirability of price discrimination. Some people benefit from it; others lose. This can be illustrated by considering the effects of price discrimination on the following aspects of the market.

TC 3
p26

Distribution effects on those customers who previously purchased the good at a uniform price

Those paying the higher price will probably feel that price discrimination is unfair to them. Price has risen for them and their consumer surplus is lower. On the other hand, those who previously purchased the good but are now paying a lower price will feel better off. Their consumer surplus will be higher. Judgements could be made about whether the gains were more socially desirable than the losses.

KE 4
p14

The impact of any extra sales

In Figure 8.15, the quantity of sales under price discrimination remained the same as under uniform pricing. However, in some circumstances the quantity of sales may increase. There may be some consumers, such as pensioners, who previously could not afford to buy the good when the firm used uniform pricing. The lower price, made possible by price discrimination, now enables them to purchase the good. These extra sales will have a positive impact on the welfare of society. They will increase both consumer surplus and profit.

Misallocation effects

Price discrimination may cause a negative allocation effect. Under uniform pricing the product is allocated through the price mechanism to those consumers who value it the most, given their incomes. The implementation of third-degree

price discrimination could result in some units of the product being reallocated away from those consumers with a higher willingness to pay to those with a lower willingness to pay.

Without any restrictions, mutually beneficial trade might be able to take place between the buyers. Those consumers with a higher valuation of the good could, under some circumstances, purchase it from those with a lower valuation at a price that would improve the welfare of both parties. However, the seller blocks this resale from taking place and in the process reduces society's welfare.

Competition

As explained above, a firm may use price discrimination to drive competitors out of business. This is known as *predatory pricing*. For example, in many towns, large bus companies have used profits they make in *other* towns where they have a monopoly to subsidise their bus fares and thereby drive competitors out of business, only then to raise prices above those that the competitors had been charging. On the other hand, a firm might use the profits from its high-priced market to break into another market and withstand a possible price war. Competition is thereby increased.

Profits

Price discrimination raises a firm's profits. This could be seen as an undesirable redistribution of income in society, especially if the average price of the product is raised. On the other hand, the higher profits may be reinvested and lead to innovation or lower costs in the future.

Definition

Predatory pricing Where a firm sets its prices below average cost in order to drive competitors out of business.

BOX 8.8

JUST THE TICKET?

CASE STUDIES AND APPLICATIONS

Price discrimination in the cinema

One of the commonest forms of price discrimination is where children are charged a lower price than adults, whether on public transport or for public entertainment. Take the case of cinema tickets. In most cinemas, children pay less than adults during the day. In the evening, however, many cinemas charge both adults and children the same price.

But why do cinemas charge children less during the day? After all, the child is seeing the same film as the adult and occupying a whole seat. In other words, there is no difference in the 'product' that they are 'consuming'. And why are children charged the higher price in the evenings, given that the seat and the film are the same as during the day?

The answer has to do with revenue maximisation and the price elasticity of demand. Once a cinema has decided to show a film, the marginal costs of an additional customer are zero. There are no additional staffing, film-hire, electricity or other costs. With marginal costs equal to zero, profits will be maximised where marginal revenue is also equal to zero: in other words, where total revenue is maximised.

Take the case of a cinema with 500 seats. This is illustrated in the diagrams, which show the demand and marginal revenue curves for both adults and children. It is assumed that the elasticity of demand for children's tickets is greater than that for adults' tickets. Diagram (a) shows demand during the late afternoon (i.e. after school). Here the demand by children is relatively high compared with adults, but the overall demand is low. Diagram (b) shows demand during the evening. Here there is a higher overall level of demand, especially by adults, many of whom work during the day.

For the afternoon screening (diagram (a)), revenue is maximised from children by charging them a price of £8.00,

(a) Number of tickets (afternoon)

(b) Number of tickets (evening and total)

i.e. at the point on the demand curve where $MR = 0$. At this price, 200 child tickets will be sold.

Assuming that the same adult price is charged in both the afternoon and the evening, we need to look at the *total* demand for full-priced tickets (i.e. for both afternoon and evening screenings) in order to ascertain the revenue-maximising price. This will be a price of £14.00, where total adult $MR = 0$ (see diagram (b)). This will lead to 100 adult tickets being sold in the afternoon and 500 in the evening.

But why are reduced-price tickets not available for children in the evening? In diagram (b), the sale of low-priced tickets for children would lead to demand exceeding the 500-seat capacity of the cinema. Each time an adult was turned away because the seat had already been sold to a child, the cinema would lose.

1. Which type of price discrimination is the cinema pursuing: first, second or third degree? Could it pursue either of the other two types?
2. If all cinema seats could be sold to adults in the evenings at the end of the week, but only a few on Mondays and Tuesdays, what price discrimination policy would you recommend to the cinema in order for it to maximise its weekly revenue?
3. Would the cinema make more profit if it could charge adults a different price in the afternoon and the evenings?
4. Would you advise that the cinema extend its practice of price discrimination to include other groups? If so, which groups should be targeted?
5. Are there any other advantages, beyond the additional revenues generated, to having more people in the cinema? Are there any disadvantages?

Section summary

1. If the costs to the firm of supplying different customers do not vary, then price discrimination is the practice of selling the same or similar products to different customers for different prices. If the costs of supplying different customers *does* vary, then price discrimination is the practice of selling the same or similar product at different prices where the difference in price cannot be fully accounted for by the difference in the cost of supply.
 2. Price discrimination allows the firm to earn a higher revenue from a given level of sales.
 3. First-degree price discrimination is where the consumer is charged the maximum he or she is prepared to pay.
- Second-degree price discrimination is where the consumer is offered a range of different prices for the same or similar product. They are free to choose whichever option they wish but the lower prices are conditional on some features of the purchase. Third-degree price discrimination is where consumers are divided into groups and the groups with the lower price elasticity of demand are charged the higher prices.
4. Whether price discrimination is in the consumer's interest or not is uncertain. Some individuals will gain and some will lose

END OF CHAPTER QUESTIONS

1. Assume there are just two firms (X and Y) and they are considering which of two alternative prices to charge. The decisions are made simultaneously: i.e. without either firm knowing the choice of its rival. This various profits are illustrated in the following pay-off matrix.

Table 8.4 Profits for firms X and Y at different prices

		X's price	
		£25	£19
Y's price	£20	A £6m, £6m	B £2m, £5m
	£15	C £4m, £3m	D £4m, £4m

- (a) What is firm Y's best response to each of the different prices firm X could charge? Does firm Y have a dominant strategy?
 - (b) What is firm X's best response to each of the different prices firm Y could charge? Does firm X have a dominant strategy?
 - (c) What is/are the Nash equilibrium/equilibria? What is the most likely outcome of this game? Explain your answer.
2. Assume that a monopolistically competitive industry is in long-run equilibrium. On a diagram like Figure 8.1(b), show the effect of a fall in demand on a firm's price and profit in (a) the short run and (b) the long run.
 3. In what ways is a monopolistically competitive firm likely to be less efficient than one under perfect competition?
 4. Are there any shops in your area that stay open later than others? If so, does this affect the prices they charge? Why do you think this is?
 5. Give three examples of oligopolistic industries. In what ways do the firms in each of these industries compete? Why do they choose to compete in the way that they do?
 6. Why, under oligopoly, might a particular industry be collusive at one time and yet highly price competitive at another?
 7. What is meant by the prisoners' dilemma game when applied to the behaviour of oligopolists? Discuss some factors that will determine the outcome of the game?
 8. What three characteristics must a strategic move have if it is to be successful in altering the behaviour of a competitor later in the game?
 9. Give two examples of price discrimination. Which category of price discrimination are they? In what ways do the consumers gain or lose? What information would you need to be certain in your answer?
 10. Explain why the rise in e-commerce might increase the number of firms engaging in person-specific pricing.
 11. For a firm to be able to implement a strategy of price discrimination it must be able to prevent resale amongst its customers. What factors would make it more difficult for a consumer to resell a good?

Variations in the mark-up	274

The traditional theories of the firm that we have been looking at in the previous three chapters assume that firms aim to maximise profits. Although this is an accurate assumption for many firms, for many it is not.

Some firms would *like* to maximise profits, but have insufficient information to enable them to do so. Others do not even want to maximise profits, if that means sacrificing some other aim, such as rapid growth or increased market share.

In this chapter, we focus on the behaviour of decision makers in firms. We look at various aims they might pursue as an alternative to maximum profits: aims such as maximum sales revenue or maximum growth. We also examine the implications of pursuing alternative aims for the profitability of the firm and for the prices paid by the consumer.

Many firms, especially larger ones, are complex organisations, with different individuals and departments pursuing their own agenda. What happens when these various goals come into conflict? How does conflict get resolved? What are the implications for consumers and other 'stakeholders'? We examine these issues in section 9.5.

Finally, we ask how prices are determined in practice. If firms do not use marginal revenue and marginal cost concepts in setting their prices, or if they are not aiming to achieve maximum profits, how do they choose the price to charge? As we shall see, firms often base their prices on average cost.

9.1 PROBLEMS WITH TRADITIONAL THEORY

The traditional profit-maximising theories of the firm have been criticised for being unrealistic. The criticisms are mainly of two sorts: (a) that firms wish to maximise profits but for some reason are unable to do so; or (b) that firms have aims other than profit maximisation. Let us examine each in turn.

Difficulties in maximising profit

One criticism of traditional theory is that firms do not use *MR* and *MC* concepts. This may well be true, but firms could still arrive at maximum profit by trial and error adjustments of price, or by finding the output where *TR* and *TC* are furthest apart. Provided they end up maximising profits, they will be equating *MC* and *MR*, even if they did not adopt that as a strategy. In this case, traditional models will still be useful in predicting price and output.

Lack of information

The main difficulty in trying to maximise profits is a *lack of information*.

Firms may well use accountants' cost concepts not based on opportunity cost. If it were thereby impossible to measure true profit, a firm would not be able to maximise profit except by chance.

What cost concepts are there other than those based on opportunity cost? Would the use of these concepts be likely to lead to an output greater or less than the profit-maximising one?

More importantly, firms are unlikely to know even approximately their demand curves and hence their *MR* curves. Even though they will know how much they are selling, this only gives them one point on their demand curve and no point at all on their *MR* curve. In order to make an informed guess of marginal revenue, they would need an idea of how responsive demand will be to a change in price.

But how are they to estimate this price elasticity? Market research may help. But this may be unreliable.

The biggest problem in estimating the firm's demand curve is in estimating the actions and reactions of *other* firms and their effects. Even under collusion there will still be a considerable uncertainty.

As we saw in Chapter 8, game theory may help a firm decide its price and output strategy. But for this to be accurate, it requires that a firm knows the consequences for its profits of each of the possible reactions of its rivals. In reality, no firm will have this information, because it will not know for sure how consumers will respond to each of its rivals' alternative strategies.

Time period

Finally, there is the problem of deciding the time period over which the firm should be seeking to maximise profits. Firms operate in a changing environment. Demand curves shift; supply curves shift. Some of these shifts occur as a result of factors outside the firm's control, such as changes in

competitors' prices and products. Some, however, change as a direct result of a firm's policies, such as an advertising campaign or the installation of new equipment. The firm is not, therefore, faced with static cost and revenue curves from which it can read off its profit-maximising price and output. Instead it is faced with a changing and unpredictable set of curves. If it chooses a price and output that maximises profits this year, it may be entirely the wrong decision months, or even weeks, later.

Take a simple example. The firm may be considering whether to invest in new equipment. If it does, its costs will rise in the short run and thus short-run profits will fall. On the other hand, if the quality of the product thereby increases, demand is likely to increase over the longer run. Also, variable costs will decrease if the new equipment is more efficient. In other words, long-run profit is likely to increase, but probably by an uncertain amount.

Given these problems in trying to work out complex strategies to maximise profits, managers may fall back on simple rules of thumb or mental shortcuts for pricing and output decisions (see page 225).

Alternative aims

An even more fundamental attack on traditional theory is that firms do not even *aim* to maximise profits (even if they could).

The traditional theory of the firm assumes that it is the *owners* of the firm who make price and output decisions. It is reasonable to assume that owners *will* want to maximise profits. The question is, however, whether the owners do in fact make the decisions.

In *public limited companies* the shareholders are the owners. Presumably they will want the firm to maximise profits so as to increase their dividends and the value of their shares. Shareholders elect directors. Directors in turn employ professional managers who are often given considerable discretion in making decisions. There is therefore a *separation between the ownership and control* of a firm. (See Case Study 9.1 on the student website for an examination of the legal structure of firms.)

So what are the objectives of managers? Will *they* want to maximise profits, or will they have some other aim?

We can assume that they want to *maximise their own utility*. They may, for example, pursue higher salaries, greater power or a more prestigious company car. Different managers in the same firm may well pursue different aims. These aims may conflict with profit maximisation.

Definition

Public limited company A company owned by its shareholders. Shareholders' liability is limited to the value of their shares. Shares may be bought and sold publicly - on the stock market.

BOX 9.1

WHAT DO YOU MAXIMISE?

CASE STUDIES AND APPLICATIONS

Managers are only human too

You are a student studying economics. So what do you maximise?

Do you attempt to maximise the examination marks you will get? If so, you will probably have to spend most of each week studying. Obviously you will have to have breaks for food and sleep, and you will need some recreation, but you will need to spend most of your time studying.

What is more likely is that you will, in some rather vaguely defined way, try to maximise your happiness. Getting good marks in your exams is just one element contributing to this aim, and you will have to weigh it against the opportunity cost of studying – namely, time not spent out with friends, playing sport, working for money, etc.

To argue that managers seek to maximise profits to the exclusion of everything else is rather like arguing that you

seek to maximise your exam marks. Managers' happiness (or utility) will depend on many factors, including their salaries, the pleasantness of their job, their power and the friendship of their colleagues.

Achieving profits may be an important aim (after all, it does contribute to a manager's utility), but the effort required to make additional profits will involve an opportunity cost to the manager – having, say, to work longer hours or firing a close colleague.

1. When are increased profits in the manager's personal interest?
2. Does the way you allocate your time between study and leisure vary at different times of the year? If so, why?

Managers will still have to ensure that *sufficient* profits are made to keep shareholders happy, but that may be very different from *maximising* profits.

Alternative theories of the firm to those of profit maximisation, therefore, tend to assume that large firms are *profit satisficers*. That is, managers strive hard for a minimum target level of profit, but are less interested in profits above this level.

Such theories fall into two categories: first, those theories that assume that firms attempt to maximise some other aim, provided that sufficient profits are achieved (these are examined in section 9.3); and second, those theories that assume that firms pursue a number of potentially conflicting aims, of which sufficient profit is merely one (these are examined in section 9.5).

The nature of institutions and organisations is likely to influence behaviour. There are various forces influencing people's decisions in complex organisations. Assumptions that an organisation will follow one simple objective (e.g. short-run profit maximisation) are thus too simplistic in many cases.

Make a list of six possible aims that a manager of a high street department store might have. Identify some conflicts that might arise between these aims.

Definitions

Profit satisficing Where decision makers in a firm aim for a target level of profit rather than the absolute maximum level.

Section summary

1. There are two major types of criticism of the traditional profit-maximising theory: (a) firms may not have the information to maximise profits; (b) they may not even want to maximise profits.
2. Lack of information on demand and costs and on the actions and reactions of rivals, and a lack of use of opportunity cost concepts, may mean that firms adopt simple 'rules of thumb' for pricing.
3. In large companies, there is likely to be a separation between ownership and control. The shareholders (the owners) may want maximum profits, but it is the managers who make the decisions, and managers are likely to aim to maximise their own utility rather than that of the shareholders. This leads to profit 'satisficing'.

9.2

BEHAVIOURAL ECONOMICS OF THE FIRM

Is firm behaviour consistent with the rational choice model?

Section 5.2 in Chapter 5 introduced behavioural economics, the field of study that integrates some simple insights

from psychology into standard economic theory. We saw how ideas such as heuristics, loss aversion, present bias and reciprocity can sometimes predict human behaviour more effectively than the traditional approach.

The focus in Chapter 5 was on consumer behaviour. In this chapter, we consider how behavioural economics can be applied to the theory of the firm. For example, in what ways might managerial decision making deviate from that predicted by rationality? How might a firm's actions be affected by managers who have a strong preference for fairness?

Some potential heuristics

Firms operate in complex environments, dealing with imperfect information and uncertainty about both the present and the future. Trying to work out and implement a profit-maximising strategy in these situations is a cognitively demanding task that places great strain on a manager's computational capacity. Rather like consumers, managers may respond by using heuristics (rules of thumb/mental shortcuts) to simplify things. Some heuristics might include the following:

Copying the strategy of the most profitable businesses in the market. This is only possible if a firm can observe the actions and profits made by its rivals. If some firms follow a strategy of imitation in an oligopolistic market, it might lead to more intense competition, with lower prices and higher output. Some research has also found that firms which simply imitate do at least as well as those that successfully calculate their own profit-maximising strategy.

Focusing on relative rather than absolute profits. It is easier to see if a firm is making more profit than its competitors than if it is making the maximum profit possible. Therefore managers may judge their success by comparing their firm's performance with that of their rivals. There may also be financial incentives to behave in this way as bonuses are often based on relative, as opposed to absolute, profits.

This type of behaviour may lead to firms implementing strategies that reduce their own profits (e.g. an aggressive price war) if it reduces the profits of their rivals by a greater amount. Section 9.5 discusses how having multiple goals may also lead to managers focusing on their relative performance.

Making a satisfactory/target level of profit. Instead of constantly looking for new opportunities to maximise profits in a dynamic market, managers may instead only change a firm's strategy when its profits fall below some target level.

The most influential early exponents of this approach were Richard Cyert and James March¹ (see section 9.5 for more detail). Their research made use of case studies of four multinational firms. They used the observations obtained to develop models of the firm, where decisions resulted from a sequence of behaviours. Their work highlighted the limitations of the neoclassical assumption of profit maximisation and proved to be highly influential in two ways. First it led to the study of behaviour, both of firms and the individual decision makers with them. Second, the research methods used have been adopted by experimentalists, not only in economics, but across the social sciences.

Which is easier – for managers to make decisions that maximise profits or for consumers to make decisions

that maximise their utility? Discuss some of the arguments in favour of each case.

Managerial preferences for fairness

As we saw in Chapter 8, the behaviour of a firm in an oligopoly depends on how it thinks its rivals will react to its actions. In collusive oligopoly firms agree to limit competition in order to maximise joint profits. Game theory allows us to examine these strategic decisions in more depth. A consistent assumption is that firms are attempting to maximise profits and believe that their rivals will always behave in a rational and selfish manner (i.e. try to maximise their own profits). But is this always a reasonable assumption?

Rather than being rational profit maximisers, some managers may have a strong preference for fairness. In particular, they may care about the equitable distribution of profits between firms in their industry. If a profit-maximising firm takes actions that enable it to obtain a larger share of the profits, firms with managers who have a strong preference for fairness might be willing to take costly actions to punish them. By costly, we mean actions that reduce the firm's own profits as well as those of its rivals. Many research experiments have found evidence of people being willing to reduce their own earnings to punish other 'players' for what they consider to be unfair behaviour.

Preferences for fairness may increase the chances of collusive oligopoly by reducing the likelihood of cheating. Take the following example. Imagine an industry that is dominated by two large firms (firm A and firm B). These two firms make a collusive agreement to charge prices above the competitive level for an indefinite period of time. If they both stick to the deal they split the higher level of industry profits between them. We explained in Chapter 8 how the chances of both firms sticking to the deal depends on a number of factors, including the expected size of any punishment for cheating. What impact do fairness preferences have on the size of expected punishment?

Assume the sole objective of the managers at firm A is to maximise profits, while those at firm B have a strong preference for fairness. If they both stick to the terms of the collusive agreement, the managers at firm B will think the outcome is fair.

If firm A knows that firm B has this strong preference for fairness this will have an impact on its expected costs of cheating. It knows that firm B will be willing to take further actions that reduce its own profits as long as it reduces the profits of firm A by a greater amount. This helps to equalise the profits between the two businesses, something firm B values, even though they both end up with lower profits. If firm A anticipates this more aggressive response from the fairness-minded firm B, this will deter it from cheating in the first place. What about firm B? If firm A sticks to the agreement, firm B will not cheat because it believes the outcome to be fair.

¹ Richard Cyert and James March, *A Behavioural Theory of the Firm* (Blackwell, 1963).

BOX 9.2

HOW FIRMS INCREASE PROFITS BY UNDERSTANDING 'IRRATIONAL' CONSUMERS

EXPLORING ECONOMICS

In section 5.2 we looked at behavioural economics as applied to consumer behaviour. We examined some of the reasons why people might not always act in the way that traditional economics predicts. This suggests that there may be an opportunity for business to increase profits by taking this 'irrationality' into account.

The role of 'special offers'

We all love a bargain and firms know this. If you walk around any supermarket, or look at online shopping sites, you will notice how many special deals are offered to entice us. 'Sale price'; 'Reduced'; '15% off'; 'Free delivery'; 'Everything must go'.

One thing that these all have in common is that they are only available for a limited time. Behavioural economists suggest that the combination of a special offer and a looming deadline pushes us into a state of excitement. We buy in a frenzy and fail to compute whether the benefits are worth the cost. In particular, there is evidence that we spend money on items that we would not have bought at the same price if there wasn't a special offer involved. We see the original price as a signal of quality and the reduced price as an unmissable opportunity.

The cost of inaction

Have you ever joined a gym? Every January thousands of people do, when they make new year's resolutions to get fit and lose weight. By March most of them have stopped going. A report published in January 2011 suggested that Britons are wasting millions of pounds each year on unused memberships.¹ We could argue that this is a result of poor information (we underestimate the effort required and overestimate the pleasure involved) or of uncertainty (we can't anticipate how we will feel about visiting the gym later in the year). However, neither of these factors explains why we fail to cancel unused gym memberships once the contract allows us to do so.

The answer lies in our tendency to inertia and procrastination; we intend to cancel the membership and the associated direct debit, yet we fail to do so. This inertia is demonstrated in a number of other markets – households have a legal right to switch energy suppliers, yet the majority fail to do so unless they are targeted by salespeople. Many people take out savings accounts which offer high interest

rates for a limited period – but then forget, or can't be bothered, to switch to other accounts at the end of the introductory period. As with the failure to cancel gym membership, the intention may be there, but our inertia leads to failure to maximise our utility.

Alternative contracts

If firms make profits from our inertia, they may also vary contracts to respond to our own understanding of our failure to behave rationally. There is an argument that suggests that at least some consumers will recognise the irrational behaviour that is costing them money. Does this mean that fitness clubs face losing members and lower profits? Not necessarily; some companies seek to appeal to the 'informed consumer' and to extend their customer base by offering rolling contracts, and by offering a 'no-frills' experience.

In 2010, two Harvard graduates set up a business, Gym-Pact, which bought group gym memberships from a number of existing gyms. Gym-Pact then sold on these memberships; but rather than a regular deal, they offered 'motivational' contracts to individuals, who pay more if they miss their regular workouts. The pair came up with this idea after studying behavioural economics as part of their degree; they learnt that people react more strongly to immediate certainties than to future possibilities.

This business model turned out to be short-lived. However, the founders did not give up on the principle. By 2014, Gym-Pact had become Pact, a business that brings together members who commit to working out, to logging their food intake and to eating vegetables. Those who succeed are rewarded with small cash sums, of up to £5 per day. Those who fail are charged for their lack of willpower. Pact makes money as the intermediary.

1. Insurance companies are keen to offer their customers ongoing renewal, where the annual premium is automatically charged to a credit card. Explain the advantages to the company? Are there benefits to the customers in this arrangement?
2. UK consumer protection laws require that goods offered at 'sale prices' have previously been offered at the higher price for at least 28 days. Why is this in the customer's interest?
3. Think of two or three things that you intend to do when you 'get around to it'? Are there any business opportunities that might arise from this type of procrastination?

¹ Britons spend £37 m a year on wasted gym memberships and slimming classes', *Daily Mail*, 13 May 2017.

In reality, the outcome of these examples of strategic interdependence will depend on a number of factors, including (a) the knowledge each firm has about the preferences of its rivals and (b) the strength of its own fairness preferences compared with its desire to make profits.

Some potential biases

Economists have long identified over-optimism as a trait seen in many people. Adam Smith commented that 'the

chance of gain is by every man, more or less over-valued, and the chance of loss is by most men under-valued'.² A number of factors may make over-optimism even greater among managers than the population as a whole.

² See: Adam Smith, *An Inquiry into the Nature and Causes of the Wealth of Nations*, book 1, chapter 10, para. 29.

Why might it present problems for a firm if managers are over-confident? Can you think of any reason why CEOs might be more inclined to optimism than the population average?

There is also survey evidence that managers include sunk costs as well as avoidable costs, when making pricing decisions.³ This can lead to different prices from those set by a profit-maximising firm (we examine cost-based pricing in section 9.6).

Why may managers choose to set prices that cover all costs, including sunk costs?

Can firms make use of behavioural economics?

Firms might be able to make use of behavioural economics if they are rational but their customers use heuristics or make systematic mistakes. Indeed, there is evidence that firms have been making use of some of its principles for many years. For example, they develop marketing strategies that do not

concentrate solely on price, but are tailored to consumers' (sometimes irrational) preferences. Examples include offering 'buy one, get one free' and loyalty points. In Box 9.2 we look at some examples of how businesses can bring the lessons of behavioural economics into their pricing and marketing.

Of course there are other aspects to running a business than understanding consumer behaviour. Since, for most firms labour is a major input, it will be important to account for the motivation of employees – to ensure that they work hard and that their actions are aligned with the interests of the firm. Mechanisms of reward (and possibly punishment) may be most effective if the behaviour of workers and their preference for fairness is fully understood. This is considered in more detail in Chapter 10.

Are there other points in the supply chain/production process where firms could make use of a better understanding of behavioural economics?

Section summary

1. Behavioural economics is relevant for understanding why and how the aims and strategies of firms deviate from traditional profit maximisation. This deviation is in part explained by managers using various mental shortcuts or heuristics to simplify complex decisions made in conditions of uncertainty. Some examples include imitation and focusing on performance.
2. Since firms are managed by individuals, who are motivated by a number of possible factors such as fairness, we should not be surprised if companies do not always appear to adopt 'selfish' strategies. The strength and awareness of any preferences for fairness will help to determine the equilibrium outcome in the market.
3. Firms can make use of the principles identified in behavioural economics to increase profits. Opportunities may arise in the relationship with consumers, particularly when looking at marketing and pricing. There may also be examples where greater understanding of behaviour can be used to inform contracts with employees, or with suppliers.
4. Levels of optimism and attitudes to risk will vary among owners and managers. If a firm is unwilling to make bold decisions it may increase its chances of survival, but will pay for this with lower profits. Over-cautious strategies may also leave a firm vulnerable, if its competitors are able to gain market share by being bold.

9.3 ALTERNATIVE MAXIMISING THEORIES

Long-run profit maximisation

The traditional theory of the firm is based on the assumption of *short-run* profit maximisation. Many actions of firms may be seen to conflict with this aim and yet could be consistent with the aim of *long-run profit maximisation*. For example, policies to increase the size of the firm or the firm's share of the market may involve heavy advertising or low prices to the detriment of short-run profits. But if this results in a larger market share, the resulting economic power may enable the firm to make larger profits in the long run.

At first sight, a theory of long-run profit maximisation would seem to be a realistic alternative to the traditional short-run profit-maximisation theory. In practice, however, the theory is not a very useful predictor of firms' behaviour and is very difficult to test.

A claim by managers that they were attempting to maximise long-run profits could be an excuse for virtually any policy. When challenged as to why the firms had, say,

Definition

Long-run profit maximisation An alternative theory which assumes that managers aim to shift cost and revenue curves so as to maximise profits over some longer time period.

³ See for example: Steve Buchheit and Nick Feltovich, 'Experimental evidence on a sunk-cost paradox: a study of pricing behavior in Bertrand-Edgeworth duopoly', *University of Aberdeen Discussion Paper, 2008-4* (April 2008).

BOX 9.3

WHEN IS A THEORY NOT A THEORY?

EXPLORING
ECONOMICS

Have you heard the joke about the man sitting in a railway carriage who was throwing pieces of paper out of the window? A fellow traveller was curious and asked him why he kept doing this.

'It keeps the elephants down', was the reply.

'But', said the other man, 'there are no elephants around here.'

'I know', said the first man. 'Effective, isn't it?'

Let's reformulate this joke.

Once upon a time there was this boss of a company who kept doing strange things. First he would spend a massive amount of money on advertising, and then stop. Then he would pay a huge wage increase 'to keep his workforce

happy'. Then he would close the factory for two months to give everyone a break. Then he would move the business, lock, stock and barrel, to a new location.

One day he was talking to an accountant friend, who asked, 'Why do you keep doing these strange things?'

'I have to do them to make the business profitable', was the reply.

'But your business is profitable', said the accountant.

'I know. It just goes to show how effective my policies are.'

1. Why might it be difficult to refute a theory of long-run profit maximisation?
2. If a theory cannot in principle be refuted, is it a useful theory?

undertaken expensive research or high-cost investment, or had engaged in a damaging price war, the managers could reply 'Ah, yes, but in the long run it will pay off.' This is very difficult for shareholders to refute (until it is too late!).

Even if long-run profit maximisation *is* the prime aim, the means of achieving it are extremely complex. The firm will need a plan of action for prices, output, investment, etc., stretching from now into the future. But today's pricing and marketing decisions affect tomorrow's demand. Therefore, future demand curves cannot be taken as given. Today's investment decisions will affect tomorrow's costs. Therefore, future cost curves cannot be taken as given either. These shifts in demand and cost curves will be very difficult to estimate with any precision. Quite apart from this, the actions of competitors, suppliers, unions, the future state of the economy, and so on are difficult to predict. Thus the picture of firms making precise calculations of long-run profit-maximising prices and outputs is an unrealistic one.

It may be useful, however, simply to observe that firms, when making current price, output and investment decisions, try to judge the approximate effect on new entrants, consumer demand, future costs, etc., and try to avoid decisions that would appear to conflict with long-run profits. Often this will simply involve avoiding making decisions (e.g. cutting price) that may stimulate an unfavourable result from rivals (e.g. rivals cutting their price).

TC
p129

Managerial utility maximisation

One of the most influential of the alternative theories of the firm has been that developed by O. E. Williamson⁴ in the 1960s. Williamson argued that, provided satisfactory levels of profit are achieved, managers often have the discretion to

choose what policies to pursue. In other words, they are free to pursue their *own* interests. And what are the managers' interests? To maximise their own utility, argued Williamson.

Williamson identified a number of factors that affect a manager's utility. The four main ones were salary, job security, dominance (including status, power and prestige) and professional excellence.

Of these only salary is *directly* measurable. The rest have to be measured indirectly. One way of doing this is to examine managers' expenditure on various items, and in particular on *staff*, on *perks* (such as a company car) and on *discretionary investment*. The greater is the level of expenditure by managers on these items, the greater is likely to be their status, power, prestige, professional excellence and job security, and hence utility.

Having identified the factors that influence a manager's utility, Williamson developed several models in which managers seek to maximise their utility. He used these to predict managerial behaviour under various conditions and argued that they performed better than traditional profit-maximising theory.

One important conclusion was that average costs are likely to be higher when managers have the discretion to pursue their own utility. For example, perks and unnecessarily high staffing levels add to costs. On the other hand, the resulting 'slack' allows managers to rein in these costs in times of low demand (see page 269). This enables them to maintain their profit levels. To support these claims he conducted a number of case studies. These did indeed show that staff and perks were cut during recessions and expanded during booms, and that new managers were frequently able to cut staff without influencing the productivity of firms.

Sales revenue maximisation (short-run)

Perhaps the most famous of all alternative theories of the firm is that developed by William Baumol in the late 1950s.

⁴ O. E. Williamson, *The Economics of Discretionary Behaviour* (Prentice Hall, 1964), p. 3.

This is the theory of *sales revenue maximisation*. Unlike the theories of long-run profit maximisation and managerial utility maximisation, it is easy to identify the price and output that meet this aim – at least in the short run.

So why would managers want to maximise their firm's sales revenue? The answer is that the success of managers, and in particular sales managers, may be judged according to the level of the firm's sales. Sales figures are an obvious parameter of the firm's health. Managers' salaries, power and prestige may depend directly on sales revenue. The firm's sales representatives may be paid commission on their sales. Thus sales revenue maximisation may be a more dominant aim in the firm than profit maximisation, particularly if it has a dominant sales department.

Sales revenue will be maximised at the top of the TR curve at output Q_1 in Figure 9.1. Profits, by contrast, would be maximised at Q_2 . Thus, for given total revenue and total cost curves, sales revenue maximisation will tend to lead to a higher output and a lower price than profit maximisation.

? Draw a diagram with MC and MR curves. Mark the output (a) at which profits are maximised; (b) at which sales revenue is maximised.

The firm will still have to make sufficient profits, however, to keep the shareholders happy. Thus firms can be seen to be operating with a profit constraint. They are *profit satisficers*.

The effect of this profit constraint is illustrated in Figure 9.2. The diagram shows a total profit (Π) curve. (This is found by simply taking the difference between TR and TC at each output.) Assume that the minimum acceptable profit is Π (whatever the output). Any output greater than Q_3 will give a profit less than Π . Thus the sales revenue maximiser that is also a profit satisficer will produce Q_3 , not Q_1 . Note, however, that this output is still greater than the profit-maximising output Q_2 .

Figure 9.1 Sales-revenue-maximising output

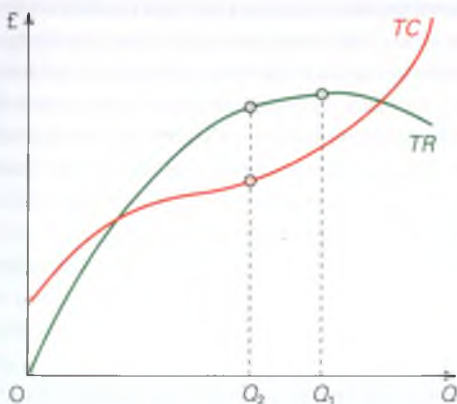

Figure 9.2 Sales revenue maximising with a profit constraint

If the firm could maximise sales revenue and still make more than the minimum acceptable profit, it would probably spend this surplus profit on advertising to increase revenue further. This would have the effect of shifting upwards the TR curve and also the TC curve (since advertising costs money).

Sales revenue maximisation will tend to involve more advertising than profit maximisation. The profit-maximising firm will advertise up to the point where the marginal revenue of advertising equals the marginal cost of advertising (assuming diminishing returns to advertising). The firm aiming to maximise sales revenue will go beyond this, since further advertising, although costing more than it earns the firm, will still add to total revenue. The firm will continue advertising until surplus profits above the minimum have been used up.

? Since advertising increases a firm's costs, will prices necessarily be lower with sales revenue maximisation than with profit maximisation?

Growth maximisation

Rather than aiming to maximise *short-run* revenue, managers may take a longer-term perspective and aim for *growth maximisation* in the size of the firm. They may directly gain

Definitions

Sales revenue maximisation An alternative theory which assumes that managers aim to maximise the firm's short-run total revenue.

Growth maximisation An alternative theory which assumes that managers seek to maximise the growth in sales revenue (or the capital value of the firm) over time.

* LOOKING AT THE MATHS

We can express sales revenue maximisation algebraically. We start with the situation with no profit constraint.

Unconstrained sales revenue maximisation

Assume that the total revenue function is given by

$$TR = bQ - cQ^2 \quad (1)$$

This will give a straight-line *MR* function given by

$$MR = \frac{dTR}{dQ} = b - 2cQ$$

Total revenue is maximised where $MR = 0$, since, when total revenue is maximised, any increase in output will give a zero rise in total revenue. In other words, at the top of the total revenue curve in Figures 9.1 and 9.2, the slope of the curve is zero (the tangent to the curve is horizontal). Thus:

$$MR = b - 2cQ = 0$$

i.e.

$$2cQ = b$$

i.e.

$$Q = \frac{b}{2c} \quad (2)$$

Thus, if the total revenue function were

$$TR = 120 - 3Q^2$$

then, from equation (2), total revenue would be maximised at an output (Q), where

$$Q = \frac{b}{2c} = \frac{120}{2 \times 3} = 20$$

Constrained sales revenue maximisation

If there is a profit constraint, we can write the objective function as $\text{Max } TR$, subject to $(TR - TC) \geq T\Pi^*$ where $T\Pi^*$ is the minimum profit that must be achieved. Assume that the TR and TC functions are given by

$$TR = bQ - cQ^2$$

and

$$TC = a + dQ - eQ^2 + gQ^3$$

Note that these two equations match the shapes of the TR and TC curves in Figures 9.1 and 9.2. The constraint can now be written:

$$TR - TC = -a + (b - d)Q + (e - c)Q^2 - gQ^3 \geq T\Pi^*$$

We can use this to solve for Q . An example of this is given in Maths Case 9.1 on the student website.

utility from being part of a rapidly growing 'dynamic' organisation; promotion prospects are greater in an expanding organisation since new posts tend to be created; larger firms may pay higher salaries; managers may obtain greater power in a larger firm.

Growth is probably best measured in terms of a growth in sales revenue, since sales revenue (or 'turnover') is the simplest way of measuring the size of a business. An alternative would be to measure the capital value of a firm, but this will depend on the ups and downs of the stock market and is thus a rather unreliable method.

If a firm is to maximise growth, it needs to be clear about the time period over which it is setting itself this objective. For example, maximum growth over the next two or three years might be obtained by running factories to absolute maximum capacity, cramming in as many machines and workers as possible, and backing this up with massive advertising campaigns and price cuts. Such policies, however, may not be sustainable in the longer run. The firm may simply not be able to finance them. A longer-term perspective (say, five to ten years) may require the firm to 'pace' itself, and perhaps to direct resources away from current production and sales into the development of new products that have a potentially high and growing long-term demand.

Growth may be achieved either by internal expansion or by merger.

Growth by internal expansion

Internal growth requires an increase in sales, which requires an increase in the firm's productive capacity. In order to increase its sales, the firm is likely to engage in extensive product promotion and to try to launch new products. In order to increase *productive capacity*, the firm will require new investment. Both product promotion and investment will require finance.

In the short run, the firm can finance growth by borrowing, by retaining profits or by a new issue of shares. What limits the amount of finance that a firm can acquire, and hence the rate at which it can grow? If the firm *borrow*s too much, the interest payments it incurs will make it difficult to maintain the level of dividends to shareholders. Similarly, if the firm *retains* too much profit, there will be less available to pay out in dividends. If it attempts to raise capital by a *new issue of shares*, the distributed profits will have to be divided between a larger number of shares. Whichever way it finances investment, therefore, the more it invests, the more the dividends on shares in the short run will probably fall.

This could lead shareholders to sell their shares, unless they are confident that *long-run* profits and hence dividends will rise again, thus causing the share price to remain high in the long run. If shareholders do sell their shares, this will cause share prices to fall. If they fall too far, the firm runs the risk of being taken over and of certain managers losing their jobs. The

takeover constraint therefore requires that the growth-maximising firm distribute sufficient profits to avoid being taken over.

In the long run, a rapidly growing firm may find its profits increasing, especially if it can achieve economies of scale and a bigger share of the market. These profits can then be used to finance further growth.

Growth through vertical integration

If market conditions make growth through increased sales difficult, then a firm may choose to grow through vertical integration. This has a number of advantages.

Economies of scale. These can occur by the business performing complementary stages of production within a single business unit. The classic example of this is the steel manufacturer combining the furnacing and milling stages of production, saving the costs that would have been required to reheat the iron had such operations been undertaken by independent businesses. Clearly, for most firms, the performing of more than one stage on a single site is likely to reduce transport costs, as semi-finished products no longer have to be moved from one plant to another.

Reduced uncertainty. A business that is not vertically integrated may find itself subject to various uncertainties in the marketplace. Examples include uncertainty over future price movements, over supply reliability or over access to markets.

Barriers to entry. Vertical integration may give the firm greater power in the market by enabling it to erect entry barriers to potential competitors. For example, a firm that undertakes backward vertical integration and acquires a key input resource may effectively close the market to potential new entrants, either by simply refusing to supply a competitor, or by charging a very high price for the input, such that new firms face an absolute cost disadvantage.

 See if you can identify two companies that are vertically integrated and what advantages they gain from such integration.

The major problem with vertical integration is that it may reduce the firm's ability to respond to changing market demands. A business that integrates may find itself tied to its own supply source. If, by contrast, it were free to choose between suppliers, inputs might be obtained at a lower price than the firm could achieve by supplying itself.

Many firms are finding that it is better *not* to be vertically integrated but to focus on their core business and to outsource their supplies, their marketing and many other functions. That way they put alternative suppliers and distributors in competition with each other.

Growth through diversification

An alternative internal growth strategy to vertical integration is that of diversification. A good example of a highly diversified company is Virgin. Its interests include planes,

trains, finance, music, mobile phones, holidays, hotels, wine, cinemas, broadband, health care, publishing, balloon flights and even space travel.

If the current market is saturated or in decline, diversification might be the only avenue open to the business if it wishes to maintain a high growth performance. In other words, it is not only the level of profits that may be limited in the current market, but also the growth of sales.

Diversification also has the advantage of spreading risks. If a business produces a single product in a single market, it is vulnerable to changes in that market's conditions. If a farmer produces nothing but potatoes and the potato harvest fails, the farmer is ruined. If, however, the farmer produces a whole range of vegetables, or even diversifies into livestock, then they are less subject to the forces of nature and the unpredictability of the market.

Growth by merger

A merger may be the result of the mutual agreement of two firms to come together. Alternatively, one firm may put in a takeover bid for another. This involves the first firm offering to buy the shares of the second for cash, to swap them for shares in the acquiring company, or to issue fixed-interest securities (debentures). The shareholders of the second firm then vote on whether to accept the offer. (Technically this is an 'acquisition' or 'takeover' rather than a merger, but the term 'merger' is generally used to include both mutual agreements and acquisitions.)

There are three types of merger:

- A **horizontal merger** is where firms in the same industry and at the same stage of production merge. For example, in October 2016 AB-InBev (the biggest brewing business in the world) announced that it had completed its £79 billion takeover of SABMiller (the second biggest brewing in the world). This merger is discussed in more detail in Box 14.3 (page 431).
- A **vertical merger** is where firms in the same industry but at different stages in the production of a good merge: e.g. during 2015 and 2016, Ikea purchased a number of forests in Romania to gain greater control over the supply of wood it uses to produce furniture.

Definitions

Takeover constraint The effect that the fear of being taken over has on a firm's willingness to undertake projects that reduce distributed profits.

Horizontal merger Where two firms in the same industry at the same stage in the production process merge.

Vertical merger Where two firms in the same industry at different stages in the production process merge.

■ A **conglomerate merger** is where firms in different industries merge: e.g. Google has acquired approximately 200 firms across a range of different sectors including robotics, video broadcasting, education and smoke alarms. In April 2015, it purchased Thrive Audio, a business that makes headphones for 3D sound.

Motives for merger

But why do firms want to take over others? Economists have identified a number of possible motives.

Merger for growth. Mergers provide a much quicker means to growth than does internal expansion. Not only does the firm acquire new capacity, it also acquires additional consumer demand. There is a danger for growth-maximising firms, however, from being taken over themselves. If they are growing rapidly and yet have a relatively low profit and a low stock market value, they will be attractive to predators.

Merger for economies of scale. Once the merger has taken place, the constituent parts can be reorganised through a process of 'rationalisation'. The result can be a reduction in costs. For example, only one head office will now be needed. Reduced costs are a way of increasing profits and thereby increasing the rate of growth. In fact, the evidence suggests that most mergers result in few if any cost savings: either potential economies of scale are not exploited due to a lack of rationalisation, or diseconomies result from the disruptions of reorganisation. New managers installed by the parent company are often seen as unsympathetic, and morale may go down.

Merger for monopoly power. Here the motive is to reduce competition and thereby gain greater market power and larger profits. With less competition, the firm will face a less elastic demand and will be able to charge a higher percentage above marginal cost. This obviously fits well with the traditional theory of the firm.

 Which of the three types of merger (horizontal, vertical and conglomerate) are most likely to lead to (a) reductions in average costs; (b) increased market power?

Merger for increased market valuation. A merger can benefit shareholders of *both* firms by leading to a potential increase in the stock market valuation of the merged firm. If both sets of shareholders believe that they will make a capital gain, then they are more likely to give the go-ahead to the merger.

In practice, however, there is little evidence to suggest that mergers lead to a capital gain. In the early stages of a merger boom, as in 2005–6, when some good deals may be had, the share price of acquiring firms may rise. But as the merger boom develops, more marginal firms are acquired. Take the merger boom of the late 1990s. In some 80 per cent of cases, there was a significant fall in the share value of the acquiring firm.

Merger to reduce uncertainty. There are two major sources of uncertainty for firms. The first is the behaviour of rivals.

Mergers, by reducing the number of rivals, can correspondingly reduce uncertainty. At the same time they can reduce the costs of competition (e.g. by reducing advertising). The second source of uncertainty is the economic environment. In a period of rapid change, such as often accompanies a boom, firms may seek to protect themselves by merging with others.

Merger due to opportunity. Sometimes mergers occur simply as a consequence of opportunities that suddenly and unexpectedly arise. Such mergers are largely unplanned and thus virtually impossible to predict. Dynamic business organisations are constantly on the lookout for such opportunities.

Other motives. Other motives for mergers include:

- Getting bigger so as to make the firm less likely to be taken over itself.
- Merging with another firm to prevent it being taken over by an unwanted predator (the 'White Knight' strategy).
- Asset stripping. This is where a firm buys another and then breaks it up, selling off the profitable bits and probably closing down the remainder.
- Empire building. This is where owners or managers like the power or prestige of owning or controlling several (preferably well-known) companies.
- Broadening the geographical base of the company by merging with a firm in a different part of the country or the world.
- Reducing levels of taxation. It has been argued that a number of takeovers in the pharmaceutical industry have been motivated by the desire to reduce the company's tax bill. For example, the American pharmaceutical company Pfizer made a \$100 billion bid to purchase the UK business, AstraZeneca, in April 2014. The plan was to merge the two companies into a holding company with its tax domicile in the UK and thus being liable to UK corporation tax of 20 per cent (or even 10 per cent on profits from patented inventions – the Patent Box scheme) rather than US corporation tax of nearly 40 per cent. Even allowing for various foreign incomes and tax exemptions, Pfizer was still paying around 27.5 per cent in tax in 2013 and thus the merger would allow it to make considerable tax savings. The bid, however, ultimately failed.

These theories, alongside the general area of mergers and acquisitions, are the subject of ongoing research, but most are in need of greater empirical investigation and support.

-  1. Which of the above theories overlap and in what way?
2. Why do you think it is difficult to find adequate empirical support for any of them?

Definitions

Mergers and the relationship between growth and profit

In order for a firm to be successful in a takeover bid, it must be sufficiently profitable to finance the takeover. Thus the faster it tries to grow and the more takeovers it attempts, the higher must be its profitability.

In addition to being an obvious means to the growth of the firm, mergers may be a means of increasing profits, since mergers can lead to both lower average costs through economies of scale and higher average revenue through increased market power over prices. These profits in turn may be seen as a means of financing further growth.

It can therefore be seen that, whichever way it is financed, growth is closely linked to profits. High profits can help a firm grow. Rapid growth can lead to a rapid growth in profits.

These are not inevitable links, however. For example, long-run profits may not increase if a firm invests in risky projects or projects with a low rate of return. Expansion alone is no guarantee of profits. Also, high profits will not necessarily lead to growth if a large proportion is distributed to shareholders and only a small proportion is reinvested. High profits may help growth, but they do not guarantee it.

Growth through strategic alliances

One means of achieving growth is through the formation of **strategic alliances** with other firms. They are a means whereby business operations can be expanded relatively quickly and at relatively low cost, and are a common way in which firms can deepen their involvement in global markets.

There are many types of strategic alliance between businesses, covering a wide range of alternative collaborative arrangements.

Joint ventures. A **joint venture** is where two or more firms decide to create, and jointly own, a new independent organisation. Hulu, the television on demand and streaming business, is a joint venture between Disney, 21st Century Fox, NBCUniversal and Time Warner.

Consortia. In recent years, many consortia have been created. Camelot, the company that runs the UK National Lottery, and Trans Manche Link, the company that built the Channel Tunnel, are two examples. A **consortium** is usually created for very specific projects, such as major civil engineering work. As such they have a focused objective, and once the project is completed, the consortium is usually dissolved.

Franchising. A less formal strategic alliance is where a business agrees to **franchise** its operations to third parties. McDonald's, Costa and Coca-Cola are good examples of businesses that use a franchise network. In such a relationship, the franchisee is responsible for manufacturing and/or selling, and the franchiser retains responsibility for branding and marketing.

Subcontracting. Like franchising, **subcontracting** is a less formal source of strategic alliance, where companies maintain their independence. When a business subcontracts, it employs an independent business to manufacture or supply some service rather than conduct the activity itself. Car manufacturers are major subcontractors. Given the multitude and complexity of components that are required to manufacture a car, the use of subcontractors to supply specialist items, such as brakes and lights, seems a logical way to organise the business.

Networks. **Networks** are less formal than any of the above alliances. A network is where two or more businesses work collaboratively but without any formal relationship binding one to the other. Such a form of collaboration is highly prevalent in Japan. Rather than a formal contract regulating the behaviour of the partners to the agreement, their relationship is based upon an understanding of trust and loyalty.

Why form strategic alliances?

As a business expands, possibly internationally, it may well be advantageous to join with an existing player in the market. Such a business would have local knowledge and an established network of suppliers and distributors.

In addition, strategic alliances allow firms to share risk. The Channel Tunnel and the consortium of firms that built it is one such example. The construction of the Channel Tunnel was a massive undertaking and far too risky for any single firm to embark upon. With the creation of a consortium, risk was spread and the various consortium members were able to specialise in their areas of expertise.

Projects that might have prohibitively high start-up costs, or running costs, may become feasible if firms co-operate and pool their capital. In addition, an alliance of firms, with their combined assets and credibility, may find it easier to generate finance, whether from investors in the stock market or from the banking sector.

Definitions

Strategic alliance Where two firms work together, formally or informally, to achieve a mutually desirable goal.

Joint venture Where two or more firms set up and jointly own a new independent firm.

Consortium Where two or more firms work together on a specific project and create a separate company to run the project.

Franchise A formal agreement whereby a company uses another company to produce or sell some or all of its product.

Subcontracting Where a firm employs another firm to produce part of its output or some of its input(s).

Network An informal arrangement between businesses to work together towards some common goal.

BOX 9.4 MERGER ACTIVITY

A worldwide perspective

What have been the trends, patterns and driving factors in mergers and acquisitions¹ (M&As) around the world over the past 25 years? An overview is given in chart (a).

The 1990s

The early 1990s saw relatively low M&A activity as the world was in recession, but as world economic growth picked up, so worldwide M&A activity increased. Economic growth was particularly rapid in the USA, which became a major target for many acquisitions.

There was also an acceleration in the process of 'globalisation'. With the dismantling of trade barriers around the world and increasing financial deregulation, international competition increased. Companies felt the need to become bigger in order to compete more effectively.

In Europe, M&A activity was boosted by the development of the Single Market, which came into being in January 1993. Companies took advantage of the abolition of trade barriers in the EU, which made it easier for them to operate on an EU-wide basis. As 1999 approached, and with it the arrival of the euro, so European merger activity reached fever pitch, stimulated also by the strong economic growth experienced throughout the EU.

By the 2000s, the number of annual worldwide M&As was three times the level in 1990. Very large deals included a €29.4 billion marriage of pharmaceutical companies Zeneca of the UK and Astra of Sweden in 1998, a €205 billion takeover of telecoms giant Mannesmann of Germany by Vodafone of the UK in 1999 and a €50.8 billion takeover of Orange™ of the UK by France Telecom in 2000.

Other sectors in which merger activity was rife included financial services and the privatised utilities sector. In the UK, in particular, most of the privatised water and electricity companies were acquired, with buyers attracted by the sector's monopoly profits. French and US buyers were prominent.

The 2000s

The number of cross-border deals peaked at 10 517 in 2000 and had a combined total value of over \$960 billion. However, a worldwide economic slowdown after 2000 led to a fall in both the number and value of mergers throughout most of the world. The value of cross-border M&As in 2003 was \$165 billion – a fall of 83 per cent from the peak of three years earlier. Activity began to increase again after 2003 as economic growth in the world economy began to accelerate. Two major target regions were (a) the 10 countries that joined the EU in 2004 plus Russia and (b) Asian countries, especially India and China.

In 2007, the number of cross-border mergers reached a new peak of 12 044 with a combined market value of over \$1000 billion. However, the Great Recession of 2008–9 led to both the number and value of cross-border deals falling dramatically. Recession is a difficult time for deal making and the number of withdrawn mergers – that is, where two firms agree in principle to merge but later pull out of the deal – increased. As diagram (a) shows, the value of cross-border M&As in 2009 was \$288 billion – a fall of 72 per cent from the record high in 2007.

(a) Cross-border mergers and acquisitions by target

Note: The data cover only those deals that involve an acquisition of an equity of more than 10%.

Source: 'Cross Border Mergers & Acquisitions', *World Investment Report Annex Tables* (UNCTAD, June 2017), Tables 9 and 11.

The 2010s

With the faltering recovery of 2010 there was a small increase in global M&As. However, the eurozone crisis and fears about the state of the public finances in the USA had a negative impact on the number of deals in 2012 and 2013.

Economic growth and growing business confidence saw M&A activity grow quickly again in 2015. The combined market value of deals was over \$700 billion – the highest value since the financial crisis, with nine deals of over \$50 billion. The ability of firms to borrow money cheaply because of historically low interest rates, slow rates of internal growth and large cash reserves were seen as important drivers behind this increase. The USA, with its accelerating rate of economic growth, was a very popular target country.

Given the uncertainty generated by the Brexit vote in the UK and the election of President Trump in the USA, many observers were surprised to see continued strong growth in M&A activity in 2016.

The worldwide pattern of cross-border M&A activity has also changed between the mid-1990s and the post-financial crisis period of 2010–15, although 2015 proved to be different from the rest of the post-crisis period. Diagram (b) illustrates three trends.

- First, North America saw a fall in its global share of cross-border M&As from 24.6 per cent in the mid-1990s to 20.1 per cent between 2010 and 2015; and its share measured by value fell from 32.2 per cent to 30.4 per cent. However, its share by value in 2015 was unusually high at 43 per cent compared with an average of 19.7 per cent over the previous five years.
- Second, Asian countries (excluding Japan) saw a dramatic increase in their share of the number of cross-border M&As from 7.7 per cent in the mid-1990s to 16 per cent for the

period 2010–15. Their share of the value increased from 5.2 per cent to 12 per cent. Two nations in the region, China and India, have been particularly attractive because their economies have grown rapidly; they have low costs, cheap skilled labour and low tax rates. However M&A investment in both countries fell significantly in 2015. In the case of China, it fell from \$54.9 billion in 2014 to \$9.66 billion in 2015.

- Third, EU countries saw a reduction in their share of cross-border M&As from 49.4 per cent to 39.8 per cent and a fall in their share of the value from 42.1 per cent to 37.7 per cent.

Different types and consequences of M&A activity

When viewed in terms of long-run trends, cross-border M&As have become more common as globalisation has gathered pace. In the mid-1990s they accounted for about 16 per cent of all deals, whereas now they account for over 40 per cent.

Although the number of cross-border deals in the UK in 2016 was less than domestic deals, the *value* of cross-border deals was far higher than domestic ones. The Office for National Statistics reported that the value of M&As, where a foreign company purchased a UK company, was £187.4 billion² – the highest figure since records began in 1969.

Cross-border M&As can be an effective strategy for firms that want to gain large-scale entry into an overseas market. One motivating factor for AB-InBev's takeover of SABMiller is to gain access to the fast-growing beer market in Africa. However, these types of takeover can raise concerns about national sovereignty: i.e. the extent to which governments have control over their industrial base when foreign firms own businesses in the domestic economy. For example, following concerns expressed by the South African government, AB-InBev made a

(b) Cross-border mergers and acquisitions by target region (% of total number and value)

Source: 'Cross Border Mergers & Acquisitions', *World Investment Report Annex Tables* (UNCTAD, June 2017), Tables 9 and 11.

commitment to maintain permanent employment in that country at the same level for at least five years.

Horizontal cross-border mergers

These are the most common type of merger. A horizontal merger or acquisition of a domestic firm by an overseas firm may not alter the number of firms competing in the sector if the foreign firm merely replaces an existing firm. Its presence may generate greater competition and innovation in the industry if the new owners bring with them fresh ideas.

If the foreign firm is already present in the domestic economy and it then takes over a rival, the number of firms in the industry is reduced. This could lead to less competition and higher prices. Alternatively, the newly merged firm may benefit from lower costs that it can pass on to its customers in the form of lower prices.

Vertical cross-border mergers

Vertical and conglomerate cross-border M&As are less common than their horizontal counterparts, but also come with potential costs as well as benefits. For example, a backward vertical M&A can help a firm compete globally by reducing its supply costs, but it can impose harsh terms on suppliers in the domestic economy where it operates in order to achieve this. Forward vertical M&A into the retail sector can help a foreign firm secure a domestic market and offer customers a better service. However, they may now move away from supplying rival retailers on comparable terms so that customer choice is reduced.

Conglomerate cross-border mergers

There was a wave of these mergers in the 1960s as firms tried to diversify, but they are now far less popular. The tendency instead has been for many companies to try to become more focused, by selling off parts of the business that are not seen as 'core activities'. For example, in October 2012, the conglomerate Kraft Foods split its business into a global snacks business, named Mondelez International, and a food business, named Kraft Foods Group. In 2015, Kraft Foods Group merged with Heinz to become Kraft Heinz.

There is no doubt that many M&As have been good for society and are a sign of a healthy capital market. However, evidence has found that approximately two-thirds of deals fail to achieve the anticipated gains.

1. Are the motives for merger likely to be different in a recession from those in a period of rapid economic growth? What would you predict about the pattern of mergers over the next few years, given the current state of the economy?
2. Use newspaper and other resources to identify the anticipated benefits (extra revenue and lower costs) of a recent cross-border merger. Do you think they are realistic?

1 By 'acquisitions' we mean takeovers or the acquiring of at least 5 per cent of a company's shares.

2 'Mergers and acquisitions involving UK companies: Oct to Dec 2016', *Statistical Bulletin* (ONS).

The past 30 years have seen a flourishing of strategic alliances. They have become a key growth strategy for business both domestically and internationally. They are seen as a way of expanding business operations quickly without the difficulties associated with the more aggressive approach of acquisition or the more lengthy process of merger.

Growth through going global

In many respects, a firm's global strategy is simply an extension of its strategy within its own domestic market. However, opening up to global markets can provide an obvious means for a business to expand its markets and spread its risks. It is also a means of reducing costs, whether through economies of scale or from accessing cheap sources of supply or low-wage production facilities.

A firm's global growth strategy may involve simply exporting or opening up factories abroad, or it may involve merging with businesses abroad or forming strategic alliances. As barriers to trade and to the international flow of capital have reduced, so more and more businesses have sought to become multinational. The result is that the global business environment has tended to become more and more competitive.

Equilibrium for a growth-maximising firm

What will a growth-maximising firm's price and output be? Unfortunately there is no simple formula for predicting this.

In the short run, the firm may choose the profit-maximising price and output – so as to provide the greatest funds for investment. On the other hand, it may be prepared to sacrifice some short-term profits in order to mount an advertising campaign. It all depends on the strategy it considers most suitable to achieve growth.

In the long run, prediction is more difficult still. The policies that a firm adopts will depend crucially on the assessments of market opportunities made by managers. But this involves judgement, not fine calculation. Different managers will judge a situation differently

One prediction can be made: growth-maximising firms are likely to diversify into different products, especially as they approach the limits to expansion in existing markets.

Alternative maximising theories and the public interest

It is difficult to draw firm conclusions about the public interest.

In the case of sales revenue maximisation, a higher output will be produced than under profit maximisation, but the consumers will not necessarily benefit from lower prices, since more will be spent on advertising – costs that will be reflected in a higher price.

In the case of growth and long-run profit maximisation, there are many possible policies that a firm could pursue. To the extent that a concern for the long run encourages firms to look to improved products, new products and new techniques, the consumer may benefit from such a concern. To the extent, however, that growth encourages a greater level

of industrial concentration through merger, the consumer may lose from the resulting greater level of monopoly power.

As with the traditional theory of the firm, the degree of competition a firm faces is a crucial factor in determining just how responsive it will be to the wishes of the consumer.

How will competition between growth-maximising firms benefit the consumer?

Section summary

1. Rather than seeking to maximise short-run profits, a firm may take a longer-term perspective. It is very difficult, however, to predict the behaviour of a long-run profit-maximising firm, since (a) different managers are likely to make different judgements about how to achieve maximum profits and (b) demand and cost curves may shift unpredictably both in response to the firm's own policies and as a result of external factors.
2. Managers may seek to maximise their own utility, which, in turn, will depend on factors such as salary, job security and power within the organisation. However, given that managerial utility depends on a range of variables, it is difficult to use the theory to make general predictions of firms' behaviour.
3. Managers may gain utility from maximising sales revenue. They will, however, still have to ensure that a satisfactory level of profit is achieved. The output of a firm which seeks to maximise sales revenue will be higher than that for a profit-maximising firm. Its level of advertising will also tend to be higher. Whether price will be higher or lower depends on the relative effects on demand and cost of the additional advertising.
4. Many managers aim for maximum growth of their organisation, believing that this will help their salaries, power, prestige, etc.
5. Growth may be by internal expansion. This can be financed by ploughing back profits, by share issue, or by borrowing. Whichever method a firm uses, it will require sufficient profits to avoid becoming vulnerable to a takeover.
6. Vertical integration can reduce a firm's costs through various economies of scale. It can also help to reduce uncertainty, as the vertically integrated business could secure supply routes and/or retail outlets.
7. Growth may be by merger. Mergers can be horizontal, vertical or conglomerate. Merger activity tends to occur in waves. Various motives have been suggested for mergers, including growth, economies of scale, market power, increased share values, reduction in uncertainty, and simply taking advantage of opportunities as they occur.
8. One means of achieving growth is through the formation of strategic alliances with other firms. They have the advantage of allowing easier access to new markets, risk sharing and capital pooling. Many firms' growth strategy includes expansion abroad.
9. As with long-run profit-maximising theories, it is difficult to predict the price and output strategies of a growth-maximising firm. Much depends on the judgements of particular managers about growth opportunities.
10. Alternative aims will benefit the consumer to the extent that they encourage firms to develop new products and to find more efficient methods of production. They may be against the consumer's interest to the extent that they lead firms to engage in extensive advertising or to merge with a resulting increased concentration of market power.

9.4

ASYMMETRIC INFORMATION AND THE PRINCIPAL-AGENT PROBLEM

Principals and agents

A useful way to think about alternative maximisation theories is as examples of the *principal-agent problem*. Let us examine this problem.

One of the features of a complex modern economy is that people (principals) have to employ others (agents) to carry out their wishes. If you want to sell a house, it is more convenient to go to an estate agent than to do it yourself.

These agents have specialist knowledge and can save you, the principal, a great deal of time and effort. It is an example of the benefits of the specialisation and division of labour.

It is the same with firms. They employ people with specialist knowledge and skills to carry out specific tasks. Companies frequently employ consultants to give them advice, or engage the services of specialist firms such as an advertising agency. Even employees of a company can be seen as 'agents' of their employer. In the case of workers, they can be seen as the agents of management. Junior managers are the agents of senior management. Senior managers are the agents of the directors, who are themselves agents of the shareholders. Thus in large firms there is often a complex chain of principal-agent relationships.

Asymmetric information

But these relationships have an inherent danger for the principal: there is *asymmetric information* between the two sides.

The agent knows more about the situation than the principal – of course, this is part of the reason why the principal employs the agent in the first place. The danger is that the agent may well not act in the principal's best interests, and may be able to get away with it because of the principal's imperfect knowledge. The estate agent may try to convince the vendor that it is necessary to accept a lower price, while the real reason is to save the agent time, effort and expense.

In firms, too, agents may not act in the best interests of their principals. For example, workers may be able to get away with not working very hard, preferring instead an easy

Definitions

Asymmetric information Where one party in an economic relationship (e.g. an agent) has more information than another (e.g. the principal).

BOX 9.5 THE US SUB-PRIME HOUSING CRISIS

Obvious in hindsight

The causes of the financial crisis of 2007–8, and of the subsequent global recession, are numerous and complex. However, there was one factor which made a major contribution to the collapse of confidence in the banking sector – the increased rate of mortgage defaults in the US housing market.

Background to the crisis

Up to 2006, the USA had experienced over a decade of sharply increasing house prices alongside growth in the number of homeowners, attracted by the promise of high returns. Over this period the US financial system was awash with funds flowing in from growing economies in Asia, and interest rates were low. The result was an easing of credit conditions and a sharp increase in the availability of mortgages. Home ownership was approaching 70 per cent, a historic high and an increase of around 7 per cent on the previous decade. Many of these new buyers were on low incomes, or had poor credit ratings – collectively they are known as *sub-prime borrowers*.

In 2006, the housing market in the USA peaked and values started to fall. This had an immediate effect on consumer confidence and demand for owner-occupied housing fell sharply, leading to a collapse in house prices. The 'house price bubble' had burst.

As the world moved into a recession, many borrowers found it hard to maintain their mortgage payments, particularly those on low incomes who had borrowed large amounts. The resulting high level of defaults and foreclosures (or repossessions) had an immediate and serious impact on the value of financial institutions across the world.

Sub-prime borrowers

Why was the sub-prime market so vulnerable to falling house prices? The answer lies in both the amount of lending that took place and the type of mortgages that were taken out by these borrowers. The role of mortgage-brokers, who acted as agents, also proved to be crucial.

Borrowers with low incomes were mostly sold adjustable-rate mortgages, which left them vulnerable to future interest rate rises. In addition, they were encouraged to accept deals with fixed lower payments in the first few years and higher rates after that, regardless of interest rate adjustments. The result was that they would often see mortgage payments double, or even treble, after a couple of years. For most this would present a major problem, since their wages were unlikely to have risen that fast.

However, the brokers had a solution; over the period of increasing house prices sub-prime borrowers were easily able to refinance their housing loans when the time came for higher payments. This ensured that the sub-prime borrowers could retain their properties while the brokers generated further transaction fees. But once prices started to fall, this option disappeared and so the numbers defaulting on their mortgages increased sharply.

Securitisation of sub-prime debt

Since the mid-1990s, many financial institutions have chosen not to hold mortgages through to the end of their term, retaining the associated risk. Instead, they have sold them on to other investors in the form of mortgage-backed securities (MBSs). This practice increased the incentives for banks to offer mortgages to sub-prime borrowers, since now they did not have to bear the full risk of default throughout a 20- or 25-year term.

life. Similarly, given the divorce between the ownership and control of a company, managers (agents) may pursue goals different from those of shareholders (principals). Thus *X inefficiency* is likely to occur (see Box 7.5).

So asymmetric information creates a problem for principals – known as the **principal-agent problem**:

KEY
IDEA
25

The principal-agent problem. Where people (principals), as a result of a lack of knowledge, cannot ensure that their best interests are served by their agents. Agents may take advantage of this situation to the disadvantage of the principals.

So how can principals tackle the problem? There are two elements in the solution:

- The principals must have some way of *monitoring* the performance of their agents. For example, a company might

employ efficiency experts to examine the operation of its management.

- Second, there must be *incentives* for agents to behave in the principals' interests. For example, managers' salaries could be closely linked to the firm's profitability.

Alternative theories of the firm therefore place considerable emphasis on incentive mechanisms in explaining the behaviour of managers and the resulting performance of their companies.

In a competitive market, managers' and shareholders' interests are more likely to coincide. Managers have to ensure

Definitions

Principal-agent problem Where people (principals), as a result of lack of knowledge, cannot ensure that their best interests are served by their agents.

CASE STUDIES AND
APPLICATIONS

The rate of securitisation increased sharply between 1997 and 2007, with 75 per cent of sub-prime mortgages being sold on to third parties by 2006. It played a pivotal role in the financial crisis (see pages 558–66). Once the US housing market collapsed, the effect was felt not only by American mortgage lenders, but also by financial institutions and investors across the world, all of whom had bought mortgage-backed securities or similar financial instruments.

The role of asymmetric information

One question of interest is what light can behavioural economics and the role of asymmetric information shed on the sub-prime market and the broader financial crisis. There is little doubt that throughout the market, economic principals (and agents for that matter) were not in possession of complete information and thus were unable to make rational decisions in the way that traditional theory would predict.

The opportunity for asymmetric information arose, in part, because mortgage brokers, acted as agents for the principals. Since they were paid by transaction fees, their incentive was to complete as many mortgages as possible, regardless of the possibility of future default; this is an example of *moral hazard* (see page 135).

In particular:

- Sub-prime borrowers were permitted to self-certify their incomes; this provided them with a mechanism to conceal full information about their earnings/debts. Why would they do this? They may have suffered from present bias and other types of bounded rationality associated with making probabilistic judgements.

- There is evidence that many borrowers were not given full, or clear, information about the escalating payments that they would face under their repayment plans. As a result they could not anticipate the problems they would face after two or three years.
- The commissions received by brokers were not transparent; thus borrowers could not readily identify the motives that lay behind being sold products that would require refinancing after some years.
- The financial institutions that bought mortgage-backed securities relied on credit ratings agencies to verify the risks involved. These agencies consistently rated the instruments as lower risk than they turned out to be. It is a matter of debate as to whether this was done deliberately, or as a consequence of over-reliance on risk-reducing practices. No matter, the result was that high-risk, sub-prime mortgages ended up in the portfolios of investors who would not have bought them if they had had full information.

1. Why was the market for sub-prime mortgages sustainable from 1996 to 2005? Explain how this changed in 2006.
2. The credit ratings agencies were paid by the companies that had been heavily involved in the market for sub-prime mortgages. Explain why this presents a moral hazard.
3. Financial regulation has endowed the judgements of the three credit ratings agencies with legal backing and has protected them from competition. Explain why this presented a problem in the process of securitisation.
4. If you were set the task of preventing similar sub-prime issues in the future, what regulations would you put in place?

p135

that the company remains efficient or it may not survive the competition and they might lose their jobs. In monopolies and oligopolies, however, where supernormal profits can often be relatively easily earned, the interests of shareholders and managers are likely to diverge. Here it will be in shareholders' interests to institute incentive mechanisms that ensure that their agents, the managers, are motivated to strive for profitability.

The adverse impact of asymmetric information

If effective monitoring and incentive systems cannot be found, then asymmetric information might prevent firms from achieving the most efficient outcomes. Consider the example of a small business seeking finance for investment purposes. Banks and financial institutions are unlikely to have full access to information about the business or the individuals who own it. Since investment opportunities often also involve some uncertainty about

the future, the likely outcome is a lower level of lending than is desirable.

Explain why the existence of asymmetric information may be damaging for both parties in an economic exchange, not only for the one who has incomplete information.

Firms also face asymmetric information about the quality of supplies and the ability of customers to pay; the latter may be a particular issue for transactions that take place between firms and where credit is extended. If firms recognise these issues when writing contracts, they may be able to address the problem and achieve better outcomes. But often the problem only becomes apparent when it is too late.

On occasion the impact of asymmetric information can be so serious that the consequences are devastating, not only for the individual market, but also for the wider economy. One example of this is examined in Box 9.5.

Section summary

1. The problem of managers not pursuing the same goals as the owners is an example of the *principal-agent problem*. Agents (in this case, the managers) may not always carry out the wishes of their principals (in this case, the owners).
2. Possible solutions for owners are to (a) monitor the performance of managers, and (b) create incentives for managers to behave in the owners' interests. If they are ineffective then asymmetric information may prevent firms from achieving their most efficient outcomes.

9.5 MULTIPLE AIMS

Satisficing and the setting of targets

Large firms are often complex institutions with many departments (sales, production, design, purchasing, personnel, finance, etc.). Each department is likely to have its own specific set of aims and objectives, which may come into conflict with those of other departments. These aims in turn will be constrained by the interests of shareholders, workers, customers and creditors (collectively known as *stakeholders*), who will need to be kept sufficiently happy.

In many firms, targets are set for production, sales, profit, stockholding, etc. If, in practice, target levels are not achieved, a 'search' procedure will be started to find out what went wrong and how to rectify it. If the problem cannot be rectified, managers will probably adjust the target downwards. If, on the other hand, targets are easily achieved, managers may adjust them upwards. Thus the targets to which

managers aspire depend to a large extent on the success in achieving *previous* targets. Targets are also influenced by expectations of demand and costs, by the achievements of competitors and by expectations of competitors' future behaviour. For example, if it is expected that the economy is likely to move into recession, sales and profit targets may be adjusted downwards.

Definitions

Stakeholders (in a company) People who are affected by a company's activities and/or performance (customers, employees, owners, creditors, people living in the neighbourhood, etc.). They may or may not be in a position to take decisions, or influence decision taking, in the firm.

BOX 9.6

STAKEHOLDER POWER?

CASE STUDIES AND APPLICATIONS

Who governs the firm?

The concept of the 'stakeholder economy' became fashionable in the late 1990s. Rather than the economy being governed by big business, and rather than businesses being governed in the interests of shareholders (many of whom are big institutions, such as insurance companies and pension funds), the economy should serve the interests of everyone. But what does this mean for the governance of firms?

The stakeholders of a firm include customers, employees (from senior managers to the lowest-paid workers), shareholders, suppliers, lenders and the local and national communities.

The supporters of a stakeholding economy argue that all these interest groups ought to have a say in the decisions of the firm. Trade unions or workers' councils ought to be included in decisions affecting the workforce, or indeed all company decisions. They could be represented on decision-making bodies and perhaps have seats on the board of directors. Alternatively, the workforce might be given the power to elect managers.

Banks or other institutions lending to firms ought to be included in investment decisions. In Germany, where banks finance a large proportion of investment, banks are represented on the boards of most large companies.

Local communities ought to have a say in any projects (such as new buildings or the discharge of effluent) that affect the local environment. Customers ought to have more say in the quality of products being produced: for example, by being given legal protection against the production of shoddy or unsafe goods.

Where interest groups cannot be directly represented in decision making, companies ought to be regulated by the government in order to protect the interests of the various groups. For example, if farmers and other suppliers to supermarkets are paid very low prices, then the purchasing behaviour of the supermarkets could be regulated by some government agency.

But is this vision of a stakeholder economy likely to become reality? Trends in the international economy suggest that the opposite might be occurring. The growth of multinational corporations, with their ability to move finance and production to wherever it is most profitable, has weakened the power of employees, local interest groups and even national governments.

Employees in one part of the multinational may have little in the way of common interests with employees in another. In fact, they may vie with each other: for example, over which plant should be expanded or closed down. With new 'flexible labour markets', firms are making more use of casual, part-time, temporary or agency workers. These employees are generally 'outsiders' to decision making within the firm (see Box 10.8).

Also, the widespread introduction of share incentive schemes for managers has increasingly made profits their driving goal. Finally, the policies of opening up markets and deregulation – policies that have been adopted by many governments round the world in recent years – have again weakened the power of many stakeholders.

Nevertheless, many firms in recent years have put greater emphasis on 'corporate social responsibility' (CSR), seeing it as important to have an ethical dimension to their business practices. Whether this is a genuine commitment to the interests of society, or simply an attempt to win a larger market by gaining a good public image, clearly varies from firm to firm. CSR and business ethics are explored in Case Study 9.4 on the student website.

Are customers' interests best served by profit-maximising firms, answerable primarily to shareholders, or by firms where various stakeholder groups are represented in decision taking?

If targets conflict, the conflict could be settled by a bargaining process between managers. In this case, the outcome of the bargaining will depend on the power and ability of the individual managers concerned and the governance structure in which they operate. Thus a similar set of conflicting targets may be resolved differently in different firms.

Organisational slack

Since changing targets often involves search procedures and bargaining processes and is therefore time-consuming, and since many managers prefer to avoid conflict, targets tend to be changed fairly infrequently. Business conditions, however, often change rapidly. To avoid the need to change

targets, therefore, managers will tend to be fairly conservative in their aspirations. This leads to the phenomenon known as **organisational slack** – a term coined by Cyert and March (see above page 253)

When the firm does better than expected, it will allow slack to develop. This slack can then be taken up if the firm does worse than expected. For example, if the firm

Definitions

Organisational slack Where managers allow spare capacity to exist, thereby enabling them to respond more easily to changed circumstances.

produces more than it planned, it will build stocks of finished goods and draw on them if subsequently production falls. It would not, in the meantime, increase its sales target or reduce its production target. If it did, and production then fell below target, the production department might not be able to supply the sales department with its full requirement.

Thus keeping targets fairly low and allowing slack to develop allows all targets to be met with minimum conflict.

Organisational slack, however, adds to a firm's costs. If firms are operating in a competitive environment, they may be forced to cut slack in order to survive. In the 1970s, many Japanese firms succeeded in cutting slack by using *just-in-time* methods of production. These involve keeping stocks to a minimum and ensuring that inputs are delivered as required. Clearly, this requires that production is tightly controlled and that suppliers are reliable. Many firms today have successfully cut their warehouse costs by using such methods. These methods are examined in Box 10.8.

Multiple goals: predictions of behaviour

Conservatism

Some firms may be wary of change, seeing it as risky. They may prefer to stick with current practices. This could apply to pricing policies, marketing techniques, product design and range, internal organisation of the firm, etc. This is simple heuristics: if it works, stick with it.

If something does not work, managers will probably change it, but again they may be cautious: perhaps imitating successful competitors.

This safe, satisficing approach makes prediction of any given firm's behaviour relatively straightforward. You simply examine its past behaviour. Making generalisations about all such cautious firms, however, is more difficult. Different firms will have established different rules of behaviour depending on their experiences of their own particular market.

Comparison with other firms

Managers may judge their success by comparing their firm's performance with that of rivals. For example, growing market share may be seen as a more important indicator of 'success' than simple growth in sales. Similarly, they may compare their profits, their product design, their technology or their industrial relations with those of rivals. To many managers it is *relative* performance that matters, rather than absolute performance.

What predictions can be made if this is how managers behave? The answer is that it depends on the nature of competition in the industry. The more profitable, innovative and efficient are the competitors, the more profitable, innovative and efficient will managers try to make their particular firm.

The further ahead of their rivals that firms try to stay, the more likely it is that there will be a 'snowballing' effect, with each firm trying to outdo the other.

Will this type of behaviour tend to lead to profit maximisation?

Satisficing and the public interest

Firms with multiple goals will be satisficers. The greater the number of goals of the different managers, the greater is the chance of conflict, and the more likely it is that organisational slack will develop. Satisficing firms are therefore likely to be less responsive to changes in consumer demand and changes in costs than profit-maximising firms. They may thus be less efficient.

On the other hand, such firms may be less eager to exploit their economic power by charging high prices, or to use aggressive advertising, or to pay low wages.

The extent to which satisficing firms do act in the public interest will, as in the case of other types of firm, depend to a large extent on the amount and type of competition they face, and their attitudes towards this competition. Firms that compare their performance with that of their rivals are more likely to be responsive to consumer wishes than firms that prefer to stick to well-established practices. On the other hand, they may be more concerned to 'manipulate' consumer tastes than the more traditional firm.

Are satisficing firms more likely to suffer from X inefficiency (see Box 7.5) than firms which seek to maximise profit or sales revenue?

Definitions

Just-in-time methods Where a firm purchases supplies and produces both components and finished products as they are required. This minimises stockholding and its associated costs. It does, however, put pressure on the supply chain and increases the probability that on occasion firms may not be able to meet demand – for example in times of bad weather.

Section summary

1. In large firms, decisions are taken by or influenced by a number of different people, including various managers, shareholders, workers, customers, suppliers and creditors. If these different people have different aims, a conflict between them is likely to arise. A firm cannot maximise more than one of these conflicting aims. The alternative is to seek to achieve a satisfactory target level of a number of aims.
2. If targets were easily achieved last year, they are likely to be made more ambitious next year. If they were not achieved, a search procedure will be conducted to identify how to rectify the problem. This may mean adjusting targets downwards, in which case there will be some form of bargaining process between managers.
3. Life is made easier for managers if conflict can be avoided. This will be possible if slack is allowed to develop in various parts of the firm. If targets are not being met, the slack can then be taken up without requiring adjustments in other targets.
4. Satisficing firms may be less innovative, less aggressive and less willing to initiate change. If they do change, it is more likely to be in response to changes made by their competitors. Managers may judge their performance by comparing it with that of rivals.
5. Satisficing firms may be less aggressive in exploiting a position of market power. On the other hand, they may suffer from greater X inefficiency.

9.6 PRICING IN PRACTICE

What is the typical procedure by which firms set prices? Do they construct marginal cost and marginal revenue curves (or equations) and find the output where they are equal? Do they then use an average revenue curve (or equation) to work out the price at that output?

As we saw in section 9.1, firms often do not have the information to do so, even if they wanted to. In practice, firms look for rules of pricing that are relatively simple to apply.

Cost-based pricing

One approach is *average cost* or *mark-up pricing*. Here producers work out the price by simply adding a certain percentage (mark-up) for profit on top of average costs (average fixed costs plus average variable costs). It is a very straightforward heuristic.

$$P = AFC + AVC + \text{profit mark-up}$$

Choosing the mark-up

The level of profit mark-up on top of average cost will depend on the firm's aims: whether it is aiming for high or even maximum profits, or merely a target based on previous profit. It will also depend on the likely actions of rivals and their responses to changes in this firm's price and how these responses will affect demand.

If a firm could estimate its demand curve, it could then set its output and profit mark-up at levels that will avoid a shortage or surplus. Thus in Figure 9.3 it could choose a lower

Figure 9.3 Choosing output and profit mark-up

output (Q_1) with a higher mark-up (fg) or a higher output (Q_2) with a lower mark-up (hj), depending on its aims. If the firm could not estimate its demand curve, it could adjust its mark-up and output over time by a process of trial and error, according to its success in meeting profit and sales aims.

Definitions

Average cost or mark-up pricing Where firms set the price by adding a profit mark-up to average cost.

BOX 9.7

HOW DO COMPANIES SET PRICES?

In 1996, the Bank of England published a survey of price-setting behaviour in 654 UK companies.¹ Among other things, the survey sought to establish what factors influenced companies' pricing decisions. The results are shown in table (a).

Companies were asked to rank alternative methods of pricing of their main product . . . The most popular response was that prices were set with respect to market conditions. The top preference² for almost 40 per cent of respondents was that prices were set at the highest level that the market could bear. An additional 25 per cent of respondents stated that they set prices in relation to their competitors – this was the second choice most popular among companies . . .

The survey also confirmed the importance of company-specific factors. The first preference of about 20 per cent of respondents was that price was made up of a direct cost per unit plus a variable percentage mark-up . . . A further 17 per cent of companies, particularly retailing companies, stated that they priced on the basis of costs plus a fixed percentage mark-up.

Cost plus mark-ups tended to be more important for small companies . . . which cannot afford expensive market research.

The survey also sought to establish those factors which could cause prices to change – either up or down (see table (b)).

The Bank survey asked companies to rank those factors most likely to push prices up or down. It found that there were substantial differences between the factors that influenced price increases and those that influenced price decreases. First, many more companies said that cost rises were likely to push prices up than said that cost reductions were likely to push prices down. Second, a rise in demand seemed less likely to lead to a price increase than a fall in demand was to lead to a price cut . . .

The importance of strategic interaction with competitors suggests that when contemplating a price cut, companies need to consider the chance of sparking off a price war . . . The finding that companies were much more likely to match rival price falls than they are to follow rival price rises appears to support the importance of strategic behaviour.

(a) *How are prices determined?*

	1st	%	2nd	%	3rd	%
Market level	257	39	140	21	78	12
Competitors' prices	161	25	229	35	100	15
Direct cost plus variable mark-up	131	20	115	18	88	14
Direct cost plus fixed mark-up	108	17	49	8	42	6

Higher market share	14	2	Lower market share	69	11
Fall in productivity	5	1	Rise in productivity	22	3

^aNumbers citing a scenario as most important.

Note: Top preferences only.

Source: S. Hall, M. Walsh and T. Yates, 'How do UK companies set prices?', *Bank of England Quarterly Bulletin*, May 1996, Table D, p. 188.

More recent surveys

Europe-wide survey. A European study of 2006 reported similar results to the 1996 UK survey. This European study brought together surveys conducted by nine Eurosystem national central banks on the price-setting behaviour of over 11 000 European firms.³

The research found that price-setting behaviour is consistent across Europe, with mark-up pricing the dominant

strategy in the eurozone and price discrimination widely practised. The asymmetries noted above with respect to price increases and decreases were also seen.

Further Bank of England survey. In 2008, the Bank of England conducted another survey of price-setting behaviour. This time 693 firms responded, with a spread across industry consistent with shares in UK GDP. The findings broadly supported those of the 1996 survey.

(c) Most important factors leading to a rise or fall in price

Price rise	Rank	Price reduction	Rank
Increase in cost of labour	1	Actual decline in demand	1
Increase in the prices of fuel, raw materials or other inputs	2	Actual price reduction by domestic competitor(s)	2
Actual rise in demand	3	Expected decline in demand	3
Increasing costs arising out of regulation	4	Significant reduction in market share	4
Actual price increase by domestic competitor(s)	5	Expected price reduction by domestic competitor(s)	5
Expected rise in demand	6	Decrease in the prices of fuel, raw materials or other inputs	6
Increase in financing costs	7	Decrease in cost of labour	7
Expected price increase by one or more of your domestic rivals	8	Decrease in costs arising out of regulation	8

Source: Jennifer Greenslade and Miles Parker, 'Price-setting behaviour in the United Kingdom', *Bank of England Quarterly Bulletin*, 2008 Q4.

[The survey revealed that] different factors influenced price rises and price falls. Higher costs – in particular, labour costs and raw materials – were the most important driver behind price rises, whereas lower demand and competitors' prices were the main factor resulting in price falls.⁴

Companies were asked to rank the importance of 11 factors in determining both price rises and price reductions. Table (c) shows the eight most important 6 in determining price changes (based on share of companies responding 'important' or 'very important').

Unlike the 1996 survey, companies were asked about *expected* changes in key variables, including demand, costs and rivals' prices. These were important determinants for many companies.

The survey confirmed that a majority of firms use mark-up pricing, with 58 per cent describing it as 'very important'. More than half of these firms *adjust* their mark-up according to market conditions. Competitors' prices and market demand are the two most important factors leading to a fall in price. The increase in the cost of labour and prices of fuel and raw materials are the two most important factors leading to a price rise.

Price flexibility

Evidence from the USA⁵ and the eurozone study suggests that the frequency and magnitude of price changes varies enormously from product to product.

Generally speaking, the greater the share of raw materials in a product, the more often its price moves: petrol prices change, on average, in five months out of six in both America and Europe; the prices of fresh food are altered far more frequently than those of processed food. The prices of services are stickier than those of goods. This may be because services tend to be more labour-intensive than goods, and because wages are stickier (downwards, anyway) than other prices.⁶

For most products, prices change relatively infrequently in Europe, with retail prices changing on average just over once per year. In the USA, sales are much more common, especially with clothes, furniture and processed food. The prices of

services also change more frequently in the USA. In Europe services are more regulated and wages (a large proportion of the cost of most services) are less flexible.

How often individual prices move is an important question. Shifts in prices are like the traffic lights of an economy, signalling to people to buy more of this and less of that, to spend or to save, or to find new jobs. If the lights change readily, resources can be redirected smoothly; if they get stuck, so does the economy. In particular, if neither prices nor wages fall easily, the cost in output and jobs of reducing inflation can be high. Sticky prices also mean that an inflationary shock – an increase in oil prices, say – can take a long time to work its way through the system.⁷

As far as the magnitude of price changes is concerned, in both the USA and Europe, price changes are typically much bigger than the rate of inflation. In Europe, average price increases are 8 per cent and average price reductions 10 per cent.

1. Which of the following is more likely to be consistent with the aim of maximising profits: pricing on the basis of (a) cost per unit plus a variable percentage mark-up; (b) cost per unit plus a fixed percentage mark-up?
2. Explain the differences between the importance attached to the different factors leading to price increases and those leading to price reductions.
3. Why do you think percentage price changes are bigger than the rate of inflation?

1 Simon Hall, Mark Walsh and Tony Yates, 'How do UK companies set prices?', *Bank of England Quarterly Bulletin*, May 1996.

2 Companies were able to show more than one response as their top preference. This means the total percentage of companies expressing first preferences for all of the explanations of price determination exceeds 100 per cent.

The equilibrium price and output

Is it possible to identify an equilibrium price and output for the firm that sets its prices by adding a mark-up to average cost? To answer this we can identify a supply curve for the firm.

If a firm is aiming for a particular profit *per unit* of output and does not adjust this target, the firm's supply curve is derived by adding the mark-up to the AC curve. This is shown by curve S_1 in Figure 9.4. If, however, a firm is aiming for a particular level of *total* profit, and does not adjust this target, its supply curve will be like curve S_2 . The greater the output, the less the profit per unit needs to be (and hence the less the mark-up) to give a particular level of total profit.

In either case, price and quantity can be derived from the intersection of demand and supply. Price and output will change if the demand or cost (and hence supply) curve shifts.

The main problem here is in predicting the demand curve, since it depends not only on consumer tastes but on the prices and behaviour of competitors. In practice, firms will usually base their assumptions about future sales on current figures, add a certain percentage to allow for growth in demand and then finally adjust this up or down if they decide to change the mark-up.

Variations in the mark-up

In most firms, the mark-up is not rigid. In expanding markets, or markets where firms have monopoly/oligopoly power, the size of the mark-up is likely to be greater. In contracting markets, or under conditions of rising costs and constant demand, a firm may well be forced to accept lower profits and thus reduce the mark-up.

Multi-product firms often have different mark-ups for their different products depending on their various market

conditions. Such firms will often distribute their overhead costs unequally between their products. The potentially most profitable products, often those with the least elastic demands, will probably be required to make the greatest contribution to overheads.

The firm is likely to take account of the actions and possible reactions of its competitors. It may well be unwilling to change prices when costs or demand change, for fear of the reactions of competitors (see the discussion of kinked demand curve theory on pages 231–2). If prices are kept constant but costs change, either due to a movement along the AC curve in response to a change in demand, or due to a shift in the AC curve, the firm must necessarily change the size of the mark-up.

All this suggests that, whereas the mark-up may well be based on a target profit, firms are often prepared to change their target and hence their mark-up, according to market conditions.

1. If the firm adjusts the size of its mark-up according to changes in demand and the actions of competitors, could its actions approximate to setting price and output where $MC = MR$?
2. Some firms set their prices by adding a mark-up to average variable cost (the mark-up would be larger to include an element to cover fixed cost). Why might this make pricing easier for the firm? (See Box 6.7.)

*LOOKING AT THE MATHS

Using a mark-up approach to find the profit-maximising price

Could the firm use a mark-up approach to set the *profit-maximising* price? It could, provided it bases its mark-up on marginal cost (MC), rather than average cost, and provided it knows the price elasticity of demand (P_{ϵ_D}) for its product. The rule is:

$$P = \frac{MC}{1 + (1/P_{\epsilon_D})}$$

This is simply the formula for the profit-maximising price that we derived in section 7.3 (see page 205), except that we have used MC rather than MR (where profits are maximised, $MC = MR$). Proof of this formula is given in Maths Case 7.2 on the student website.

Thus if $MC = £10$ and $P_{\epsilon_D} = -5$, the firm should charge a price of

$$\frac{£10}{1 + (1/-5)} = \frac{£10}{1 - 1/5} = \frac{£10}{0.8} = £12.50$$

The weakness of this pricing rule is that it applies only at the profit-maximising output. If the firm is currently a long way from that output, MC and P_{ϵ_D} may diverge considerably from the values that the firm should use in its calculation. If, however, the firm is producing relatively near to its profit-maximising output, the rule can give a price that is a close approximation to the profit-maximising price.

Section summary

- Many firms set prices by adding a profit mark-up to average cost. This cost-plus pricing is most likely when firms are profit satisficers or when they do not have the information to find the price that will equate marginal cost and marginal revenue.
- The mark-up could be based on achieving a target level of either *total* profit or profit per unit. In either case, a supply curve can be derived by adding the corresponding mark-up to the average cost curve.
- For firms keen to increase profit, the size of the mark-up can be varied as market conditions permit the target profit to be increased.

END OF CHAPTER QUESTIONS

- Assume that a firm faces a downward-sloping demand curve. Draw a diagram showing the firm's *AR*, *MR*, *AC* and *MC* curves. (Draw them in such a way that the firm can make supernormal profits.) Mark the following on the diagram:
 - The firm's profit-maximising output and price.
 - Its sales-revenue-maximising output and price.
 - Its sales-maximising output and price (subject to earning at least normal profit).

Could the answer to (a) and (b) ever be the same?
 Could the answer to (b) and (c) ever be the same?
- Would it be possible for firms to calculate their maximum-profit output if they did not use marginal cost and marginal revenue concepts?
- What is meant by the principal-agent problem? Give two examples of this problem that you have come across in your own experience.
- 'A firm will always prefer to make more profit rather than less.' Do you agree with this statement? Is it compatible with alternatives to the profit-maximising theory of the firm?
- A firm under monopoly or oligopoly that aims to maximise sales revenue will tend to produce more than a firm that aims to maximise profits. Does this conclusion also apply under (a) perfect competition and (b) monopolistic competition, given that there is freedom of entry?
- What are the potential costs and benefits of mergers to (a) shareholders; (b) managers; (c) customers?
- Why is it difficult to test the assumption that firms seek to maximise *long-run* profits?
- Do behavioural theories of the firm allow us to make any predictions about firms' prices and output?
- Are 'special offers' likely to benefit consumers?

Who are the poor? Who are the rich?	313

Why do film stars, footballers and investment bankers earn such large incomes? Why, on the other hand, do cleaners, hospital porters and workers in clothing factories earn very low incomes? These are the types of question that the theory of distribution seeks to answer. It attempts to explain why some people are rich and others poor.

The explanation for differences in wages lies in the working of labour markets. In sections 10.1 and 10.2, we will consider how labour markets operate. In particular, we will focus on the determination of wage rates in different types of market: ones where employers are wage takers, ones where they can choose the wage rate, and ones where wage rates are determined by a process of collective bargaining. In the final two sections, we turn to capital and land and ask what determines the rewards that their owners receive.

This chapter examines the theory of income distribution by showing how the rewards to factors of production (labour, capital and land) depend on market conditions. Chapter 11, on the other hand, looks at income distribution in practice. It looks at inequality and poverty and at government policies to tackle the problem.

10.1 WAGE DETERMINATION UNDER PERFECT COMPETITION

Perfect labour markets

When looking at the market for labour, it is useful to distinguish between perfect and imperfect markets. Although in practice few labour markets are totally perfect, many are at least approximately so.

The assumptions of perfect labour markets are similar to those of perfect goods markets. The main one is that everyone is a **wage taker**. In other words, neither employers nor employees have any economic power to affect wage rates. This situation is not uncommon. Small employers are likely to have to pay the 'going wage rate' to their employees, especially when the employee is of a clearly defined type, such as an electrician, a bar worker, a data analyst or a porter. As far as employees are concerned, being a wage taker means competing with other identical (or very similar) workers. It also means not being a member of a union and therefore not being able to use collective bargaining to push up the wage rate.

The other assumptions of a perfect labour market are as follows:

Freedom of entry. There are no restrictions on the movement of labour. Workers are free to move to different jobs or to areas of the country where wages are higher. There are no barriers erected by, say, unions, professional associations or the government. Of course, it takes time for workers to change jobs and maybe to retrain. This assumption therefore applies only in the long run.

Perfect knowledge. Workers are fully aware of what jobs are available at what wages and with what conditions of

employment. Likewise, employers know what labour is available and how productive that labour is.

Homogeneous labour. It is usually assumed that, in perfect markets, workers of a given category are identical in terms of productivity. For example, it would be assumed that all bricklayers are equally skilled and motivated.

Which of the above assumptions do you think would be correct in each of the following cases?

- Supermarket checkout operators.
- Agricultural workers.
- Crane operators.
- Economics teachers.
- Call-centre workers.
- Professional footballers.
- Bar workers.

Wage rates and employment under perfect competition are determined by the interaction of the market demand and supply of labour. This is illustrated in Figure 10.1(a).

Generally, it would be expected that the supply and demand curves slope the same way as in goods markets. The higher the wage paid for a certain type of job, the more workers will want to do that job and, generally, the more hours each will be willing to work. This gives an upward-sloping supply curve of labour. On the other hand, the higher the wage that employers have to pay, the less labour they will employ. They may produce less, or they may substitute other factors of production, like machinery, for labour. Thus the demand curve for labour slopes downwards.

Figure 10.1(b) shows how an individual employer has to accept this wage. The supply of labour to that employer is infinitely elastic. In other words, at the market wage W_m , there is no limit to the number of workers available to that employer (but no workers at all will be available below it: they will all be working elsewhere). At the market wage W_m , the employer will employ Q_1 hours of labour.

Definition

Wage taker An employer or employee who has no power to influence the market wage rate.

Figure 10.1 A perfectly competitive labour market

BOX 10.1

LABOUR AS A FACTOR OF PRODUCTION

EXPLORING ECONOMICS

Is this any way to treat a worker?

The theory that wages depend on demand and supply is often referred to as the 'neoclassical' theory of wages. Treated as pure theory, it is value free and does not involve moral judgements. It does not say, for example, whether the resulting distribution of income is fair or just.

In practice, however, the neoclassical theory is often used in such a way as to imply moral judgements. It is a theory that tends to be associated with the political right and centre: those who are generally in favour of markets and the capitalist system. Many on the political left are critical of its implied morality. They make the following points:

- By treating labour as a 'factor of production', it demeans labour. Labour is not the same as a piece of land or a machine.
- It legitimises the capitalist system, where some people own land and capital while others have only their own labour. It implies that people have a right to income from their property even if that property is unequally distributed among the population.
- It implies that labour has no rights to the goods that it produces. These goods are entirely the property of the employer, even though it is the workers who made them.

Karl Marx (1818–83) was highly critical of these values and the way that the capitalist system led to extremes of wealth and poverty. He argued that labour was the only true source of value. After all, it is labour that makes machines, labour that works the land, labour that mines coal and other natural resources. Property, he argued, is therefore a form of theft. When capitalists extract profits from their enterprises, he continued, they are stealing part of the value produced by labour.

Neoclassical economists defend their position against the Marxist 'labour theory of value' by arguing the following:

- They are merely describing the world. If people want to draw pro-capitalist conclusions from their theory, then that is up to them.
- If the labour theory of value is used in any practical way to evaluate costs and output, it will lead to a misallocation of resources. Labour is not the only scarce resource. Land, for example, is also scarce and needs to be included in calculations of costs, otherwise it will be used wastefully.

Assume that it is agreed by everyone that it is morally wrong to treat labour as a mere 'factor of production', with no rights over the goods produced. Does this make the neoclassical theory wrong?

Figure 10.1(c) shows how an individual worker also has to accept this wage. In this case it is the demand curve for that worker that is infinitely elastic. In other words, there is as much work as the worker chooses to do at this wage, but none at all above it.

We now turn to look at the supply and demand for labour in more detail.

The supply of labour

We can look at the supply of labour at three levels: the supply of hours by an individual worker, the supply of workers to an individual employer, and the total market supply of a given category of labour. Let us examine each in turn.

The supply of hours by an individual worker

Work involves two major costs (or 'disutilities') to the worker:

- When people work they sacrifice leisure.
- The work itself may be unpleasant or tedious.

Each extra hour worked will involve additional disutility. This **marginal disutility of work (MDU)** will tend to increase as people work more hours. There are two reasons for this. First, the less leisure they have left, the greater is the disutility they experience in sacrificing a further hour of leisure. Second, any unpleasantness they experience in

doing the job tends to increase due to boredom, tiredness, or frustration.

Re-word the explanation of marginal disutility of work in terms of the marginal utility of leisure.

This increasing marginal disutility (see Figure 10.2(a)) will tend to give an upward-sloping supply curve of hours by an individual worker (see Figure 10.2(b)). The reason is that, in order to persuade people to work more hours, a higher hourly wage must be paid to compensate for the higher marginal disutility incurred. This helps to explain why overtime rates are higher than standard rates.

Under certain circumstances, however, the supply of hours curve might bend backwards (see Figure 10.3). The reason is that when wage rates go up, two opposing forces operate on the individual's labour supply.

On one hand, with higher wage rates people tend to work more hours, since time taken in leisure now involves a greater sacrifice of income and hence consumption. They

Definition

Marginal disutility of work The extra sacrifice/hardship to a worker of working an extra unit of time in any given time period (e.g. an extra hour per day).

Figure 10.2 Marginal disutility of work and an individual's supply of labour**Figure 10.3** Backward-bending supply curve of labour

thus substitute income (i.e. work) for leisure. This is called the **substitution effect** of the increase in wage rates.

On the other hand, people may feel that with higher wage rates they can afford to work less and have more leisure. This is called the **income effect**. It reflects the fact that leisure is a *normal good*, one which is consumed in greater quantities as incomes rise.

With two effects working in opposite directions, the relative size of the effects determines the slope of the individual's supply curve. At lower wage rates, it is generally assumed that the substitution effect outweighs the income effect. A rise in the wage rate acts as an incentive and encourages a person to

work more hours. At higher wage rates, however, the income effect might outweigh the substitution effect. As wages rise, people may feel they can afford to give up some consumption in exchange for more leisure time.

If the wage rate becomes high enough for the income effect to outweigh the substitution effect, the supply curve will begin to slope backwards. This occurs above a wage rate of W_1 in Figure 10.3.

These considerations are particularly important for a government when thinking about policies on income tax. Conservative governments have often argued that cuts in income taxes are the equivalent of giving people a pay rise, and that they provide an incentive for people to work harder. This analysis is only correct, however, if the substitution effect dominates. If the income effect dominates, people will work *less* after the tax cut. These questions are examined in Chapter 11.

The supply of labour to an individual employer

Under perfect competition, the supply of labour to a particular firm will be perfectly elastic, as in Figure 10.1(b). The firm is a 'wage taker' and thus has no power to influence wages. Take the case of a small firm that wishes to employ a temporary receptionist via an agency. It has to pay the 'going rate', and presumably will be able to employ as many receptionists as it likes (within reason) at that wage rate.

The market supply of a given type of labour

This will typically be upward sloping, as in Figure 10.1(a). The higher the wage rate offered in a particular type of job, the more people will want to do that job.

Definitions

Substitution effect of a rise in wage rates Workers will tend to substitute income for leisure as leisure now has a higher opportunity cost. This effect leads to *more* hours being worked as wage rates rise.

Income effect of a rise in wage rates Workers get a higher income for a given number of hours worked and may thus feel they need to work *fewer* hours as wage rates rise.

BOX 10.2

USING INDIFFERENCE CURVE ANALYSIS TO DERIVE THE INDIVIDUAL'S SUPPLY CURVE OF LABOUR

EXPLORING ECONOMICS

Indifference curve analysis (see section 4.3) can be used to derive the individual's supply curve of labour. The analysis can show why the supply curve may be backward bending.

Assume that an individual can choose the number of hours to work and has 12 hours a day to divide between work and leisure (the remaining 12 being for sleep, shopping, travelling, etc.). In the diagram, with an hourly wage rate of £10, budget line B_1 shows all the possible combinations of daily income and leisure hours. For example, at point x the individual has an income of £80 by working eight hours and having four hours of leisure.

At an hourly wage of £20, the budget line becomes B_2 , and at an hourly wage of £25 it becomes B_3 .

The choice of hours worked at different wage rates

The diagram also shows three indifference curves. Each indifference curve shows all those combinations of income and leisure that give the individual a particular level of utility. The curves are bowed in towards the origin, showing that increasingly higher incomes are necessary to compensate for each hour of leisure sacrificed. Curve I_3 shows a higher level of utility than I_2 , and I_2 a higher level than I_1 .

At a wage rate of £10 per hour, the individual can move along budget line B_1 . Point x shows the highest level of utility that can be achieved. The individual thus supplies eight hours of labour (and has four hours of leisure).

At the higher wage rate of £20 per hour, the individual is now on budget line B_2 and maximises utility at point y by working nine hours. Thus the higher wage has encouraged the individual to work one more hour. So far, then, the individual's supply curve would be upward sloping: a higher wage rate leads to more labour hours supplied.

At the still higher wage rate of £25 per hour, the individual is on budget line B_3 , and now maximises utility at point z . But this means that only eight hours are now worked. The supply curve has begun to bend backwards. In other words, the individual is now in a position to be able to afford to take more time off in leisure. The income effect has begun to offset the substitution effect.

1. Using the analysis developed in Chapter 4, try to show the size of the income and substitution effects when moving from point x to point y and from point y to point z .
2. Illustrate on an indifference diagram the effect on the hours a person works of (a) a cut in the rate of income tax; (b) the introduction of a weekly tax credit, worth £30 to all adults irrespective of income.

The position of the market supply curve of labour depends on the number of people willing and able to do the job at each given wage rate. This depends on three things:

- The number of qualified people. Of course, if the job is unskilled then a large number of people will be 'qualified'.
- The non-wage benefits or costs of the job, such as the pleasantness of the working environment, job satisfaction or dissatisfaction, status, the degree of job security, pensions and other fringe benefits.
- The wages and non-wage benefits in alternative jobs.

A change in the wage rate will cause a movement along the supply curve. A change in any of these other three determinants will shift the whole curve.

Which way will the supply curve shift if the wage rates in alternative jobs rise?

The elasticity of the market supply of labour

How responsive will the supply of labour be to a change in the wage rate? If the market wage rate goes up, will a lot more labour become available or only a little? We looked at elasticity of demand and supply in Chapter 3; a similar analysis is used for the labour market. Thus the responsiveness (elasticity) depends on (a) the difficulties and costs of changing jobs and (b) the time period under consideration.

Another way of looking at the elasticity of supply of labour is in terms of the **mobility of labour**: the willingness and ability of labour to move to another job, whether in a

Definition

Mobility of labour The willingness and ability of labour to move to another job.

different location (geographical mobility) or in a different industry (occupational mobility). The mobility of labour (and hence the elasticity of supply of labour) will be higher when there are alternative jobs in the same location, when alternative jobs require similar skills, and when people have good information about these jobs. It is also much higher in the long run, when people have the time to move or to acquire new skills and when the education system has time to adapt to the changing demands of industry.

1. Assume that there is a growing demand for computer programmers. As a result more people train to become programmers. Does this represent a rightward shift in the supply curve of programmers, or merely the supply curve becoming more elastic in the long run, or both? Explain.
2. Which is likely to be more elastic, the supply of coal miners or the supply of shop assistants? Explain.

If the demand for a particular category of worker increases, the wage rate will rise. The more inelastic the supply of labour, the higher the rise will be. Workers already employed in that industry will get the benefit of that rise, even though they are doing the same job as before. They are now earning a premium above the wage that was necessary to attract them into the industry in the first place. This premium is called **economic rent**. Case Study 10.1 on the student website explores this concept and its relationship with the elasticity of supply of labour.

The demand for labour: the marginal productivity theory

In the traditional 'neoclassical' theory of the firm, which we examined in Chapters 8 and 9, it is assumed that firms aim to maximise profits. The same assumption is made in the neoclassical theory of labour demand. This theory is generally known as **marginal productivity theory**.

The profit-maximising approach

How many workers will a profit-maximising firm want to employ? The firm will answer this question by weighing up the costs of employing extra labour against the benefits. It will use exactly the same principles as in deciding how much output to produce.

Definition

Economic rent The excess that a factor of production is paid over the amount necessary to keep it in its current employment.

Marginal productivity theory The theory that the demand for a factor depends on its marginal revenue product.

BOX 10.3

IMMIGRATION AND THE UK LABOUR MARKET

Free movement of people and the single European market

On 23 June 2016, a majority of those who voted in the UK referendum on membership of the European Union (EU) voted 'leave'. Many commentators argue that a major reason for the result was the desire of many people to see an end to the free movement of people to the UK from the EU.

The free movement of people is one of the four key principles that underpins the EU's single market (the others being free movement of goods, services and capital). The full implications of this rule for patterns of migration became clear when the so-called EU8 countries (Czech Republic, Estonia, Hungary, Latvia, Poland, Slovakia and Slovenia) joined the EU in 2004.

When new countries gain EU membership, existing countries are usually given the option of introducing transitional arrangements. This typically involves the placing of restrictions on the free movement of citizens from new member states for a period of up to seven years. Most existing members of the EU decided to use this option following the accession of the EU8 countries. Without controls, they feared that their labour markets would become overwhelmed by a large inflow of new economic migrants.

The UK, along with Sweden and Ireland, chose a different course of action. They decided against any transitional arrangements and allowed immediate free

movement for people from the EU8 countries into their labour markets.

The impact of this decision on the volume of immigration was quite dramatic. The number of EU8 nationals living in the UK increased from 125 000 in 2004 to over a million in 2012. Immigration from the EU as a proportion of total immigration into the UK increased from around 10 per cent in 1990 to 44 per cent in 2016.

Given this larger-than-expected immigration from 2004, the UK government decided to introduce transitional arrangements for the full seven-year period after Bulgaria and Romania joined the EU in 2007. Citizens from these countries had to apply to the Home Office to obtain authorisation to take a job. Restrictions were lifted when the seven-year period came to an end in 2014.

Impact of EU immigration on the UK economy

What impact has this big increase in immigration had on the labour market in the UK and the economy more generally? The predictions of economic theory are inconclusive. At the microeconomic level, we would expect an increase both in labour supply and in the elasticity of supply. This could result in lower rates of wages and employment for the UK-born labour force.

In the goods market, the firm will maximise profits where the marginal cost of an extra unit of *goods* produced equals the marginal revenue from selling it: $MC = MR$.

In the labour market, the firm will maximise profits where the marginal cost of employing an extra *worker* equals the marginal revenue that the worker's output earns for the firm: MC of labour = MR of labour. The reasoning is simple. If an extra worker adds more to a firm's revenue than to its costs, the firm's profits will increase. It will be worth employing that worker. But as more workers are employed, diminishing returns to labour will set in (see page 151). Each extra worker will produce less than the previous one, and thus bring in less revenue for the firm. Eventually, the marginal revenue from extra workers will fall to the level of their marginal cost. At that point, the firm will stop employing extra workers. There are no additional profits to be gained from employing further workers. Profits are at a maximum.

Measuring the marginal cost and revenue of labour

Marginal cost of labour (MC_L). This is the extra cost of employing one more worker. Under perfect competition, the firm is too small to affect the market wage. It faces a horizontal supply curve (see Figure 10.1(b) on page 278). Thus the additional cost of employing one more person will simply be the wage: $MC_L = W$.

Marginal revenue of labour (MRP_L). The marginal revenue that the firm gains from employing one more worker is called the **marginal revenue product** of labour. The MRP_L is found by multiplying two elements – the **marginal physical product** of labour (MPP_L) and the marginal revenue gained by selling one more unit of output (MR):

$$MRP_L = MPP_L \times MR$$

The MPP_L is the extra output produced by the last worker. Thus if the last worker produces 100 tonnes of output per week (MPP_L), and if the firm earns an extra £4 for each additional tonne sold (MR), then the worker's MRP is £400. This extra worker is adding £400 to the firm's revenue.

The profit-maximising level of employment for a firm

The MPP curve was illustrated in Figure 6.3 (see page 159). As more workers are employed, there will come a point when diminishing returns set in (point *b*). The MPP_L curve thus

Definition

CASE STUDIES AND APPLICATIONS

Immigrants also buy goods and services, so at a macroeconomic level we would expect a general increase in demand. This would have a positive impact on the demand for labour.

In order to see which effect is stronger, a number of studies have analysed UK labour market data.

In March 2014, a government report¹ was published which synthesised the research up until this point. It concluded that there was little evidence of long-term damage to British workers' prospects, with the labour market adjusting in both booms and times of recession, albeit more slowly in the latter.

In 2016, a study by the Centre for Economic Performance² found that UK-born workers in those parts of the country that had the highest levels of EU immigration did not experience bigger falls in wages and employment than the rest of the country. It also found that EU immigration had little impact on the pay and jobs of low-skilled workers.

What is more, according to a University College London study,³ between 2000 and 2012, EU immigrants made a substantial net contribution to UK finances, paying considerably more in taxes than claiming in benefits.

Immigration has remained a controversial issue. Commonly held views of its impact on the labour market often seem at odds with the available evidence. Opposition to high levels of

immigration has also been driven by a number of non-economic reasons.

At the time of writing, the exact nature of the controls that will be imposed on immigrants from the EU is uncertain. For example, will the government impose a work permit system similar to the one that already applies to non-EU immigrants? Will the rules be stricter or more lenient?

If new controls significantly reduce immigration, it will be interesting to see the impact it has on the UK economy. No doubt economists will be analysing the data.

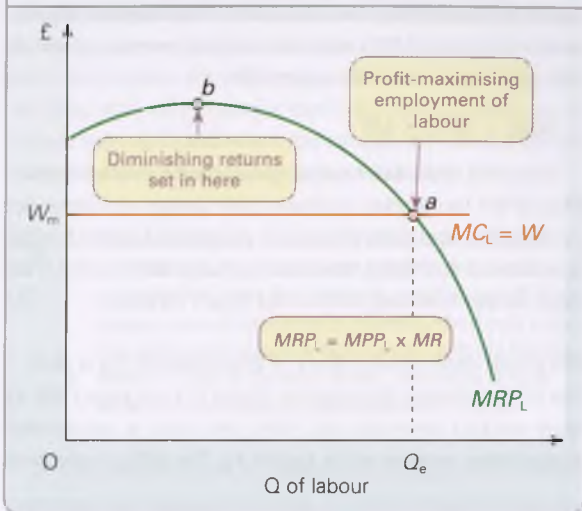

Draw a diagram illustrating the UK's decision to open up labour markets to workers from the Accession countries. Show the situation both before and after. Consider both the position and slope of the labour supply curve and the impact on the number employed and on wages. Would you expect there to be any movement in the demand for labour?

Figure 10.4 The profit-maximising level of employment

slopes down after this point. The MRP_L curve will be a similar shape to the MPP_L curve, since it is merely being multiplied by a constant figure, MR . (Under perfect competition MR equals P and does not vary with output.) The MRP_L curve is illustrated in Figure 10.4, along with the MC_L 'curve'.

? Why is the MC_L curve horizontal?

Profits will be maximised at an employment level of Q_e , where MC_L (i.e. W) = MRP_L . Why? At levels of employment below Q_e , MRP_L exceeds MC_L . The firm will increase profits by employing more labour. At levels of employment above Q_e , MC_L exceeds MRP_L . In this case, the firm will increase profits by reducing employment.

Derivation of the firm's demand curve for labour

No matter what the wage rate, the quantity of labour demanded will be found from the intersection of W and MRP_L (see Figure 10.5). At a wage rate of W_1 , Q_1 labour is demanded; at W_2 , Q_2 is demanded; at W_3 , Q_3 is demanded.

Thus the MRP_L curve will show the quantity of labour employed at each wage rate. But this is just what the demand curve for labour shows. Thus the MRP_L curve is the demand curve for labour.

There are three determinants of the demand for labour:

- The wage rate. This determines the position on the demand curve, i.e. the quantity demanded.
- The productivity of labour (MPP_L). This determines the position of the demand curve.
- The demand for the good being produced. The higher the demand for the good, the higher its price, and hence the higher will be the MR , and the MRP_L . This too determines the position of the demand curve. It shows how the demand for labour (and other factors) is a

* LOOKING AT THE MATHS

The marginal product of labour can be expressed using calculus. It is the rate of increase in output of good X with respect to changes in the quantity of labour:

$$MPP_L = \frac{\partial X}{\partial L}$$

The marginal revenue product of labour is thus given by

$$MRP_L = MR \frac{\partial X}{\partial L}$$

Profits are maximised at the level of employment (L) where $W = MRP_L$; i.e. where

$$W = MR \frac{\partial X}{\partial L} \quad (1)$$

We can easily move from this to the level of profit-maximising output of good X (where $MC = MR$). Rearranging equation (1), we get

$$\frac{W}{\partial X / \partial L} = MR \quad (2)$$

But, assuming that labour is the only variable factor, the marginal cost (of output) is the extra cost of employing labour (the only extra cost) per unit of output. In other words:

$$MC = \frac{W}{\partial X / \partial L} \quad (3)$$

i.e.

$$MC = MR$$

Thus, not surprisingly, the profit-maximising employment of labour (where $W = MRP_L$) will yield the profit-maximising output (where $MC = MR$).

Figure 10.5 Deriving the firm's demand curve for labour

derived demand: i.e. one derived from the demand for the good. For example, the higher the demand for houses, and hence the higher their price, the higher will be the demand for bricklayers.

A change in the wage rate is represented by a movement *along* the demand curve for labour. A change in the productivity of labour or the demand for the good *shifts* the curve.

Derivation of the industry demand curve for labour

This is not simply the sum of the demand curves of the individual firms. The firm's demand curve is based on a constant P and MR , no matter how many workers the firm employs (this is one of the assumptions of perfect competition). In Figure 10.6, when the wage rate falls from W_1 to W_2 the firm will employ more labour by moving from a to b along its demand curve MRP_1 .

The trouble with this analysis is that when the wage rate falls, it will affect *all* employers. They will all want to employ more labour. But when they do, the total industry output will increase, and hence P (and MR) will be pushed down. This will shift the firm's MRP curve to the left and lead to a lower level of employment at point c . Therefore, when we allow for the effect of lower wages on the market price of the good, the firm's demand curve for labour will be the *green* line passing through points a and c .

Thus the *industry* demand curve for labour is the (horizontal) sum of the *green* lines for each firm, and is therefore less elastic than the firm's MRP curve.

? What will determine the elasticity of this curve?

The elasticity of demand for labour

The elasticity of demand for labour (with respect to changes in the wage rate) will be greater:

- The greater the price elasticity of demand for the good. A fall in W leads to higher employment and more output. This will drive P down. If the market demand for the good is elastic, this fall in P will lead to a lot more being sold and hence to a lot more people being employed.
- The easier it is to substitute labour for other factors and vice versa. If labour can be readily substituted for other factors, then a reduction in W will lead to a large increase in labour used to replace these other factors.
- The greater the elasticity of supply of complementary factors. If the wage rate falls, a lot more labour will be demanded if plenty of complementary factors can be obtained at little increase in their price.

Definition

Derived demand Demand for a factor of production that depends on the demand for the good that uses it.

Figure 10.6 Using the firm's demand curves for labour to derive the industry demand curves for labour

- The greater the elasticity of supply of substitute factors. If the wage rate falls and more labour is used, less substitute factors will be demanded and their price will fall. If their supply is elastic, a lot less will be supplied and therefore a lot more labour will be used instead.
- The greater the wage cost as a proportion of total costs. If wages are a large proportion of total costs and the wage rate falls, total costs will fall significantly; therefore production will increase significantly, and so too will the demand for labour.
- The longer the time period. Given sufficient time, firms can respond to a fall in wage rates by reorganising their production processes to make use of the now relatively cheap labour.

? For each of the following jobs, check through the above list of determinants (excluding the last), and try to decide whether demand would be relatively elastic or inelastic: firefighters; telesales operators; app developers; bus drivers; accountants; farm workers; car workers.

Wages and profits under perfect competition

The wage rate (W) is determined by the interaction of demand and supply in the labour market. It will be equal to the value of the output that the last person produces (MRP_L).

Profits to the individual firm arise from the fact that the MRP_L curve slopes downwards (diminishing returns). Thus the last worker adds less to the revenue of firms than was added previously by workers already employed.

If *all* workers in the firm receive a wage equal to the MRP of the *last* worker, everyone but the last worker will receive a wage less than their MRP . This excess of MRP_L over W of previous workers provides a surplus to the firm over its wages

bill (see Figure 10.7). Part of this will be required for paying non-wage costs; part will be profits for the firm.

Perfect competition between firms ensures that profits are kept down to *normal* profits. If the surplus over wages is such that *supernormal* profits are made, new firms will enter the industry. The price of the good (and hence MRP_L) will fall, and the wage rate will be bid up, until only normal profits remain.

Equality and inequality under perfect competition

The mythical world of perfect wage equality

Under certain very strict assumptions, a perfectly competitive market will lead to perfect equality of wage rates. All workers will earn exactly the same. These strict assumptions are as follows:

- All workers have identical abilities.
- There is perfect mobility of labour.
- All jobs are equally attractive to all workers.
- All workers and employers have perfect knowledge.
- Wages are determined entirely by demand and supply.

Given these assumptions, if consumer demand rose in any industry, the demand for labour would rise. As a result, wage rates would begin to rise. Immediately workers would flood into this industry, attracted by the higher wages. Very quickly, then, wage rates would be competed back down to the level in the rest of the economy. Likewise if wage rates began to fall in any industry, workers would leave, thereby eliminating any labour surplus and preventing the fall in wage rates.

Under these conditions, therefore, not only would the labour supply curve to a *firm* be infinitely elastic, but so too would the labour supply curve to each *industry* at the universal wage rate.

Of course, in the real world these conditions do not hold and we do not see perfectly competitive labour markets.

Huge inequalities of wages exist. But even if markets *were* perfect, inequality would be expected to persist.

Causes of inequality under perfect competition

In the short run, inequality will exist under perfect competition because it takes time for changes in demand and supply conditions to bring new long-run equilibria. Thus expanding industries will tend to pay higher wage rates than contracting industries.

But even after enough time has elapsed for all adjustments to be made to changes in demand and supply, long-run wage differentials will still exist for the following reasons:

- Workers do not have identical abilities.
- Workers are not perfectly mobile, even in the long run. People have different preferences about where they want to live and the jobs they like to do. They may not have access to training or may be unable to afford to retrain. Workers may not have the innate talent to do particular jobs, even if they did retrain.
- Jobs differ enormously in terms of the skills they require and in terms of their pleasantness or unpleasantness.

What is more, since demand and supply conditions are constantly changing, long-run general equilibrium throughout the economy will never be reached.

Who are the poor? Who are the rich?

The lowest paid will be those whose labour is in low demand or high supply. Low demand will be due to low demand for the good or low labour productivity. High supply will be due to low mobility out of industries in decline or to a surplus of people with the same skills or qualifications. Thus, for example, workers who possess few skills, are working in contracting industries, do not want to move from the area and will not or cannot retrain will be low paid.

The highly paid will be those whose labour is in high demand or low supply. Thus workers who possess skills or talents that are in short supply, especially if those skills take a long time for others to acquire, and those who are working in expanding industries, will tend to earn high wages.

Although the movement of labour from low-paid to high-paid jobs will tend to reduce wage differentials, considerable inequality will persist even under perfect competition. It is, therefore, not possible to eliminate poverty and inequality by 'freeing up' markets and encouraging workers to 'stand on their own feet' or 'get on their bikes'.

Furthermore, in the real world there exist many market imperfections, which tend to make inequality greater. These imperfections are examined in the next section.

Finally, income inequality under capitalism will also arise from the unequal distribution of the ownership of land and capital. Even under perfect competition, considerable inequality will therefore exist if wealth is concentrated in the hands of the few.

Figure 10.7 Wages and profits

Section summary

1. Wages in a perfect market are determined by supply and demand.
2. The supply curve of hours by an individual worker reflects the increasing marginal disutility of work. Its shape depends on the relative sizes of the substitution and income effects of a wage change. The substitution effect is positive: higher wages encourage people to work more by substituting wages for leisure. The income effect, however, is negative: higher wages make people feel that they can afford to enjoy more leisure. If the income effect is bigger than the substitution effect, the supply curve for labour hours will bend backwards.
3. The supply of labour to a particular employer under perfect competition is infinitely elastic.
4. The market supply is typically upward sloping. Its elasticity depends on labour mobility.
5. The demand for labour depends on a worker's marginal revenue product. This is the extra revenue that a firm will gain from the output of an extra worker. The profit-maximising firm will continue taking on extra workers until MRP_L is equal to $MC_L (= W$ under perfect competition).
6. The elasticity of demand for labour depends on the elasticity of demand for the good being produced, the ease of substituting labour for other factors and vice versa, the elasticity of supply of substitute and complementary factors, wages as a proportion of total costs, and the time period involved.
7. Although market forces will tend to lead to the elimination of differentials as workers move from low-paid to high-paid jobs, nevertheless inequality can persist even under perfect competition. People have different abilities and skills; people are not perfectly mobile; and jobs differ in their labour requirements.
8. Inequality is also caused by market imperfections and by unequal ownership of land and capital.

10.2 WAGE DETERMINATION IN IMPERFECT MARKETS

In the real world, firms and/or workers are likely to have the power to influence wage rates: they are not wage takers. This is one of the major types of labour market imperfection.

When a firm is the only employer of a certain type of labour, this situation is called a **monopsony**. A monopsony may arise in a market for particular types of labour; Royal Mail is a monopsony employer of postal workers. Alternatively, and more commonly, it may arise in a local market. Thus a factory may be the only employer of certain types of labour in that district. When there are just a few employers, this is called **oligopsony**. Oligopsony is much more common than monopsony, just as in goods markets oligopoly is much more common than monopoly.

In monopsonistic or oligopsonistic labour markets the employers have market power. Workers too may have market power as members of unions. When a single union bargains on behalf of a certain type of labour, it is acting as a monopolist. When there is more than one union, they are oligopolists.

When a monopsonist employer faces a monopolist union, the situation is called **bilateral monopoly**.

Definitions

Monopsony A market with a single buyer or employer.

Oligopsony A market with just a few buyers or employers.

Bilateral monopoly Where a monopsony buyer faces a monopoly seller.

Firms with market power in employing labour (monopsony, etc.)

Monopsonists (and oligopsonists too) are 'wage setters', not 'wage takers'. A large employer in a small town, for example, may have considerable power to resist wage increases or even to force wage rates down. The National Health Service has considerable power in setting wages for health workers in the UK.

Such firms face an upward-sloping supply curve of labour. This is illustrated in Figure 10.8. If the firm wants to take on more labour, it will have to pay a higher wage rate

Figure 10.8 Monopsony

to attract workers away from other industries. But conversely, when employing less labour it will be able to pay a lower wage rate.

The supply curve shows the wage rate that must be paid to attract a given quantity of labour. The wage it pays is the *average cost* to the firm of employing labour (AC_L). The supply curve is also therefore the AC_L curve.

The *marginal cost* of employing one more worker (MC_L) will be above the wage (AC_L). The reason is that the wage rate has to be raised to attract extra workers. The MC_L will thus be the new higher wage paid to the new employee *plus* the small rise in the total wages bill for existing employees: after all, they will have to be paid the higher wage too.

The profit-maximising employment of labour would be at Q_1 , where $MC_L = MRP_L$. The wage paid would thus be W_1 .

If this had been a perfectly competitive labour market, equilibrium employment would have been at the higher level Q_2 , with the wage rate at the higher level W_2 , where $W = MRP_L$. The monopolist is therefore forcing the wage rate down by restricting the number of workers employed.

1. The following table shows data for a monopolist employer. Fill in the missing figures. How many workers should the firm employ if it wishes to maximise profits?

Number of workers	Wage rate (£)	Total cost of labour (£)	Marginal cost of labour (£)	Marginal revenue product (£)
1	100	100		
2	105	210	110	230
3	110	330	120	240
4	115	240
5	120	230
6	125	210
7	130	190
8	135	170
9	140	150

2. Will a monopsony typically also be a monopoly? Give examples of monopsonists that are not monopolists, and monopolists that are not monopsonists.

Labour with market power (union monopoly or oligopoly)

The extent to which unions will succeed in pushing up wage rates depends on their power and willingness to take action. It also depends on the power of firms to resist and on their ability to pay higher wages. In particular, the scope for unions to gain a better deal for their members depends on the sort of market in which the employers are producing.

If the employers are producing under perfect or monopolistic competition, wage rates will only rise at the expense of employment. Firms are earning only normal profit. Thus if unions force up wage rates, the marginal firms will make losses and eventually leave the industry. Fewer workers will be employed. The fall in output will lead to higher prices. This will enable the remaining firms to pay a higher wage rate.

Figure 10.9 illustrates these effects. If unions succeed in raising the wage from W_1 to W_2 , employment will fall from Q_1 to Q_2 . There will be a surplus of people ($Q_3 - Q_2$) wishing to work in this industry for whom no jobs are available.

The union faces a second effect. Not only will jobs be lost as a result of the higher wage rate, but there is also a danger that those who are unemployed as a result might undercut the union wage.

In a competitive goods market, wage rates can only be increased without a reduction in the level of employment if, as part of the bargain, the productivity of labour is increased. This is called a *productivity deal*. The MRP curve,

Definition

Productivity deal Where a union agrees to changes in working practices that will increase output per worker. This may be in return for a rise in the wage rate.

BOX 10.4 LIFE AT THE MILL

CASE STUDIES AND APPLICATIONS

Monopsony in Victorian times

A dramatic illustration of the effects of extreme monopsony power is that of the textile mill in nineteenth-century England. When a mill was the only employer in a small town, or when factory owners colluded as oligopsonists, things could be very bad for the worker. Very low pay would be combined with often appalling working conditions.

Friedrich Engels described the life of the textile factory worker as follows:

The factory worker is condemned to allow his physical and mental powers to become atrophied. From the age of eight he enters an occupation which bores him all day long. And there is no respite from this boredom. The machine works ceaselessly. Its wheels, belts and spindles hum and rattle

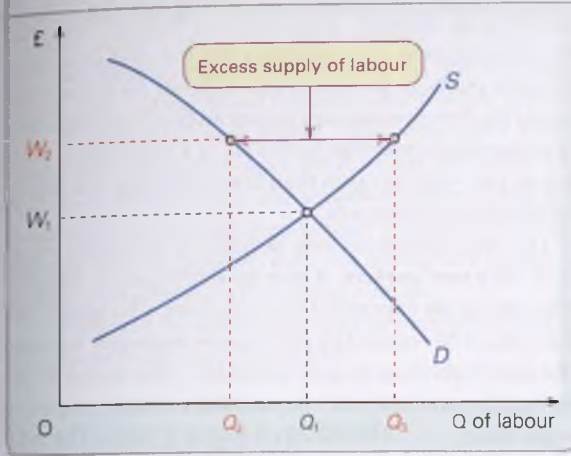

ceaselessly in his ears, and if he thinks of taking even a moment's rest, the overlooker is always there to punish him with a fine. It is nothing less than torture of the severest kind to which the workers are subjected by being condemned to a life-sentence in the factory, in the service of a machine which never stops.¹

1. Why did competition between employers not force up wages and improve working conditions?
2. Were the workers making a 'rational economic decision' when they chose to work in such factories?

1 F. Engels, *The Condition of the Working Class in England*, translated by W. O. Henderson and W. H. Chaloner (Basil Blackwell, 1971), pp. 199–200.

Figure 10.9 Monopoly union facing producers under perfect competition

and hence the demand curve in Figure 10.9, shifts to the right.

Which of the following unions find themselves in a weak bargaining position for the above reasons?

- The shopworkers' union (USDAW).
- The tube and train drivers' union (ASLEF).
- The farm workers' union (part of Unite).

In a competitive market, then, the union is faced with the choice between wages and jobs. Its actions will thus depend on its objectives.

If it wants to *maximise employment*, it will have to content itself with a wage of W_1 in Figure 10.9, unless productivity deals can be negotiated. At W_1 , Q_1 workers will be employed. Above W_1 fewer than Q_1 workers will be *demand*ed. Below W_1 fewer than Q_1 workers will be *supply*ed.

If the union is more concerned with securing a higher wage rate, it may be prepared to push for a wage rate above W_1 and accept some reduction in employment. This is more likely if the reduction can be achieved through *natural wastage*. This is where people retire, or take voluntary redundancy, or simply leave for another job.

Firms and labour with market power (bilateral monopoly)

It is common to find the strongest unions where there is a monopsonistic labour market. In these circumstances we can think of the union monopoly as a counterweight to the

Definition

Natural wastage Where a firm wishing to reduce its workforce does so by not replacing those who leave or retire.

power of a monopsony employer. What will the wage rate be under these circumstances? What will the level of employment be? Unfortunately, economic theory cannot give a precise answer. There is no 'equilibrium' level as such. Ultimately, the wage rate and the level of employment will depend on the relative bargaining strengths and skills of unions and management.

Strange as it may seem, unions may be in a stronger position to make substantial gains for their members when they are facing a powerful employer. There is often considerable scope for them to increase wage rates *without* this leading to a reduction in employment, or even for them to increase both the wage rate *and* employment. Figure 10.10 shows how this can be so.

Assume first that there is no union. The monopsonist will maximise profits by employing Q_1 workers at a wage rate of W_1 . (Q_1 is where $MRP_L = MC_L$.)

What happens when a union is introduced into this situation? Wage rates will now result from negotiation between unions and management. Once a wage rate has been agreed, the employer can no longer drive the wage rate down by employing fewer workers. If it tries to pay less than the agreed wage, it may well be faced by a strike, and thus have a zero supply of labour.

Similarly, if the employer decides to take on *more* workers, it will not have to *increase* the wage rate, as long as the negotiated wage is above the free-market wage: as long as the wage rate is above that given by the supply curve S_1 .

The effect of this is to give a new supply curve that is horizontal up to the point where it meets the original supply curve. Assume that the union succeeds in negotiating a wage rate of W_2 in Figure 10.10. The supply curve will be horizontal at this level to the left of point x . To the right of this point it will follow the original supply curve S_1 , since to acquire

Figure 10.10 Bilateral monopoly

more than Q_3 workers the employer would have to raise the wage rate above W_2 .

If the supply curve is horizontal to the left of point x at a level of W_2 , so too will be the MC_L curve. The reason is simply that the extra cost to the employer of taking on an extra worker (up to Q_3) is merely the wage rate: no rise has to be given to existing employees. If MC_L is equal to the wage, the profit-maximising level of employment ($MC_L = MRP_L$) will now be where $W = MRP_L$. At a negotiated wage rate of W_2 , the firm will therefore choose to employ Q_1 workers.

What this means is that the union can push the wage rate right up from W_1 to W_2 and the firm will still *want* to employ Q_1 . In other words, a wage rise can be obtained *without* a reduction in employment.

If the negotiated wage rate were somewhere between W_1 and W_2 , what would happen to employment?

The union could go further still. By threatening industrial action, it may be able to push the wage rate above W_2 and still insist that Q_1 workers are employed (i.e. no redundancies). The firm may be prepared to see profits drop right down to normal level rather than face a strike and risk losses. The absolute upper limit to wages will be that at which the firm is forced to close down.

Collective bargaining

Sometimes when unions and management negotiate, *both* sides can gain from the resulting agreement. For example, the introduction of new technology may allow higher wages, improved working conditions and higher profits. Usually, however, one side's gain is the other's loss. Higher wages mean lower profits.

In collective bargaining, there are various threats or promises that either side can make. Union *threats* might include strike action, *picketing*, *working to rule* or refusing to cooperate with management: for example, in the introduction of new technology. Alternatively, in return for higher wages or better working conditions, unions might *offer* no-strike agreements, increased productivity or long-term deals over pay.

In turn, employers might *threaten* employees with redundancies or reduced benefits. Alternatively, they might *offer*, in return for lower wage increases, better rewards such as

productivity bonuses, profit-sharing schemes, more holiday or greater job security.

The outcome of negotiations. The success of a union in achieving its demands depends on its financial strength, the determination of its members and the level of support from the public in general. It also depends on the willingness of the firm to make concessions and on its profitability. Firms earning substantial profits are in a much better position to pay wage increases than firms operating in a highly competitive environment.

The wage settlement may be higher if the union represents only *core workers*. It may be able to secure a higher wage rate at the expense of non-members, who might lose their jobs or be replaced by part-time or temporary workers. The core workers can be seen as *insiders*. Their union(s) can prevent the unemployed – the *outsiders* – from competing wages down.

Industrial action imposes costs on both unions and firms. Union members lose pay. Firms lose revenue. It is usually in both sides' interests, therefore, to settle by negotiation. Nevertheless, to gain the maximum advantage, each side must persuade the other that it will carry out its threats if pushed.

The approach described so far has essentially been one of confrontation. The alternative is for both sides to concentrate on increasing the total net income of the firm by cooperating on ways to increase efficiency or the quality of the product. This approach is more likely when unions and management have built up an atmosphere of trust over time.

Recall the various strategies that rival oligopolists can adopt. What parallels are there in union and management strategies?

The role of government in collective bargaining

The government can influence the outcome of collective bargaining in a number of ways. One is to try to set an example. It may take a tough line in resisting wage demands by public-sector workers, hoping thereby to persuade employers in the private sector to do likewise.

Additionally, it could set up mechanisms to assist in arbitration or conciliation. For example, in the UK, the Advisory, Conciliation and Arbitration Service (ACAS) is largely funded by the Department of Business, Innovation and Skills (BIS) and conciliates in over 1000 disputes each year.

Definitions

Picketing Where people on strike gather at the entrance to the firm and attempt to dissuade workers or delivery vehicles from entering.

Working to rule Workers do the bare minimum they have to, as set out in their job descriptions.

Core workers Workers, normally with specific skills, who are employed on a permanent or long-term basis.

Insiders Those in employment who can use their privileged position (either as members of unions or because of specific skills) to secure pay rises.

Outsiders Those out of work or employed on a casual, part-time or short-term basis, who have little or no power to influence wages or employment.

Another approach is to use legislation. The government could pass laws that restrict the behaviour of employers or unions; that set a minimum wage rate (see Box 11.2); that prevent discrimination against workers on various grounds. The UK Conservative governments between 1979 and 1997 put considerable emphasis on reducing the power of trade unions and making labour markets more 'flexible'. Several Acts of Parliament were passed. These effectively ended *closed-shop* agreements, made secret ballots mandatory and outlawed political strikes and *secondary action*. It was also made unlawful for employers to deny employment on the grounds that an applicant does not belong to a union, or indeed to penalise them for joining a union.

The effect of these measures was considerably to weaken the power of trade unions in the UK.

The efficiency wage hypothesis

We have seen that a union may be able to force an employer to pay a wage above the market-clearing rate. But it may well be in firms' interests to pay higher wage rates, even in non-unionised sectors.

One explanation for this is the *efficiency wage hypothesis*. This states that the productivity of workers rises as the wage rate rises. As a result, employers may be willing to offer wage rates above the market-clearing level, attempting to balance increased wage costs against gains in productivity. But why might higher wage rates lead to higher productivity? There are three main explanations.

Less 'shirking'

In many jobs it is difficult to monitor the effort individuals put into their work. Workers may thus get away with shirking or careless behaviour. This is an example of the principal-agent problem (see section 9.4 and Box 10.9). The worker, as an agent of the employer (the principal), is not necessarily going to act in the principal's interest.

The business could attempt to reduce shirking by imposing a series of sanctions, the most serious of which would be dismissal. The higher the wage rate, the greater will be the cost to the individual of dismissal, and the less likely it is, therefore, that workers will shirk. The business will benefit not only from the additional output but also from a reduction in the costs of having to monitor workers' performance. As a consequence the *efficiency wage rate* for the business will lie above the market-determined wage rate.

Reduced labour turnover

If workers receive on-the-job training or retraining, then to lose a worker once the training has been completed is a significant cost to the business. Labour turnover, and hence its associated costs, can be reduced by paying a wage above the market-clearing rate. By paying such a wage rate the business is seeking a degree of loyalty from its employees.

Morale

A simple reason for offering wage rates above the market-clearing level is to motivate the workforce – to create the feeling that the firm is a 'good' employer that cares about its employees. As a consequence, workers might be more industrious and more willing to accept the introduction of new technology (with the reorganisation and retraining that it involves).

The paying of efficiency wages above the market-clearing wage will depend upon the type of work involved. Workers who occupy skilled positions, especially where the business has invested time in their training (thus making them costly to replace) are likely to receive efficiency wages considerably above the market wage. By contrast, workers in unskilled positions, where shirking can be easily monitored, where little training takes place and where workers can be easily replaced, are unlikely to command an 'efficiency wage premium'. In such situations, rather than keeping wage rates high, the business will probably try to pay as little as possible.

Other labour market imperfections

The possession of power by unions and/or firms is not the only way in which real-world labour markets diverge from the perfectly competitive model.

- Workers or employers may have imperfect information.
- Wages may respond very slowly to changes in demand and supply, causing disequilibrium in labour markets to persist.
- Firms may not be profit maximisers. Likewise workers may not seek to maximise their 'worker surplus' – the excess of benefits from working (i.e. wages) over the disutility of working (displeasure in doing the job and lost leisure).

Some of the forms and effects of these three imperfections are examined in Case Study 10.3. on the student website.

Definitions

Closed shop Where a firm agrees to employ only union members.

Secondary action Industrial action taken against a company not directly involved in a dispute (e.g. a supplier of raw materials to a firm whose employees are on strike).

Efficiency wage hypothesis The hypothesis that the productivity of workers is affected by the wage rate that they receive.

Efficiency wage rate The profit-maximising wage rate for the firm after taking into account the effects of wage rates on worker motivation, turnover and recruitment.

BOX 10.5

THE RISE AND DECLINE OF THE LABOUR MOVEMENT IN THE UK

Modern trade unionism had its birth with the industrial revolution of the eighteenth and nineteenth centuries. Unions were seen as a means of improving the lot of industrial workers, most of whom suffered low pay and poor working conditions. But, with great hostility from employers, membership grew slowly. By the end of the nineteenth century, only just over 10 per cent of manual workers were in an effective union.

The big change came after the First World War, when returning troops demanded that the sacrifices made should be rewarded. Membership of trade unions increased sharply as workers sought to improve wages and working conditions. By 1920, 45 per cent of the total labour force (8.3 million workers) were in trade unions.

But it was after the Second World War that the trade union movement in the UK really became established as a substantial economic and political force. This can be explained by three crucial trends:

- The growth in the public sector meant that government was itself becoming increasingly responsible for determining wages and conditions of service for many workers.
- In their attempt to control inflation in the 1960s and 1970s, governments sought to impose an 'incomes policy' constraining wage increases. To be successful, this required acceptance by the trade union movement.
- The philosophy of many post-war governments was to govern by consent. Social contracts and discussions between government, employers and unions gave the union movement considerable influence over economic decision making.

Union power grew steadily during the 1950s and 1960s, so much so that attempts were made by successive governments

to curb its influence. However, such moves attracted fierce and widespread opposition, and legislation was in many cases abandoned. The trade union movement had become very powerful by the late 1970s with over 13 million members. The number of working days lost because of labour disputes peaked at 29 974 in 1979.

The election of the Conservative government in 1979 ushered in a new wave of trade union reform, eroding and removing many rights and privileges acquired by unions over the years.

Trade union membership stood at just below 6.5 million in 2015, around half of that seen in the late 1970s. This can be explained by a number of factors: the shift to a service-based economy; continued privatisation and the introduction of private-sector management practices, such as local pay bargaining; and contracted-out services in many of the remaining parts of the public sector. More women working and more part-time and casual work, with many people having no guaranteed hours (so-called 'zero-hour contracts'), are also contributory factors, as are the attitudes of many firms to union recognition. In many cases an aggressive management style and a highly competitive environment have made it virtually impossible for unions to gain bargaining rights in the private sector.

Union membership remains high in parts of the public sector, such as education where over 50 per cent of employees were union members in 2015. But even in these areas there is little doubt that their power has declined.

In the light of these changes, many unions have adopted a 'new realism', accepting single-union agreements and supporting flexible working practices and individualised pay packets based on performance (see Box 10.8).

However, not all the unions have lost their power. The British Medical Association is an example of a union

BOX 10.6

HOW USEFUL IS MARGINAL PRODUCTIVITY THEORY?

Reality or the fantasy world of economists?

The marginal productivity theory of income distribution has come in for a lot of criticism. Is this justified?

To start with, marginal productivity theory has been criticised for assuming perfect competition. It doesn't! Rather, it merely states that to maximise profits an employer will employ workers up to the point where the worker's marginal cost equals the extra revenue added by that worker: $MC_L = MRP_L$. This applies equally under perfect competition, monopsony and oligopsony.

What it does say is that, if there is perfect competition, then the worker's wage will equal MRP_L . It certainly does not say that $W = MRP_L$ in other market structures.

A second criticism is that employers do not behave in this 'marginal way', weighing up each additional worker's costs and revenues for the firm. There are three possible reasons for this.

Ignorance of the theory of profit maximisation. The employer may use some rule of thumb, but nevertheless is attempting to maximise profits.

This is a criticism of the theory only if the theory is supposed to describe how employers actually behave. It does not. It merely states that, if firms are attempting to maximise profits, they will in fact be equating MC_L and MRP_L , whether they realise it or not!

A worker's marginal productivity cannot be calculated.

When workers are part of a team, it is not usually possible to separate out the contribution to output of each individual. What is the marginal productivity of a cleaner, a porter or even a member of a production line? Similarly, it may not be possible to separate the contribution of workers from that of their tools. A lathe operator is useless without a lathe, as is a lathe without a lathe operator.

This is a more fundamental criticism. Nevertheless it is possible to amend the theory to take this into account. First, an employer can look at the composition of the team, or the partnership of worker and tools, and decide whether any

(although it doesn't choose to use that title) which has protected the pay and power of doctors against a very large employer. For example, it organised and co-ordinated the junior doctor strikes in 2016 in the long-running dispute with the government over contracts.

The RMT Union, which represents workers on London Underground, has been very successful in protecting its members' jobs and securing pay rises. Working closely with two other unions, ASLEF and TSSA, it has achieved above-inflation pay deals, improved working conditions and shorter hours for tube staff. ASLEF and the RMT have also been involved in the

long-running dispute with Southern (Govia Thameslink Railway Ltd) over who was responsible for closing train doors. Critics point out that this has been at the expense of inconvenience to other workers, with regular strikes taking place. However, others would cite it as an example of the benefits of a strong union, protecting its members from monopsony power.

What factors, other than the ones identified above, could account for the decline in union membership in recent years?

Trade union membership in Great Britain as a percentage of employees

Source: Based on *Trade Union Statistics 2016*, Table 1.2b (BIS and ONS).

reorganisations or alternative production methods will increase the firm's profitability (i.e. increase revenue more than costs). Second, the employer can decide whether to expand or contract the overall size of the team, or the number of workers plus machines. Here the whole team or the worker plus machine is the 'factor of production' whose marginal productivity must be weighed against its costs.

Firms are not always profit maximisers. This is a criticism only if the theory states that firms are. As long as the theory is merely used to describe what would happen if firms maximised profits, there is no problem.

This criticism, then, is really one of how the theory is used. And even if it is used to predict what will actually happen in the real world, it is still relatively accurate in the large number of cases where firms' behaviour diverges only slightly from profit maximising. It is clearly wrong in other cases.

Moral issues. A final criticism is the moral one. If economists focus their attention exclusively on how to maximise profits, it might be concluded that they are putting their seal of approval on this sort of behaviour. Of course, economists will respond by saying that they are doing no such thing: they are confining themselves to positive economics. Nevertheless, the criticism has some force. What an economist chooses to study is in part a normative decision.

Do any of the following contradict marginal productivity theory: (a) wage scales related to length of service (incremental scales); (b) nationally negotiated wage rates; (c) discrimination; (d) firms taking the lead from other firms in determining this year's pay increase?

BOX 10.7 THE PERSISTENT GENDER PAY GAP?

(a) Average hourly pay, excluding overtime, for full-time UK employees, aged 18 and over, 1970–2016 (£ per hour)

	1970	1974	1978	1982	1986	1990	1994	1998	2002	2004	2008	2012	2016

All occupations	17.38	14.96	86.1
Average gross weekly pay (incl. overtime)	691.10	562.10	81.3
Average weekly paid hours (incl. overtime)	40.2	37.6	
Average weekly overtime	1.4	0.5	

Source: Table 14.6a: Annual Survey of Hours and Earnings (National Statistics, 2016).

The data in the tables above clearly indicate that there is a gender pay gap – women earn less than men for the same category of work. How much less depends on how earnings are measured. Based on earnings per hour for full-time employees, women on average earned just under 14 per cent less than men in 2016. This wage gap has narrowed gradually over the years, falling from 37 per cent in 1970 to its current levels (see table (a) above). Based on earnings per hour for part-time employees, women on average earned just under 16 per cent less than men in 2016.

A similar picture can be seen throughout the EU.¹ In 2015, women's average hourly pay was 83.7 per cent of men's for the economy as a whole. The gender pay gap varies from one country to another. In Italy and Luxembourg it was only 5.5 per cent, whereas in Estonia it was 26.9 per cent. For full-time workers it varied from –0.4 per cent in Italy to 20.1 per cent in Latvia.

It is important not to confuse the gender pay gap with unequal pay. Unequal pay refers to situations where men and

women receive different rates of pay even though they are doing exactly the same job. This is illegal under the 2010 Equality Act. It probably still exists in some workplaces but it is very difficult to tell how significant it is in the economy as a whole.

Unequal pay provides one possible explanation for the gender pay gap but there are also a number of other reasons. For example, the existence of occupational segregation will be a contributing factor. Women are far more likely to be employed in poorly paid occupations. However, there must be other explanations as quite substantial pay gaps persist within particular occupations – see table (b).

1. If we were to look at weekly rather than hourly pay and included the effects of overtime, what do you think would happen to the pay differentials in table (a)?
2. In table (b), which of the occupations have a largely female workforce?

Discrimination

Discrimination can be another major factor in determining wages. It can take many forms: it can be by race, gender, sexual orientation, age, class, religion, etc.; it can occur

in many different aspects of society. This section is concerned with *economic discrimination*, where workers of identical ability receive different pay for doing the same job, or are given different chances of employment or promotion.

So why has the pay gap persisted? There are a number of possible reasons:

- The marginal productivity of labour in typically female occupations may be lower than in typically male occupations. This may in part be due to simple questions of physical strength. Very often, however, it is due to the fact that women tend to work in more labour-intensive occupations. If there is less capital equipment per female worker than there is per male worker, then it would be expected that the marginal product of a woman would be less than that of a man. Evidence from the EU as a whole suggests that occupational segregation is a significant factor in explaining pay differences.
- Many women take career breaks to have children. For this reason, employers are sometimes more willing to invest money in training men (thereby increasing their marginal productivity) and more willing to promote men. A study by the Institute for Fiscal Studies (IFS)² estimated that for every year a woman takes away from work her earnings fall by 2 per cent below those who remain in work.
- Women tend to be less geographically mobile. If social norms are such that the man's job is seen as somehow more 'important' than the woman's, then a couple will often move for the man to get promotion. The woman, however, will have to settle for whatever job she can get in the same locality as her partner.
- A smaller proportion of women workers are members of unions than men. Even when they are members of unions, these are often in jobs where unions are weak (e.g. clothing industry workers and shop assistants).
- Part-time workers (mainly women) have less bargaining power, less influence and less chance of obtaining promotion. The IFS study found that when women switch from full-time to part-time work their hourly wage does not fall immediately. However, over time their growth in earnings falls behind those of people working full-time.
- Custom and practice. Many jobs done wholly or mainly by women continue to be low-paid, irrespective of productivity.

Why has the gender pay gap narrowed in the past 20 years? The IFS research suggests that the main reason is the increasing proportion of women who are now educated to 'A' level and degree standard. However, the same study also found that the gender wage gap for the highly educated has not really changed over the same period. The difference in pay between male and female graduates is approximately the same as it was in the late 1990s.

One reason for this is the possibility that in many jobs women are discriminated against when it comes to promotion, especially to senior positions. This is sometimes referred to as *people*

appointing in their own image: i.e. men favouring male applicants.

The government established the Davies review in 2010³ to examine the under-representation of women on the boards of FTSE 100 and 350 companies. In 2011, only 12.5 per cent of FTSE 100 board members were female. The first Davies report recommended a number of initiatives for businesses to improve this situation and set a target of 25 per cent by 2015. This figure was met (26.1 per cent in 2015) and Lord Davies set a new target of 33 per cent by 2020.

The government has also introduced a number of other initiatives to try to close the gender pay gap including:

- Shared parental leave. This was introduced in April 2015 and enables parents to share up to 50 weeks of leave, of which 37 is paid. At present, the take-up of the scheme has been low – approximately 5 per cent.
- Requirement on larger firms to publish pay data. Companies employing more than 250 people will have to publish information about their employee pay as it was on 5 April 2017. The information must include the mean gender gap for basic pay as well as bonuses. It also has to include the proportion of men and women in each quarter of the pay structure. Firms have until April 2018 to produce the data or they will be contacted by the Equalities and Human Rights Commission.
- Women in Finance Charter. This is a pledge for greater balance in the financial services. In March 2017, HM Treasury announced that 122 firms had signed the Women in Finance Charter.

It will be interesting to see what impact these policies have on the gender pay gap in the future.

3. *If employers were forced to give genuinely equal pay for equal work, how would this affect the employment of women and men? What would determine the magnitude of these effects?*
4. *How could family policy ensure that parents are able to work, while reducing pay differentials?*
5. *What measures could a government introduce to increase the number of women getting higher-paid jobs?*

1 *Gender Pay Gap Statistics* (Eurostat, March 2017).

2 *The Gender Wage Gap* (Institute for Fiscal Studies, August 2016).

3 *Improving the Gender Balance on British Boards, Davies Review Five Year Summary* (October 2015).

Take the case of racial discrimination by employers. Figure 10.11 illustrates the wages and employment of black and white workers by a firm with monopsony power which practises racial discrimination against black workers. Let us assume that there is no difference in the productivity of black

and white workers. Let us also assume for simplicity that there is an equal number of black workers and white workers available at any given wage rate. Finally, let us assume that there are no laws to prevent the firm discriminating in terms of either wages or employment.

BOX 10.8 FLEXIBLE LABOUR MARKETS AND THE FLEXIBLE FIRM

New work practices for old?

The past 35 years have seen sweeping changes in the ways that firms organise their workforces. Global recessions combined with rapid changes in technology led many firms to question the wisdom of appointing workers on a permanent basis to specific jobs. Instead, they want the flexibility to respond to changing situations. If demand falls, they want to be able to reduce labour without facing large redundancy costs. If demand rises, they want rapid access to additional labour. If technology changes they want to have the flexibility to move workers around, or to take on new workers in some areas and lose workers in others.

What many firms seek, therefore, is flexibility in employing and allocating labour. What countries are experiencing is an increasingly flexible labour market, as workers and employment agencies respond to the new 'flexible firm'.

There are three main types of flexibility in the use of labour:

- **Functional flexibility.** This is where an employer is able to transfer labour between different tasks within the production process. It contrasts with traditional forms of organisation where people were employed to do a specific job, and then stuck to it. A functionally flexible labour force will tend to be multi-skilled and relatively highly trained.
- **Numerical flexibility.** This is where the firm is able to adjust the size and composition of its workforce according to changing market conditions. To achieve this, the firm is likely to employ a proportion of its labour on a part-time or casual basis, or even subcontract specialist requirements. An increasingly common practice is for workers to be on 'zero-hour contracts', where the employee has no guaranteed hours at all and where actual hours may vary on a weekly basis.
- **Financial flexibility.** This is where the firm has flexibility in its wage costs. In large part it is a result of functional and numerical flexibility. Financial flexibility can be achieved by rewarding individual effort and productivity rather than paying a given rate for a particular job. Such rates of pay are increasingly negotiated at the local level rather than being nationally set. The result is not only a

widening of pay differentials between skilled and unskilled workers, but also growing differentials in pay between workers within the same industry but in different parts of the country.

The diagram shows how these three forms of flexibility are reflected in the organisation of a **flexible firm**, an organisation quite different from that of the traditional firm. The most significant difference is that the labour force is segmented. The core group, drawn from the **primary labour market**, will be composed of functionally flexible workers, who are generally on secure full-time permanent contracts. Such workers will be relatively well paid and receive wages reflecting their scarce skills.

The periphery, drawn from the **secondary labour market**, is more fragmented than the core, and can be subdivided into a first and a second peripheral group. The first peripheral group is composed of workers with a lower level of skill than

The flexible firm

Definitions

Functional flexibility Where employers can switch workers from job to job as requirements change.

Numerical flexibility Where employers can change the size of their workforce as their labour requirements change.

Financial flexibility Where employers can vary their wage costs by changing the composition of their workforce or the terms on which workers are employed.

Flexible firm A firm that has the flexibility to respond to changing market conditions by changing the composition of its workforce.

Primary labour market The market for permanent full-time core workers.

Secondary labour market The market for peripheral workers, usually employed on a temporary or part-time basis, or a less secure 'permanent' basis.

those in the core, skills that tend to be general rather than firm-specific. Thus workers in this group can be drawn from the external labour market, often through agencies. Such workers may be employed on full-time contracts, but they will generally face less secure employment than those workers in the core.

The business gains a greater level of numerical flexibility by drawing labour from the second peripheral group. Here workers are employed on a variety of short-term, part-time contracts, often again through agencies. Some of these workers may be working from home, or online from another country, such as India, where wage rates are much lower. Workers in this group have little job security.

As well as supplementing labour in the first peripheral group, the second periphery can also provide high-level specialist skills. In this instance the business can subcontract or hire self-employed labour, minimising its commitment to such workers. The business thereby gains both functional and numerical flexibility simultaneously.

The Japanese model

The application of new flexible working patterns is becoming more prevalent in businesses in the UK and elsewhere in Europe and North America. In Japan, flexibility has been part of the business way of life for many years and was crucial in shaping the country's economic success in the 1970s and 1980s. In fact, we now talk of a Japanese model of business organisation, which many of its competitors seek to emulate.

The model is based around four principles:

- **Total quality management (TQM).** This involves all employees working towards continuously improving all aspects of quality, both of the finished product and of methods of production.
- **Elimination of waste.** According to the 'just-in-time' (JIT) principle, businesses should take delivery of just sufficient quantities of raw materials and parts, at the right time and place. Stocks are kept to a minimum and hence the whole system of production runs with little, if any, slack. For example, supermarkets today have much smaller storerooms relative to the total shopping area than they did in the past, and take more frequent deliveries.

- **A belief in the superiority of team work.** Collective effort is a vital element in Japanese working practices. Team work is seen not only to enhance individual performance, but also to involve the individual in the running of the business and thus to create a sense of commitment.
- **Functional and numerical flexibility.** Both are seen as vital components in maintaining high levels of productivity.

The principles of this model are now widely accepted as being important in creating and maintaining a competitive business in a competitive marketplace.

Recent UK experience

Within the EU, prior to the recession of 2008–9, the UK was one of the most successful countries in cutting unemployment and creating jobs. Much of this has been attributed to increased labour market flexibility.

One of the puzzles of the downturn that took place from 2008 is how 'little' unemployment occurred in the UK. Of course, if you were one of the 1.6 million people unemployed in 2017, then the use of this term may stick in your throat. However, it remains a fact that, relative to output, fewer people were out of work than economic models predicted. One argument is that this happened because of the flexibility of reducing hours per worker or pay per hour rather than laying workers off. As a result, other EU member states, such as Italy and Germany, have sought to emulate many of the measures the UK has adopted.

1. Is a flexible firm more likely or less likely to employ workers up to the point where their $MRP = MC_L$?
2. Would you expect the advent of flexible firms to alter the gender balance of employment and unemployment?
3. If a firm is trying to achieve flexibility in its use of labour, do you think this would be harder or easier in a period of recession? Explain why.
4. Assume workers in a firm are allowed to choose between a 20 per cent reduction in pay or 20 per cent of the workforce being laid off. What factors would influence the workers' choice?

Figure 10.11(a) shows the MC and MRP curves for black workers. If there were no discrimination, employment of black workers would be at Q_{B_1} , where $MRP_B = MC_B$. The wage rate paid to black workers would be W_{B_1} .

Definition

Economic discrimination Where workers of identical ability are paid different wages or are otherwise discriminated against because of race, age, sex, etc.

Figure 10.11(b) shows the position for white workers. Again, if there were no discrimination, Q_{W_1} white workers would be employed at a wage of W_{W_1} ; the same wage as that of black workers. (Note that in each case the MRP curve is drawn on the assumption that the number of workers employed from the other ethnic group is constant.)

If the firm now discriminates against black workers, it will employ workers along a lower curve, $MRP_B - x$ (where x can be seen as the discriminatory factor). Employment of black workers will thus be at the lower level of Q_{B_2} and the wage they receive will be at the lower level of W_{B_2} .

BOX 10.9 BEHAVIOUR AT WORK**What motivates employees?**

Much of the work of behavioural economists concentrates on the rationality assumption used in theories of consumer behaviour. Do these models accurately predict consumer behaviour? Do consumers sometimes behave in a manner which is systematically at odds with the rationality assumption: i.e. by including sunk costs and getting excited by special offers? These are all interesting questions. Yet most of us spend as much as 25 per cent of our lives as workers and so our behaviour in the labour market also merits attention.

Dan Ariely, Professor of Psychology and Behavioural Economics at Duke University, is one of the best-known researchers on the subject. In his second book, *The Upside of Irrationality*,¹ he looks at our behaviour at work and identifies a number of areas where some experimental findings appear to contradict the predictions of economic theory.

We care about what we produce

One area that Ariely looked at was how we feel both about what we produce, and about what happens to it. Economic theory suggests workers will be motivated by the rewards they receive for their work and the associated costs. It doesn't ascribe emotions to the outcome of our labour.

Ariely set up an experiment where participants built Lego models; they were paid for each model – at a diminishing rate – and could choose how many to build. There were two sets of participants. Each knew that the models would eventually be disassembled, but for the first set this happened out of their sight after they had finished building. The second set saw the models broken up in front of them, almost immediately.

How did the 'workers' react to these different circumstances? Those who saw their models remain in a valuable state built an average of more than ten models each, and 68 per cent of them continued to produce when the price of their labour fell below a dollar. In contrast, those whose models were destroyed in front of them built an average of just over seven models and only 20 per cent were prepared to work for less than a dollar per model. Ariely concludes from this and other experiments that we are more productive when our labour has meaning; when the outputs are valued.

Bonuses and incentives

There has been a great deal of discussion about bankers' bonuses in the past few years; hardly surprising given the number of banks that taxpayers around the world have bailed out. The response from financial institutions has been predictable: if they are to retain their best staff and get them to perform in the best possible way, they have to offer large bonuses.

It may be true that bonuses are an important part of recruitment and retention, but is it true that they increase productivity? Ariely and his colleagues tested this in a series

of experiments, offering participants a variety of bonuses to reward achievement in a series of tasks. By doing this in India, where average incomes are very low, they were able to offer bonuses ranging from a day's wage through to the equivalent of five months' earnings.

Their findings were striking; those offered low and medium bonuses performed at about the same level, with a 'very good' performance on the tasks set around 30 per cent of the time. What about those who stood to gain more? Surely very large bonuses would concentrate the mind (and body, for some of the tasks were physical) and induce better performance? Well large bonuses certainly did have a noticeable effect and the results were striking. Those who could get up to five months' pay achieved a 'very good' performance less than 10 per cent of the time!

What happened? It seems that very large bonuses can lead to considerably worse performance. The pressure and the fear of not achieving the bonus combine to give a level of stress that diminishes performance, rather than enhances it.

Dan Ariely's experiment suggests that large bonuses are counter-productive. But do bonuses work at all? A research project led by Roland Fryer at Harvard University suggests not. In a study of a pay-for-performance programme in more than 200 schools in New York City, he looked at the impact of providing incentives to teachers. He found that offering bonuses to staff did not increase student achievement; furthermore there was no impact on teacher absences or on staff retention. So, in the real world, as in the laboratory, it seems that incentivising staff may not be a simple matter of offering cash, despite what the banks claim.

Lessons for employers

Academics believe that studying behaviour is inherently valuable and, of course, writers like Dan Ariely can also excite the attention and interest of a wider audience. Yet there is also an opportunity for employers to make use of these findings. Staff surveys often highlight concern about quality of outputs, in-house communications and the need to feel part of decision making. If firms are able to gain a better understanding of workers' motivation and to set rewards and incentives that account for this, the outcome may be higher productivity and a happier workforce.

1. *Dan Ariely suggests that bonuses should be based on an average of the previous five years' performance. Explain why this might lead to better performance than a simple annual bonus.*
2. *In Chapter 6, we identified specialisation and division of labour as a source of economies of scale. How might this principle be altered if we care about the finished product of our labour?*

¹ Dan Ariely, *The Upside of Irrationality* (Harper Collins 2010).

How will discrimination against black workers affect wages and employment of white workers? Let us consider two cases.

In the first case, assume that the employer practises economic discrimination purely in the negative sense: i.e. it discriminates against black workers but employs white

Figure 10.11 The effect of racial discrimination by a monopsonist employer

workers on profit-maximising principles. Thus white workers would be employed up to that point where their MC equals their MRP . But the fact that fewer black workers are now being employed will mean that for any given quantity of white workers there will be fewer workers employed in total, and therefore the MRP of white workers will have increased. In Figure 9.11(b), the white workers' MRP curve has shifted to MRR_{W_2} . This has the effect of raising employment of white workers to Q_{W_2} and the wage rate to W_{W_2} .

Firms may, however, also practise economic discrimination *in favour* of certain groups. Figure 10.11(b) also illustrates this second case, where the employer practises economic discrimination in favour of white workers. Here the firm will employ workers along a higher curve, $MRR_{W_2} + y$, where y is the discriminatory factor. The effect is further to increase the wage rate and level of employment of white workers, to W_{W_1} and Q_{W_1} , respectively.

? What effect will the discrimination by the firm have on the wages and employment of black workers in other firms in the area if (a) these other firms discriminate against black workers; (b) they do not discriminate?

If the government now legislates for equal pay for equal work, then employers that discriminate will respond by further cutting back on black workers. The answer to *this* problem would seem to be for the government to pass laws that insist not only that black workers be paid the same as white workers for doing the same job, but also that they be treated equally when applying for jobs.

The type of discrimination considered so far can be seen as 'irrational' if the firm wants to maximise profits. After all, to produce a given amount of output, it would be paying out more in wages to employ white workers than black workers.

In a competitive market environment, such firms may be forced to end discrimination simply to survive the competition from non-discriminating rivals. If, however, the firm has market power, it will probably be making sufficient profits to allow it to continue discriminating. The main pressure to end discrimination is then likely to come from unions, customers, shareholders or race relations organisations.

Other examples of non-economic discrimination stem from unequal educational opportunities. If the educational system discriminates against black children, they are likely to end up with poorer qualifications. They have less *human capital* invested in them. Under these circumstances, employers, preferring to employ the best-qualified applicants, are likely to choose white people. This is particularly so in the more highly paid jobs that require a higher level of educational attainment. Tackling this problem at source means tackling weaknesses early on in the education system and breaking what has come to be known as the cycle of deprivation.

Who are the poor? Who are the rich?

To the list we made at the end of section 10.1 we can now add the following factors that will tend to make people poor:

- Lack of economic power, not belonging to a union or belonging to a union with only weak bargaining power.
- Ignorance of better job opportunities.
- Lack of will or ability to search for a better job.

Definition

Human capital The qualifications, skills and expertise that contribute to a worker's productivity.

- Discrimination against them by employers or fellow workers.

Thus before the advent of the minimum wage many people of Asian origin, especially women, working in the garment industry in back-street 'sweatshops' earned pitifully low wages.

Conversely, belonging to a powerful union, working for a profitable employer which nevertheless is not a ruthless profit maximiser, being aware of new job opportunities and having the 'get up and go' to apply for better jobs, and being white, male and middle-class are all factors that help to contribute to people earning high wages.

Section summary

1. If a firm is a monopsony employer, it will employ workers to the point where $MRP_L = MC_L$. Since the wage is below MC_L , the monopsonist, other things being equal, will employ fewer workers at a lower wage than would be employed in a perfectly competitive labour market.
2. If a union has monopoly power, its power to raise wage rates will be limited if the employer operates under perfect or monopolistic competition in the goods market. A rise in wage rates will force the employer to cut back on employment.
3. In a situation of bilateral monopoly (where a monopoly union faces a monopsony employer), the union may have considerable scope to raise the wage rate above the monopsony level, without the employer wishing to reduce the level of employment. There is no unique equilibrium wage. The wage will depend on the outcome of a process of collective bargaining between union and management.
4. Each side can make various threats or promises. The outcome of the bargaining will depend on the relative power, attitudes and bargaining skills of both sides, the firm's profitability and the information each side has about the other. The outcome also depends on the legal framework within which the negotiations take place.
5. Power is not the only factor that makes actual wage determination different from the perfectly competitive model. Firms and workers may have imperfect knowledge of the labour market; disequilibrium in labour markets may persist; firms may not be profit maximisers (see Case Study 10.3 on the student website).
6. Firms may exercise discrimination (by race, sex, age, etc.) in their employment policy. By discriminating against a particular group, an employer with market power can drive down the wages of the members of that group. Unless firms are forced not to discriminate, equal pay legislation may well lead to a reduction in the employment of members of groups that are discriminated against.

10.3 CAPITAL AND PROFIT

The non-human factors of production

In the final two sections of the chapter, we consider the market for *other* factors of production. These can be divided into two broad groups.

Land. This includes all those productive resources supplied by nature: in other words, not only land itself, but also all natural resources. (We examine land in section 10.4.)

Capital. This includes all manufactured products that are used to produce goods and services. Thus capital includes such diverse items as a blast furnace, a bus, a computer, a factory building and a screwdriver.

The capital goods described above are physical assets and are known as *physical* capital. The word 'capital' is also used to refer to various *paper* assets, such as shares and bonds. These are the means by which firms raise finance to purchase physical capital, and are known as *financial* capital. Being merely paper assets, however, they do not count as factors of production. Nevertheless, financial markets have an

important role in determining the level of investment in physical capital, and we shall be examining these markets on pages 307–9.

Factor prices versus the price of factor services

A feature of most non-human factors is that they last a period of time. A machine may last 10 years; an oil well may last 50 years before it is exhausted; farmland will last forever if properly looked after. We must therefore distinguish between the income the owner will get from *selling* the factor and that which the owner will get from *using* it or *hiring* it out.

- The income from selling the factor is the factor's *price*. Thus a machine might sell for £20 000, or a hectare of farming land for £15 000.
- The income gained from using a factor is its *return*, and the income gained from hiring a factor out is its *rental*. This income represents the value or price of the factor's *services*, expressed per period of time. Thus a machine

might earn a firm £1000 per year. A hectare of land might earn a landowner £600 rent per year.

Obviously, the price of a factor will be linked to the value of its services. The price that a hectare of land will fetch if sold will depend on the return or rent that can be earned on that land. If it is highly productive farmland, it will sell for a higher price than a piece of scrubby moorland.

When we were looking at wage rates, were we talking about the price of labour or the price of labour services? Is this distinction between the price of a factor and the price of factor services a useful one in the case of labour? Was it in Roman times?

The profit-maximising employment of land and capital

On the demand side, the same rules apply for land and capital as for labour, if a firm wishes to maximise profits. Namely, it should demand factors up to the point where the marginal cost of the factor equals its marginal revenue product: $MC_f = MRP_f$. This same rule applies whether the firm is buying the factor outright, or merely renting it.

Figure 10.12 illustrates the two cases of perfect competition and monopsony. In both cases the MRP curve slopes downwards. This is another illustration of the law of diminishing returns, but this time applied to land or capital. For example, if a farmer increases the amount of land farmed while holding other factors constant, diminishing returns to land will occur. If the same number of farm workers and the same amount of agricultural machinery and fertilisers are used but on a larger area, then returns per hectare will fall.

In Figure 10.12(a) the firm is a price taker. The factor price is given at P_1 . Profits are maximised at Q_1 where $MRP_f = P_1$ (since $P_1 = MC_f$).

In Figure 10.12(b) the firm has monopsony power. The factor price will vary, therefore, with the amount that the firm uses. The firm will again use factors to the point where $MRP_f = MC_f$. In this case, it will mean using Q_2 at a price of P_2 .

What is the difference between buying a factor and renting it? Although the $MRP_f = MC_f$ rule remains the same, there are differences. As far as buying the factors is concerned, the MC_f is the extra outlay for the firm in purchasing one more unit of the factor; and the MRP_f is all the revenue produced by that factor over its whole life (but measured in terms of what this is worth when purchased: see pages 304–6). In the case of renting, MC_f is the extra outlay for the firm in rent per period, while MRP_f is the extra revenue earned from it per period.

The demand for capital services

What we are talking about in this section is the hiring of capital equipment for a period of time (as opposed to buying it outright). The analysis is virtually identical to that of the demand for labour. As with labour, we can distinguish between an individual firm's demand and the whole market demand.

Individual firm's demand

Take the case of a small painting and decorating firm thinking of hiring some scaffolding in order to complete a job. It could use ladders, which it already owns, but the job would take longer to complete. If it hires the scaffolding for one day, it can perhaps shorten the job by, say, two or three days. If it hires it for a second day, it can perhaps save another one or two days. Hiring it for additional days may save extra still. But diminishing returns are occurring: the longer the scaffolding is up, the less intensively it will be

Figure 10.12 Profit-maximising employment of a factor

(a) Perfectly competitive factor market

(b) Firm with monopsony power in factor market

used, and the less additional time it will save. Perhaps for some of the time it will be used when ladders could have been used equally easily.

The time saved allows the firm to take on extra work. Thus each extra day the scaffolding is hired gives the firm extra revenue. This is the scaffolding's marginal revenue product of capital (MRP_K). Diminishing returns mean that it has the normal downward-sloping shape (see Figure 10.12).

Market demand

The market demand for capital services is derived in exactly the same way as the market demand for labour (see Figure 10.6 on page 285). It is the horizontal sum of the MRP_K curves of the individual firms, corrected for the fact that increased use of capital will increase output, drive down the price of the good and hence reduce MRP . This means that the market demand curve for capital is steeper than the horizontal sum of the demand curves (MRP_K) of all the firms in the market.

? Under what circumstances would the market demand for renting a type of capital equipment be (a) elastic; (b) inelastic? (Clue: turn back to page 285 and see what determines the elasticity of demand for labour.)

The supply of capital services

It is necessary to distinguish (a) the supply to a single firm, (b) the supply by a single firm and (c) the market supply.

Supply to a single firm

This is illustrated in Figure 10.13(a). The small firm renting capital equipment is probably a price taker. If so, it faces a horizontal supply curve at the going rental rate (R_e). If, however, it has monopsony power, it will face an upward-sloping supply curve as in Figure 10.12(b).

Supply by a single firm

This is illustrated in Figure 10.13(b). On the demand side, the firm is likely to be a price taker. It has to accept the going rental rate (R_e) established in the market. If it tries to charge more, then customers are likely to turn to rival suppliers.

But what will the individual supplier's supply curve look like? The theory here has a lot in common with perfect competition in the goods market (see pages 193–5): the supply curve is the firm's MC curve, only here the MC is the extra cost of supplying one more unit of capital equipment for rent over a given time period.

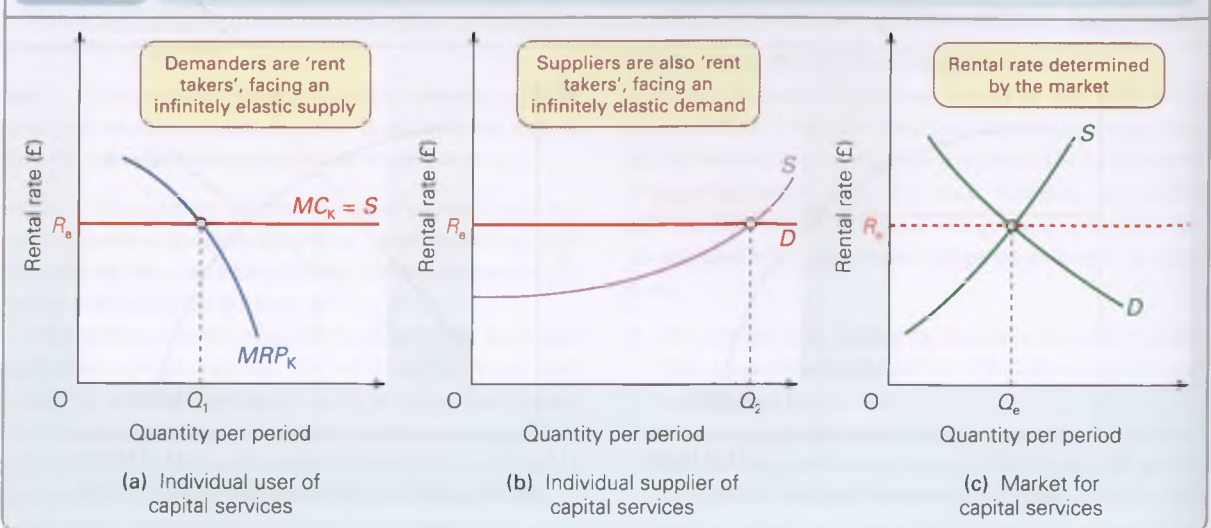

The problem with working out the marginal cost of renting out capital equipment is that the equipment probably cost a lot to buy in the first place, but lasts a long time. How then are these large costs to be apportioned to each new rental? The answer is that it depends on the time period under consideration.

The short run. In the short run, the hire company is not buying any new equipment: it is simply hiring out its existing stock of equipment. In the case of the scaffolding hire firm, the marginal costs of doing this will be as follows:

- Depreciation. Scaffolding has second-hand value. Each time the scaffolding is hired out it deteriorates, and thus its second-hand value falls. This loss in value is called 'depreciation'.
- Maintenance and handling. Hiring out equipment involves labour time (e.g. in the office) and possibly transport costs; the equipment may need servicing after being hired out.

These marginal costs are likely to rise relatively slowly. For each extra day a piece of equipment is hired out, the company will incur the same or only slightly higher additional costs. This gives a relatively flat supply curve of capital services in Figure 10.13(b) up to the hire company's maximum

Figure 10.13 Long-run equilibrium rental rate for the services of a particular type of capital

capacity. Once the scaffolding firm is hiring out all its scaffolding, the supply curve becomes vertical.

? Assume now that the firm has monopoly power in hiring out equipment, and thus faces a downward-sloping demand curve. Draw in two such demand curves on a diagram like Figure 10.13(b), one crossing the MC curve in the horizontal section, and one in the vertical section. How much will the firm supply in each case and at what price? (You will need to draw in MR curves too.) Is the MC curve still the supply curve?

The long run. In the long run, the hire company will consider purchasing additional equipment. It can therefore supply as much as it likes in the long run. The supply curve will be relatively elastic, or if it is a price taker itself (i.e. if the scaffolding firm simply buys scaffolding at the market price), the supply curve will be horizontal. This long-run supply curve will be vertically higher than the short-run curve, since the long-run MC includes the cost of purchasing each additional piece of equipment.

Maths Case 10.1 on the student website shows how this marginal cost can be calculated.

Market supply

This is illustrated in Figure 10.13(c). The market supply curve of a particular type of capital service is the sum of the quantities supplied by all the individual firms.

In the short run, the market supply will be relatively inelastic, given that it takes time to manufacture new equipment and that stocks of equipment currently held by manufacturers are likely to be relatively small. Also, capital is

heterogeneous: i.e. one piece of capital equipment is not the same as another. If there is a shortage of scaffolding, you cannot use a cement mixer instead: people would fall off! Finally, hire companies may be unwilling to purchase (expensive) new equipment immediately there is a rise in demand: after all, the upsurge in demand may turn out to be short-lived.

? If supply is totally inelastic, what determines the rental value of capital equipment in the short run?

In the *long run*, the supply curve of capital services will be more elastic because extra capital equipment can be produced. It will not be horizontal, however, but upward sloping. Its elasticity will depend on the elasticity of supply of capital equipment to the hire companies.

Determination of the price of capital services

As Figure 10.13(c) shows, in a perfect market the market rental rate for capital services will be determined by the interaction of market demand and supply. Note that the analysis here parallels that of the determination of the equilibrium wage in a given labour market (see Figure 10.1 on page 278).

? What will happen to the demand for capital services and the equilibrium rental if the price of some other factor, say labour, changes? Assume that wage rates fall. Trace through the effects on a three-section diagram like Figure 10.13. (Clue: a fall in wages will reduce costs and hence the price of the product, so that more will be sold; and it will make labour cheaper relative to capital.)

BOX 10.10 STOCKS AND FLOWS

EXPLORING ECONOMICS

The discussion of the rewards to capital and land leads to a very important distinction: that between stocks and flows.

A stock is a quantity of something held. A landowner may own 200 hectares. A farmer may have a barn with 500 tonnes of grain. You may have £1000 in a savings account. These are all stocks: they are all quantities held at a given point in time.

A flow is an increase or decrease in quantity over a specified period. The landowner may buy another 10 hectares during the year. The farmer may use 10 tonnes of grain from the barn each week as animal feed. You may save £10 per month.

Wages, rent and interest are all rewards to flows. Wages are the amount paid for the services of a person's labour for a week or month. Rent is the amount paid per period of time to use the services of land. Likewise, interest is the reward paid to people per year for the use of their money.

If an asset is sold, its value is the value of the stock. It is a simple payment at a single point in time for the transfer of a whole asset. Thus the price of land and the price of capital are stock concepts.

An important example of stocks and flows arises with capital and investment. If a firm has 100 machines, that is a stock of capital. It may choose to build up its stock by investing. Investment is a flow concept. The firm may choose to invest in 10 new machines each year. This may not add 10 to the stock of machines, however, as some may be wearing out (a negative flow).

KEY IDEA
26

Stocks and flows. A stock is a quantity of something at a given point in time. A flow is an increase or decrease in something over a specified period of time. This is an important distinction and a common cause of confusion.

? Which of the following are stocks and which are flows?

- Unemployment.
- Redundancies.
- Profits.
- A firm's stock market valuation.
- The value of property after a period of inflation.

If there is monopsony power on the part of the users of hired capital, this will have the effect of depressing the rental rate below the MRP_K (see Figure 10.12(b)). If, on the other hand, there is monopoly power on the part of hire companies, the analysis is similar to that of monopoly in the goods market (see Figure 7.8 on page 205). The firm, by reducing the supply of capital for hire, can drive up the rental rate. It will maximise profit where the marginal revenue from hiring out the equipment is equal to the marginal cost of so doing: at a rental rate (price) *above* the marginal cost.

*Demand for and supply of capital for purchase

The alternative to hiring capital is to buy it outright. This section examines the demand and supply of capital for purchase.

The demand for capital: investment

How many computers will an engineering firm want to buy? Should a steelworks install another blast furnace? Should a removal firm buy another furniture lorry? These are all **investment** decisions. Investment involves purchasing of additional capital.

The demand for capital, or 'investment demand', by a profit-maximising firm is based on exactly the same principles as the demand for labour or the demand for capital services. The firm must weigh up the marginal revenue product of that investment (i.e. the money it will earn for the firm) against its marginal cost.

The problem is that capital is durable. It goes on producing goods, and hence yielding revenue for the firm, for a considerable period of time. Calculating these benefits therefore involves taking account of their timing.

There are two ways of approaching the problem: the *present value* approach and the *rate of return* approach. In both cases, the firm is comparing the marginal benefits with the marginal costs of the investment.

Present value approach. To work out the benefit of an investment (its MRP), the firm must estimate all the future earnings it will bring and then convert them to a **present value**. It can then compare this with the cost of the investment. Let us take a simple example.

Assume that a firm is considering buying a machine. It will produce £1000 per year (net of operating costs) for four years and then wear out and sell for £1000 as scrap. What is the

benefit of this machine to the firm? At first sight the answer would seem to be £5000. This, after all, is the total income earned from the machine. Unfortunately, it is not as simple as this. The reason is that money earned in the future is less beneficial to the firm than having the same amount of money today: if the firm has the money today, it can earn interest on it by putting it in the bank or reinvesting it in some other project.

To illustrate this, assume that you have £100 today and can earn 10 per cent interest by putting it in a bank. In one year's time that £100 will have grown to £110, in two years' time to £121, in three years' time to £133.10 and so on. This process is known as **compounding**.

The principle of discounting. People generally prefer to have benefits today rather than in the future. Thus future benefits have to be reduced (discounted) to give them a present value.

It follows that if someone offered to give you £121 in two years' time, that would be no better than giving you £100 today, since, with interest, £100 would grow to £121 in two years. What we say, then, is that, with a 10 per cent interest rate, £121 in two years' time has a **present value** of £100.

The procedure of reducing future value back to a present value is known as **discounting**.

When we do discounting, the rate we use is called the **rate of discount**: in this case, 10 per cent. The formula for discounting is as follows:

$$PV = \sum \frac{R_t}{(1+r)^t}$$

where PV is the present value, R_t is the revenue from the investment in year t , r is the rate of discount (expressed as a decimal: e.g. 10% = 0.1) and \sum is the sum of each of the years' discounted earnings.

So what is the present value of the investment in the machine that produced £1000 for four years and then is sold as scrap for £1000 at the end of the four years? According to the formula it is:

$$\begin{aligned} & \text{Year 1} \quad \text{Year 2} \quad \text{Year 3} \quad \text{Year 4} \\ & = \frac{\pounds 1000}{1.1} + \frac{\pounds 1000}{(1.1)^2} + \frac{\pounds 1000}{(1.1)^3} + \frac{\pounds 2000}{(1.1)^4} \\ & = \pounds 909 + \pounds 829 + \pounds 751 + \pounds 1366 \\ & = \pounds 3852 \end{aligned}$$

Definitions

Investment The purchase by the firm of equipment or materials that will add to its stock of capital.

Present value approach to appraising investment This involves estimating the value *now* of a flow of future benefits (or costs).

Compounding The process of adding interest each year to an initial capital sum.

Discounting The process of reducing the value of future flows to give them a present valuation.

Rate of discount The rate that is used to reduce future values to present values.

Thus the present value of the investment (i.e. its *MRP*) is £3852, not £5000 as it might seem at first sight. In other words, if the firm had £3852 today and deposited it in a bank at a 10 per cent interest rate, the firm would earn exactly the same as it would by investing in the machine.

So is the investment worthwhile? It is now simply a question of comparing the £3852 benefit with the cost of buying the machine. If the machine costs less than £3852, it will be worth buying. If it costs more, the firm would be better off keeping its money in the bank.

The difference between the present value of the benefits (PV_b) of the investment and its cost (C) is known as the *net present value* (*NPV*).

$$NPV = PV_b - C$$

If the *NPV* is positive, the investment is worthwhile.

What is the present value of a machine that lasts three years, earns £100 in year 1, £200 in year 2 and £200 in year 3, and then has a scrap value of £100? Assume that the rate of discount is 5 per cent. If the machine costs £500, is the investment worthwhile? Would it be worthwhile if the rate of discount were 10 per cent?

Rate of return approach. The alternative approach when estimating whether an investment is worthwhile is to calculate the investment's *rate of return*. This rate of return is known as the firm's *marginal efficiency of capital* (*MEC*) or *internal rate of return* (*IRR*).

We use the same formula as for calculating present value:

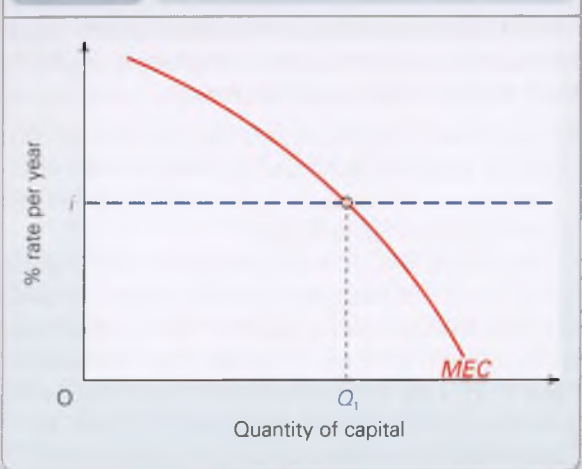

$$PV = \sum \frac{R_t}{(1+r)^t}$$

and then calculate what value of r would make the *PV* equal to the cost of investment: in other words, the rate of discount that would make the investment just break even. Say this worked out at 20 per cent. What we would be saying is that the investment would just cover its costs if the current rate of interest (rate of discount) were 20 per cent. In other words, this investment is equivalent to receiving 20 per cent interest: it has a 20 per cent rate of return (*MEC*).

Details of how to calculate the internal rate of return, along with a worked example, are given in Maths Case 10.2 on the student website.

So should the investment go ahead? Yes, if the actual rate of interest (i) is less than 20 per cent. The firm is better off

Figure 10.14 The profit-maximising stock of capital

investing its money in this project than keeping it in the bank: i.e. if $MEC > i$ the investment should proceed.

This is just one more application of the general rule that if $MRP_t > MC_t$ then more of the factor should be used: only in this case, *MRP* is expressed as a rate of return (*MEC*), and *MC* is expressed as a rate of interest (i).

The profit-maximising position is illustrated in Figure 10.14. As the firm invests more, and thus builds up its stock of capital, so *MEC* will fall due to diminishing returns. As long as *MEC* is greater than i , the firm should invest more. It should stop when the stock of capital has reached Q_1 . Thereafter it should cut investment to a level just sufficient to replace worn-out machines, and thus keep the capital stock at Q_1 .

The risks of investment. One of the problems with investment is that the future is uncertain. The return on an investment will depend on the value of the goods it produces, which will depend on the goods market. But future markets depend on consumer tastes, the actions of rivals and the whole state of the economy, none of which can be known with certainty. Investment is thus risky.

Risk may also be incurred in terms of the output from an investment. Take the case of prospecting for oil. An oil company may have a major strike, but it may simply drill dry well after dry well. If it does get a major strike, and hence earn a large return on its investment, these profits will not be competed away by competitors prospecting in other fields, because they too still run the risk of drilling dry holes.

How is this risk accounted for when calculating the benefits of an investment? The answer is to use a higher rate of discount. The higher the risk, the bigger the risk premium that must be added to the rate.

The supply of capital

It is necessary to distinguish the supply of *physical* capital from the supply of *finance* to be used by firms for the purchase of capital.

Definitions

Net present value of an investment The discounted benefits of an investment minus the cost of the investment.

Marginal efficiency of capital or internal rate of return The rate of return of an investment: the discount rate that makes the net present value of an investment equal to zero.

Supply of physical capital. The principles here are just the same as those in the goods market. It does not matter whether a firm is supplying lorries (capital) or cars (a consumer good): it will still produce up to the point where $MC = MR$ if it wishes to maximise profits.

Supply of finance. An economy will have a stock of financial capital (or 'loanable funds') held in banks and other financial institutions. These funds can be borrowed by firms for investment in new physical capital.

When people save, this will build up the stock of loanable funds. This flow of saving represents the resources released when people refrain from consumption. Among other things, saving depends on the rate of interest. This is illustrated in Figure 10.15. A rise in the interest rate will encourage people to save more, thereby increasing the supply (i.e. the stock) of loanable funds (a movement up along the supply curve).

This supply curve will be relatively inelastic in the short run, since the flow of saving over a short time period (say, a month) will have only a relatively small effect on the total stock of funds. Over a year, however, the effect would be 12 times bigger. The longer the time period, therefore, the more elastic the supply curve.

Saving also depends on the level of people's incomes, their expectations of future price changes, and their willingness to sacrifice present consumption in order to be able to have more in the future. A change in any of these other determinants will shift the supply curve.

*Determination of the rate of interest

The rate of interest is determined by the interaction of supply and demand in the market for loanable funds. This is illustrated in Figure 10.15. As we have seen, supply represents accumulated savings.

The demand curve includes the demand by households for credit and the demand by firms for funds to finance their investment. The curve slopes downwards for two reasons.

First, households will borrow more at lower rates of interest. It effectively makes goods cheaper for them to buy. Second, it reflects the falling rate of return on investment as investment increases. This is simply due to diminishing returns to investment. As rates of interest fall, it will become profitable for firms to invest in projects that have a lower rate of return: the quantity of loanable funds demanded thus rises.

Equilibrium will be achieved where demand equals supply at an interest rate of i_e and a quantity of loanable funds \mathcal{L}_e .

How will this market adjust to a change in demand or supply? Assume that there is a rise in demand for capital equipment, due, say, to an improvement in technology that increases the productivity of capital. There is thus an increase in demand for loanable funds. The demand curve shifts to the right in Figure 10.15. The equilibrium rate of interest will rise and this will encourage more savings. The end result is that more money will be spent on capital equipment.

Capital and profit

What does the analysis so far tell us about the amount of profit that firms will earn? After all, profit is the reward that the owners of firms get from owning and using capital.

Remember from Chapter 7 the distinction between normal and supernormal profit. In a perfectly competitive world, all supernormal profits will be competed away in the long run.

Another way of putting this is that a perfectly competitive firm in the long run will earn only a **normal rate of return** on capital. This means that the return on capital (after taking risk into account) will be the same as if the owners of capital had simply deposited their money in a bank instead. If a firm's capital yields a higher rate of return than this normal level (i.e. supernormal returns), other firms will be attracted to invest in similar capital. The resulting increased level of capital will increase the supply of goods. This, in turn, will lower the price of the goods and hence lower the rate of return on capital until it has fallen back to the normal level.

? Can a perfectly competitive firm earn a supernormal rate of return on capital if it continuously innovates?

If, however, capital owners have monopoly/oligopoly power and can thus restrict the entry of new firms or the copying of innovations – for example, by having a patent on a particular process – they can continue to get a supernormal return on their capital.

Figure 10.15 The market for loanable funds

Definition

Normal rate of return The rate of return (after taking risks into account) that could be earned elsewhere.

Financing investment

Sources of business finance

A firm can finance capital investment in one of three major ways:

- Internal funds (i.e. retained profits).
- Borrowing from the banking sector.
- Issuing new shares (equities) or debentures (fixed-interest loan stock).

The largest source of finance for investment in the UK is firms' own internal funds (i.e. ploughed-back profits). Given, however, that business profitability depends in large part on the general state of the economy, internal funds as a source of business finance are likely to vary considerably across the business cycle. When profits are squeezed in a recession, this source of investment will decline.

Other sources of finance, which include borrowing and the issue of shares and debentures, are known as 'external funds'. These are then categorised as short-term, medium-term or long-term sources of finance.

Short-term finance. This is usually in the form of a short-term bank loan or overdraft facility, and is used by business as a form of working capital to aid it in its day-to-day business operations.

Medium-term finance. This again is provided largely by banks, usually in the form of a loan with set repayment targets. It is common for such loans to be made at a fixed rate of interest, with repayments being designed to fit in with the business's expected cash flow. Bank lending has been the most volatile source of business finance, and has been particularly sensitive to the state of the economy. While part of the reason is the lower demand for loans during a recession, part of the reason is the caution of banks in granting loans if prospects for the economy are poor. In 2008, there was a reduction in the willingness of banks to grant loans to businesses following the credit crunch. This is examined in more detail in sections 18.2 and 22.2.

Long-term finance. Long-term finance, especially in the UK, tends to be acquired through the stock market. It will usually be in the form of *shares* (or *equities*). This is where members of the public or institutions (such as pension funds) buy a part-ownership in the company and, as a result, receive dividends on those shares. The dividends depend on the amount of profit the company makes and distributes to shareholders. The proportion of business financing from this source clearly depends on the state of the stock market.

In the late 1990s, with a buoyant stock market, the proportion of funds obtained through share issue increased. Then with a decline in stock market prices from 2000 to 2003, this proportion fell. In 2008, there were very substantial falls in the values of shares, further reducing the ability of firms to raise finance. The recovery in share prices seen in

2013 gave rise to hope that firms would be able to fund the investment needed to increase growth back to pre-recession levels.

Alternatively, firms can issue *debentures* (or *company bonds*). These securities are fixed-interest loans to firms. Debenture holders have a prior claim on company shares. Their interest must be paid in full before shareholders can receive any dividends.

Despite the traditional reliance on the stock market for external long-term sources of finance, there has been a growing involvement of banks in recent years. Prior to the credit crunch in 2008, banks had become more willing to provide finance for business start-ups and for diversification. This has been less apparent since and there is a concern that banks are inherently cautious. This risk aversion results in a problem of 'short-termism', with bankers often demanding a quick return on their money or charging high interest rates, and being less concerned to finance long-term investment.

Comparison of the UK with other European countries. In other European countries, notably Germany and France, the attitude towards business funding is quite different from that in the UK. In these countries banks provide a significant amount of long-term, fixed-rate finance. This provides a much more stable source of finance and creates an environment where banks are much more committed to the long-run health of companies.

The role of the stock market

The London Stock Exchange operates as both a primary and secondary market in capital.

As a **primary market**. The primary market is where public limited companies (see Case Study 9.1 on the student website) can raise finance by issuing new shares (equities) or fixed interest securities, whether to new shareholders or to existing ones. To raise finance on the Stock Exchange a business must be 'listed'. The Listing Agreement involves directors agreeing to abide by a strict set of rules governing behaviour and levels of reporting to shareholders. Companies must have at least three years' trading experience and

Definitions

Shares (equities) A part-ownership of a company. Companies' distributed profits are paid to shareholders in the form of dividends according to the number of shares held.

Debentures (company bonds) Fixed-interest loans to firms. These assets can be traded on the stock market and their market price is determined by demand and supply.

Primary market in capital Where shares are sold by the issuer of the shares (i.e. the firm) and where, therefore, finance is channelled directly from the purchasers (i.e. the shareholders) to the firm.

make at least 25 per cent of their shares available to the public. In March 2017, there were 937 UK and 271 international companies on the Official List.

As well as those on the Official List, there are approximately 1000 companies on what is known as the Alternative Investment Market (AIM). Companies listed here tend to be young but with growth potential, and do not have to meet the strict criteria or pay such high costs as companies on the Official List.

In 2016, nearly £16 billion's worth of new equity capital was raised through 427 main market issues and £266 billion's worth of fixed interest securities through 1672 main market issues. In addition, £4.8 billion's worth of capital was raised on the AIM.

As a secondary market. The Stock Exchange enables investors to sell *existing* shares and debentures to one another. In March 2017, on an average day £5.5 billion's worth of trading in equities and other securities took place.

The advantages and disadvantages of using the stock market to raise capital

As a market for raising capital, the stock market has a number of advantages:

- It brings together those that wish to invest and companies that seek investment, and does so in a relatively low-cost way. It thus represents a way that savings can be mobilised to generate output.
- Firms that are listed on the Stock Exchange are subject to strict regulations. This is likely to stimulate investor confidence, making it easier for business to raise finance.
- The process of merger and acquisition is facilitated by having a share system, which in turn increases competition for corporate control (see pages 210–11).

The main weaknesses of the stock market for raising capital are:

- The cost to a business of getting listed can be immense, not only in a financial sense, but also in being open to public scrutiny. Directors' and senior managers' decisions will often be driven by how the market is likely to react, rather than by what they perceive to be in the business's best interests. They always have to think about the reactions of those large shareholders in the City that control a large proportion of their shares.

- In the UK, it is often claimed that the market suffers from *short-termism*. Investors on the Stock Exchange are mainly concerned with a company's short-term performance and its share value. In responding to this, the business might neglect its long-term performance and potential.

Is the stock market efficient?

One of the arguments made in favour of the stock market is that it acts as an arena within which share values can be accurately or efficiently priced. If new information comes onto the market concerning a business and its performance, this will be quickly and rationally transferred into the business's share value. This is known as the *efficient market hypothesis*. For example, if an investment analyst found that, in terms of its actual and expected dividends, a particular share was underpriced and thus represented a 'bargain', the analyst would advise investors to buy. As people then bought the shares, their price would rise, pushing their value up to their full worth. So by attempting to gain from inefficiently priced securities, investors will encourage the market to become more efficient.

How efficient, then, is the stock market in pricing securities? Is information rationally and quickly conveyed into the share's price? Or are investors able to prosper from the stock market's inefficiencies?

We can identify three levels of efficiency.

The weak form of efficiency. Share prices often move in cycles that do not reflect the underlying performance of the firm. If information is imperfect, those with a better understanding of such cycles gain from buying shares at the trough and selling them at the peak of the cycles. They are taking advantage of the market's inefficiency.

Increasing numbers of investment analysts are using technical models to track share cycles. As they do so and knowledge becomes more perfect, so the market will become more efficient and the cycles will tend to disappear. But why?

As more people buy a company's shares as the price falls towards its trough, extra demand will prevent the price falling so far. Similarly, as people sell as the price rises towards its peak, so this extra supply will prevent the price rising so far. This is an example of stabilising speculation (see pages 71–2). As more and more people react in this way, so the cycle all but disappears. When this happens, *weak efficiency* has been achieved.

Definitions

Secondary market in capital Where shareholders sell shares to others. This is thus a market in 'second-hand' shares.

Short-termism Where firms and investors take decisions based on the likely short-term performance of a company, rather than on its long-term prospects. Firms may thus sacrifice long-term profits and growth for the sake of a quick return.

Efficient (capital) market hypothesis The hypothesis that new information about a company's current or future performance will be quickly and accurately reflected in its share price.

Weak efficiency (of share markets) Where share dealing prevents cyclical movements in shares.

The semi-strong form of efficiency. **Semi-strong efficiency** is when share prices adjust fully to publicly available information. In practice, not all investors will interpret such information correctly: their knowledge is imperfect. But increasingly more advice is available to shareholders (through stockbrokers, newspapers, online commentators, published accounts, etc.), and more shares are purchased by professional fund managers. The result is that the interpretation of public information becomes more perfect and the market becomes more efficient in the semi-strong sense.

If the market were efficient in the semi-strong sense, then no gain could be made from studying a company's performance and prospects, as this information would *already* be included in the current share price. In selecting shares, you would do just as well by pinning the financial pages of a newspaper on the wall, throwing darts at them, and buying the shares the darts hit!

The strong form of efficiency. If the stock market showed the **strong form of efficiency**, then share prices would fully reflect all available information – whether public or not. For this to be so, all 'inside' information would have to be reflected in the share price the moment the information became available.

If the market is *not* efficient at this level, then people who have access to privileged information will be able to make large returns from their investments by acting on such information. For example, directors of a company would know if the company was soon to announce better-than-expected profits. In the meantime, they could gain by buying shares in the company, knowing that the share price would rise when the information about the profits became public. Gains made from such 'insider dealing' are illegal. However, proving whether individuals are engaging in it is very difficult. By the time of its replacement by the Financial Conduct Authority in April 2013, the Financial Services Authority had secured just 23 convictions for insider dealing, prompting criticism that it was toothless.

Given the penalties for insider dealing and the amount of private information that firms possess, it is unlikely that all such information will be reflected in share prices. Thus the strong form of stock market efficiency is unlikely to hold.

Would the stock market be more efficient if insider dealing were made legal?

If stock markets were fully efficient, the expected returns from every share would be the same. The return is referred to as the **yield**: this is measured as the dividends paid on the

share as a percentage of the share's market price. For example, if you hold shares whose market price is £1 per share and you receive an annual dividend of 3p per share, then the yield on the shares is 3 per cent. But why should the expected returns on shares be the same? If any share was expected to yield a higher-than-average return, people would buy it; its price would rise and its yield would correspondingly fall.

It would only be unanticipated information, therefore, that would cause share prices to deviate from that which reflected expected average yields. Such information must, by its nature, be random, and as such would cause share prices to deviate randomly from their expected price, or follow what we call a **random walk**. Evidence suggests that share prices do tend to follow random patterns.

Challenging the efficient market hypothesis

The efficient markets hypothesis has been challenged by critics who laid the blame for the financial crisis in 2007–8 on unfounded belief in rational markets. They argued that regulators failed to understand the role that exuberance plays in financial markets. If investors are 'caught up' in the belief that share prices (or property values) will continue to increase in value, regardless of underlying information, then the result will be a bubble – a situation where assets are traded above their fundamental value.

According to behavioural economists, bubbles can be explained by a number of psychological factors. Among these are paying too little attention to the past, over-confidence, over-optimism and herding. In short, people pay too much for assets because they remember recent returns more than historical averages, because they take more notice of economic good news than bad and because everyone else is doing it. Asset bubbles are vulnerable to breaking on the basis of changes in beliefs, as we saw in the collapse of the US housing market from 2006 and the subsequent stock market crash.

What does this imply for policy makers? The argument might be made that an asset bubble is simply a magnification of any market, with both losers and winners; this does not suggest a need for intervention. However, this ignores the macroeconomic consequences of the bubble, consequences which were clearly seen from 2007 on. Behaviourists therefore believe that effective financial regulation must take account of irrationality.

Definitions

Semi-strong efficiency (of share markets) Where share prices adjust quickly, fully and accurately to publicly available information.

Strong efficiency (of share markets) Where share prices adjust quickly, fully and accurately to all available information, both public and that only available to insiders.

Yield on a share The dividend received per share expressed as a percentage of the current market price of the share.

Random walk Where fluctuations in the value of a share away from its 'correct' value are random, i.e. have no systematic pattern. When charted over time, these share price movements would appear like a 'random walk': like the path of someone staggering along drunk!

Section summary

1. It is necessary to distinguish between buying the services of land (by renting) or capital (by hiring) and buying them outright.
2. The profit-maximising employment of land and capital services will be where the factor's MRP is equal to its price (under perfect competition) or its MC (where firms have monopsony power).
3. The demand for capital services will be equal to MRP_K . Due to diminishing returns, this will decline as more capital is used.
4. The supply of capital services to a firm will be horizontal or upward sloping depending on whether the firm is perfectly competitive or has monopsony power. The supply of capital services by a firm in the short run is likely to be relatively elastic up to its maximum use, and then totally inelastic. In the long run, the supplying firm can purchase additional capital equipment for hiring out. The long-run supply curve will therefore be very elastic, but at a higher rental rate than in the short run, given that the cost of purchasing the equipment must be taken into account in the rental rate.
5. The market supply of capital services is likely to be highly inelastic in the short run, given that capital equipment tends to have very specific uses and cannot normally be transferred from one use to another. In the long run, it will be more elastic.
6. The price of capital services is determined by the interaction of demand and supply.
7. The demand for capital for purchase will depend on the return it earns for the firm. To calculate this return, all future earnings from the investment have to be reduced to a present value by discounting at a market rate of interest (discount). If the present value exceeds the cost of the investment, the investment is worthwhile. Alternatively, a rate of return from the investment can be calculated and then this can be compared with the return that the firm could have earned by investing elsewhere.
8. The supply of finance for investment depends on the supply of loanable funds, which in turn depends on the rate of interest, on the general level of thriftiness and on expectations about future price levels and incomes.
9. The rate of interest will be determined by the demand and supply of loanable funds. When deciding whether to make an investment, a firm will use this rate for discounting purposes. If, however, an investment involves risks, the firm will require a higher rate of return on the investment than current market interest rates.
10. Business finance can come from internal sources (ploughed-back profits) or from external ones. External sources of finance include borrowing and the issue of shares.
11. The stock market operates as both a primary and a secondary market in capital. As a primary market it channels finance to companies as people purchase new shares and debentures. It is also a market for existing shares and debentures.
12. The stock market helps to stimulate growth and investment by bringing together companies and people who want to invest in them. By regulating firms and by keeping transaction costs of investment low, it helps to ensure that investment is efficient.
13. The stock market does impose costs on firms, however. It is expensive for firms to be listed and the public exposure may make them too keen to 'please' the market. It can also foster short-termism.
14. The stock market is relatively efficient. It achieves weak efficiency by reducing cyclical movements in share prices. It achieves semi-strong efficiency by allowing share prices to respond quickly and fully to publicly available information. Whether it achieves strong efficiency by adjusting quickly and fully to all information (both public or insider), however, is more doubtful.

10.4 LAND AND RENT

Rent: the reward to landowners

We turn now to land. The income it earns for landowners is the *rent* charged to the users of the land. This rent, like the rewards to other factors, is determined by demand and supply.

What makes land different from other factors of production is that it has an inelastic supply. In one sense, this is obvious. The total supply of land in any area is fixed.

In another sense, supply is not *totally* inelastic. Land can be improved. It can be cleared, levelled, drained, fertilised, etc. Thus the supply of a certain type of land can be increased by expending human effort on improving it. The question is whether *land* has thereby increased, or whether the

improvements constitute *capital* invested in land, and if so whether the higher rents that such land can earn really amount to a return on the capital invested in it.

To keep the analysis simple, let us assume that land is fixed. Let us take the case of an area of 10 000 hectares surrounding the village of Oakleigh. This is shown as a vertical supply 'curve' in Figure 10.16. The demand curve for that land will be like the demand curve for other factors of production. It is the MRP curve and slopes down due to diminishing returns from land. The equilibrium rent is r_e , where demand and supply intersect.

Notice that the level of this rent depends entirely on *demand*. If a new housing development takes place in Oakleigh, due perhaps to a growth in employment in a nearby

Figure 10.16 Determination of rent

town, the demand curve will shift to D_1 and the equilibrium rent will rise to r_{e1} . But the supply of land remains fixed at 10 000 hectares. Landowners will earn more rent, but they themselves have done nothing: the higher rent is a pure windfall gain.

So why are rents in the centre of London many times higher per hectare than they are in the north of Scotland? The answer is that demand is very much higher in London.

Demand for land depends on its marginal revenue product. Thus it is differences in the *MRP* of land that explain the differences in rent from one area to another. There are two reasons for differences in *MRP*. Remember that $MRP = MPP$ (marginal physical product of the factor) \times *MR* (marginal revenue of the good produced by that factor).

Differences in MPP. Land differs in productivity. Fertile land will produce a higher output than deserts or moorland. Similarly, land near centres of population will be of much more use to industry than land in the middle of nowhere.

? What other factors will determine the *MPP* of land for industry?

Differences in MR. The higher the demand for a particular good, the higher its price and marginal revenue, and hence the higher the demand and rent for the land on which that good is produced. Thus if the demand for housing rises relative to the demand for food, the rent on land suitable for house building will rise relative to the rent on agricultural land.

To summarise: rents will be high on land that is physically productive (high *MPP*) and produces goods in high demand (high *MR*).

1. We defined the factor of production 'land' to include raw materials. Does the analysis of rent that we have just been looking at apply to raw materials?
2. The supply of land in a particular area may be totally inelastic, but the supply of land in that area for a specific purpose (e.g. growing wheat) will be upward sloping: the higher the price of wheat and thus the higher the rent that wheat producers are prepared to pay, the more will be made available for wheat production. What will determine the elasticity of supply of land for any particular purpose?

The price of land

Not all land is rented: much of it is bought and sold outright. Its price will depend on what the purchaser is prepared to pay, and this will depend on the land's rental value.

Let us say that a piece of land can earn £1000 per year. What would a person be prepared to pay for it? There is a simple formula for working this out:

$$P = \frac{R}{i} \quad (1)$$

where P is the price of the land, R is the rent per year and i is the market rate of interest.

Let us assume that the market rate of interest is 10 per cent (i.e. 0.1). Then according to the formula, a purchaser would be prepared to pay

$$\frac{\pounds 1000}{0.1} = \pounds 10\,000$$

Why should this be so? If a person deposits £10 000 in the bank, with an interest rate of 10 per cent this will earn that person £1000 per year. Assuming our piece of land is guaranteed to earn a rent of £1000 per year, then provided it costs less than £10 000 to buy, it is a better investment than putting money in the bank. The competition between people to buy this land will drive its price up until it reaches £10 000.

This is just another example of equilibrium being where marginal cost equals marginal benefit. This can be demonstrated by rearranging equation (1) to give

$$Pi = R$$

Remember that the equilibrium price of the land (P) is £10 000 and that the rate of interest (i) is 0.1. If you borrow the £10 000 to buy the land, it will cost you £1000 per year in interest payments (i.e. Pi). This is your annual marginal cost. The annual marginal benefit will be the rent (R) you will earn from the land.

1. What price would the same piece of land sell for if it still earned £1000 rent per year, but if the rate of interest were now (a) 5 per cent; (b) 20 per cent?
2. What does this tell us about the relationship between the price of an asset (like land) and the rate of interest?

BOX 10.11 THE ECONOMICS OF NON-RENEWABLE RESOURCES**What happens as stocks diminish?**

As world population rises, so the demands on resources continue to grow. Some of these resources are renewable. Water resources are replenished by rain. The soil, if properly managed, can continue to grow crops. Felled forests can be replanted. Of course, if we use these resources more rapidly than they are replenished, stocks will run down. We are all aware of the problems of seas that are overfished, or rainforests that are cleared, or reservoirs that are inadequate to meet our growing demand for water.

But whereas these resources can be replenished, others cannot. These are known as non-renewable resources. What determines the price of such resources and their rate of depletion? Will we eventually run out of resources such as oil, coal, gas and various minerals? To answer these questions, we need to distinguish between the available stock of such resources, and their use (a flow). The greater their use, the faster the stocks will run down.

Price increases over time

As stocks run down, so the price of the resources will tend to increase. Thus we can all expect to pay more for fossil fuels as remaining reserves are depleted. Owners of the reserves (e.g. mine owners and owners of oil wells) will thus find the value of their assets increasing. But how quickly will prices rise? In a perfect market, they will rise at the market rate of return on other assets (of equivalent risk). This is known as the Hotelling rule, named after Harold Hotelling who developed the argument in the early 1930s.

To understand why this is so, consider what would happen if the price of oil rose more slowly than the rate of return on other assets. People who owned oil wells would find that the value of their oil reserves was increasing less rapidly than the value of other assets. They might as well sell more oil now and invest the money in other assets, thereby getting a higher return. The extra oil coming to the market would depress the current oil price, but also reduce reserves, thereby creating a bigger shortage for the future and hence a higher future price. This would cause oil prices to rise more quickly over time (from the new lower base). Once the rate of price increase has risen to equal the rate of return on other assets, equilibrium has occurred. There will no longer be an incentive for the oil to be extracted faster.

The current price

But what determines the current price level (as opposed to its rate of increase)? This will be determined by supply and demand for the extracted resource (its flow).

In the case of a resource used by households, demand will depend on consumer tastes, the price of other goods, income, etc. Thus the greater the desire for using private cars, the greater the demand for petrol. In the case of minerals used by firms, demand will depend on the marginal revenue product of the resources. In either case, a rise in demand will cause a rise in the resource's price.

Supply will depend on three things:

- The rate of interest on other assets. As we have seen, the higher the rate of interest, the faster will the resource be extracted, in order that the mine owners (or well owners) can reinvest their profits at these higher rates of interest.
- The stock of known reserves. As new reserves are discovered, this will push down the price.
- The costs of extraction. The lower the costs, the greater will be the amount extracted, and hence the lower will be the market price of the resource.

Are we extracting non-renewable resources at the optimum rate?

If there are limited reserves of fossil fuels and other minerals, are we in danger that they will soon run out? Should we be more concerned with conservation?

In fact, the market provides an incentive to conserve such resources. As reserves run down, so the price of non-renewable resources will rise. This will create an incentive to discover alternatives. For example, as fossil fuels become more expensive, so renewable sources of energy, such as solar power, wind power and wave power, will become more economical. There will also be a greater incentive to discover new techniques of power generation and to conserve energy.

Markets, however, are imperfect. As we shall see in Chapter 12, when we consume natural resources, we do not take into account the full costs. For example, the burning of fossil fuels creates harmful environmental effects in the form of acid rain and the greenhouse effect, but these 'external' costs are not included in the price we pay.

Then there is the question of the distribution of income between present and future generations. If non-renewable resources are going to be expensive in the future, should we not be conserving these resources today in order to help our descendants? The problem is that consumers may well act totally selfishly, saying, 'Why should we conserve resources? By the time they run out, we will be dead.' We almost certainly do care about the welfare of our children and grandchildren, but what about our great-great-grandchildren, whom we will never meet?

1. Will the market provide incentives for firms to research into energy-conserving techniques, if energy prices at present are not high enough to make the use of such techniques profitable?
2. How will the existence of monopoly power in the supply of resources influence their rate of depletion?
3. If the current generation wants to consume all non-renewable resources, is there any market solution to prevent this happening? (We will return to this in Chapter 13.)

Who are the poor? Who are the rich?

We have been building up an answer to these questions as this chapter has progressed. The final part of the answer concerns the ownership of land and capital. Many people own no land or capital at all. These people will therefore earn no profit, rent or interest.

For those who are fortunate enough to own productive assets, their income from them will depend on (a) the quantity they own and (b) their rental value.

The quantity of assets owned

This will depend on the following:

- Inheritance. Some people have rich parents who leave them substantial amounts of land and capital.
- Past income and savings. If people have high incomes and save a large proportion of them, this helps them to build up a stock of assets.
- Skill in investment (entrepreneurial skill). The more skilful people are in investing and in organising production, the more rapidly will their stock of assets grow.
- Luck. When people open up a business, there are usually substantial risks. The business might flourish or fail.

The rental value

This is the income earned per unit of land and capital. It will depend on the following:

- The level of demand for the factor. This depends on the factor's *MRP*, which in turn depends on its physical productivity (*MPP*) and the demand for the good it produces and hence the good's *MR*.
- The elasticity of demand for the good. The greater the monopoly power that capital owners have in the goods market, the less elastic will be the demand for the product and the greater will be the supernormal returns they can earn on their capital.
- The elasticity of supply of the factor. The less elastic its supply, the more factor owners can gain from a high demand. The high demand will simply push up the level of economic rent that the factor will earn.
- The total factor supply by other factor owners. The further to the left the total factor supply curve, the higher the level of economic rent that each unit of the factor can earn for any given level of demand.

Thus if you are lucky enough to have rich parents who leave you a lot of money when you are relatively young; if you are a skilful investor and save and reinvest a large proportion of your earnings; if you own assets that few other people own, and which produce goods in high demand: then you may end up very rich.

If you have no assets, you will have no property income at all. If at the same time you are on a low wage or are unemployed, then you may be very poor indeed.

Section summary

1. Rent on land, like the price of other factor services, is determined by the interaction of demand and supply. Its supply is totally inelastic (or nearly so). Its demand curve is downward sloping and will equal the *MRP* of land.
2. The price of land depends on its potential rental value (its marginal benefit) and the repayment costs of borrowing to pay for the land (its marginal cost). Equilibrium is where the two are equal.
3. People's income depends not only on their wages but on whether they own any land or capital, and, if they do, the rental value of these assets. This is the final element in determining the distribution of income in the economy.

END OF CHAPTER QUESTIONS

1. The wage rate that a firm has to pay and the output it can produce vary with the number of workers as follows (all figures are hourly):

Number of workers	1	2	3	4	5	6	7	8
Wage rate (AC_L) (£)	3	4	5	6	7	8	9	10
Total output (TPP_L)	10	22	32	40	46	50	52	52

Assume that output sells at £2 per unit.

- (a) Copy the table and add additional rows for TC_L , MC_L , TRP_L and MRP_L . Put the figures for MC_L and MRP_L in the spaces between the columns.
 - (b) How many workers will the firm employ in order to maximise profits?
 - (c) What will be its hourly wage bill at this level of employment?
 - (d) How much hourly revenue will it earn at this level of employment?
 - (e) Assuming that the firm faces other (fixed) costs of £30 per hour, how much hourly profit will it make?
 - (f) Assume that the workers now formed a union and that the firm agreed to pay the negotiated wage rate to all employees. What is the maximum to which the hourly wage rate could rise without causing the firm to try to reduce employment below the level of (b) above? (See Figure 10.10.)
 - (g) What would be the firm's hourly profit now?
2. If a firm faces a shortage of workers with very specific skills, it may decide to undertake the necessary training

itself. If, on the other hand, it faces a shortage of unskilled workers, it may well offer a small wage increase in order to obtain the extra labour. In the first case, it is responding to an increase in demand for labour by attempting to shift the supply curve. In the second case, it is merely allowing a movement along the supply curve. Use a demand and supply diagram to illustrate each case. Given that elasticity of supply is different in each case, do you think that these are the best policies for the firm to follow? What would happen to wages and economic rent if it used the second policy in the first case?

3. Why do the world's top footballers earn millions of pounds per year, while the top lacrosse players are paid less than the equivalent of £30 000?
4. For what reasons is the median hourly wage rate of women some 16 per cent lower than that of men in the UK, and the average gross weekly pay, including overtime, more than 21 per cent less?
5. Given the analysis of bilateral monopoly, if the passing of minimum wage legislation forces employers to pay higher wage rates to low-paid employees, will this necessarily cause a reduction in employment?
6. Using a diagram like Figure 10.13, demonstrate what will happen under perfect competition when there is an increase in the productivity of a particular type of capital. Consider the effects on the demand, price (rental rate) and quantity supplied of the services of this type of capital.
7. What factors could cause a rise in the market rate of interest?
8. How is the market price of land related to its productivity?
9. In recent years there have been a number of changes in planning laws to make it easier for commercial properties to be converted to housing. What would be the impact on property values?

12	Markets, Efficiency and the Public Interest	347
13	Environmental Policy	391
14	Government Policy towards Business	421

We now turn to the application of microeconomics and its role in government policy. In Part C we looked at *how* market economies function at a micro level. In Part D we examine the various policies that can be adopted to deal with shortcomings of the market system.

There are various questions that governments will ask. How much monopoly power is too much? How equal do we want the distribution of income to be? How can we make markets more efficient? How can we protect the environment and prevent the depletion of resources? How can we prevent climate change?

In Chapter 11 we look at policies that address the distribution of income. In Chapter 12 we examine the issue of market failure and consider the potential for government intervention. Finally, in Chapters 13 and 14 we turn to government policies with respect to the environment and business.

Conclusions	344

In Chapter 10 we saw that there are considerable differences in wage rates, and that these depend on market conditions. Similarly, we saw that differences in rewards to owners of capital and land also depend on their respective markets.

But differences in factor rewards are only part of the explanation of inequality. In this chapter, we open out the analysis. We take a more general look at why some people are rich while others are poor, and consider the overall degree of inequality in our society: a society that includes the super-rich, with their luxury yachts, and people living in slum conditions, with not enough to feed themselves or their children. We will see how the gap between rich and poor has tended to widen over time.

We will show how inequality can be measured so that we can make comparisons over time and between countries. We will also look at how incomes are distributed between particular groups, whether by occupation, age, sex, household composition or geographical area.

The second part of the chapter considers what can be done to reduce inequality. Is the solution to tax the rich heavily, so that the money can be redistributed to the poor? Or might this discourage people from working so hard? Would it be better, then, to focus on benefits and increase the support for the poor? Or might this discourage people from taking on work for fear of losing their benefits? We look at the attitudes of governments and at some of the debates taking place today over how to reduce inequality without discouraging effort or initiative.

11.1 INEQUALITY AND POVERTY

Inequality is one of the most contentious issues in the world of economics and politics. Some people have incomes far in excess of what they need to enjoy a luxurious lifestyle, while others struggle to purchase even necessities.

The need for some redistribution from rich to poor is broadly accepted across the political spectrum. Thus the government taxes the rich (and those who most would agree are not rich) and transfers some of the proceeds to the poor, either as cash benefits or as benefits in kind. Nevertheless, there is considerable disagreement as to the appropriate amount of redistribution.

Whether the current distribution of income is desirable or not is a normative question. Economists therefore should not specify how much the government should redistribute incomes. However, economists do have a role to play in the analysis of inequality and in assessing the impact of policies. They can do the following:

- Identify the extent of inequality and analyse how it has changed over time.
- Explain why a particular level of income distribution occurs and what causes inequality to grow or to lessen.
- Examine the relationship between equality and other economic objectives such as efficiency.
- Identify various government policies to deal with problems of inequality and poverty.
- Examine the effects of these policies, both on inequality itself and on other questions such as efficiency, inflation and unemployment.
- Examine the effect of other policies, such as the reduction of the budget deficit, on inequality and poverty.

Types of inequality

There are a number of different ways of looking at the distribution of income and wealth.

The distribution of income

There are three broad ways of examining the distribution of income. First we can look at how evenly incomes are distributed among the population. This is known as the **size distribution of income**. It can be expressed between *households*, or between *individual earners*, or between *all individuals*. It can be expressed either *before* or *after* the deduction of taxes and the receipt of benefits. For example, we might want to know the proportion of pre-tax national income going to the richest 10 per cent of households.

Then there is distribution between different *factors of production*, known as the **functional distribution of income**. At the *broader* level, we could look at the distribution between the general factor categories: labour, land and capital. At a *narrower* level, we could look at distribution within the factor categories. Why are some jobs well paid while others are

badly paid? Why are rents higher in some areas than in others? We looked at this distribution in Chapter 10.

Finally, there is the question of the **distribution of income by class of recipient**. This can be by *class of person*: women, men, single people, married people, people within a particular age group or ethnic group, and so on. Alternatively, it can be by *geographical area*. Typically, this is expressed in terms of differences in incomes between officially defined regions within a country.

The distribution of wealth

Income is a *flow*. It measures the receipt of money per period of time (e.g. £25 000 per year). Wealth, by contrast, is a *stock* (see Box 10.10). It measures the value of a person's assets at a particular point in time. The distribution of wealth can be measured as a size distribution (how evenly it is distributed among the population); as a functional distribution (the proportion of wealth held in various forms, such as dwellings, land, company shares, bank deposits, etc.); or according to the holders of wealth, classified by age, sex, geographical area, etc.

Analysis of incomes below a certain level: the analysis of poverty

A major problem here is in defining just what is meant by poverty. The dividing line between who is poor and who is not is necessarily arbitrary. Someone who is classed as poor in the UK may seem rich to an Ethiopian.

The extent and nature of poverty can be analysed in a number of ways:

- The number or proportion of people or households falling into the category.
- The occupational distribution of poverty.
- The geographical distribution of poverty.
- The distribution of poverty according to age, sex, ethnic origin, marital status, educational attainment, etc.

Definitions

Size distribution of income Measurement of the distribution of income according to the levels of income received by individuals (irrespective of source).

Functional distribution of income Measurement of the distribution of income according to the source of income (e.g. from employment, from profit, from rent, etc.).

Distribution of income by class of recipient Measurement of the distribution of income between the classes of person who receive it (e.g. homeowners and non-homeowners or those in the north and those in the south).

p29KI 26
p303

It is not possible in this chapter to look at all aspects of inequality in the UK. Nevertheless some of the more important facts are considered, along with questions of their measurement and interpretation.

The size distribution of income in the UK

Figure 11.1 shows the size distribution of income in the UK. It covers income from all sources. In each chart, households are grouped into five equal-sized groups or *quintiles*, from the poorest 20 per cent of households up to the richest 20 per cent. (The general term for division into equal-sized groups is *quantiles*.) The following points can be drawn from these statistics:

- In 2015/16, the richest 20 per cent of households earned just over 48 per cent of national income, and even after the deduction of taxes this was still 40 per cent.
- The poorest 20 per cent, by contrast, earned a mere 4.1 per cent of national income, and even after the receipt of cash benefits this had risen to only 7.8 per cent.

Inequality grew dramatically in the 1980s and did not begin to fall again until 2000, and then only very slightly. Between 1977 and 2015/16 the post-tax-and-benefits share of national income of the bottom 40 per cent of households

fell from 23 per cent to 20.2 per cent, while the share of the top 20 per cent grew from 37 per cent to 40 per cent.

As measured by quintiles or even deciles (10 equal-sized groups), income inequality in the UK has changed relatively little in the past few years. However, those on the very highest incomes – the top 1 per cent and especially the top 0.1 per cent – have seen an enormous growth in their incomes, with the very rich getting a lot richer. Although there was a slight fall in the top income group's share of national income directly following the financial crisis, the gap has widened again since. A similar picture has emerged in many other developed countries.

Effects of taxes and benefits. As we shall see in section 11.2, by taxing the rich proportionately more than the poor, taxes can be used as a means of reducing inequality. In the UK, however, indirect taxes (e.g. on tobacco and alcohol) are paid proportionately more by the poor and so have the opposite effect. In 2015/16, the lowest-earning quintile of households paid 11 per cent of their gross income (original income plus cash benefits) in direct taxes (e.g. income tax, national insurance) while the highest-earning quintile paid 22.8 per cent.¹ When we look at indirect taxes, however, we see that the poorest quintile paid 29.7 per cent of their gross income in such taxes while the richest quintile paid only 15 per cent. This more than offsets the redistributive effect from direct tax being paid proportionately more by the rich. The top quintile paid approximately 38 per cent of their gross income in tax while the bottom quintile paid approximately 40 per cent.

Redistribution of income in the UK, therefore, is achieved mainly through the benefits system.

Measuring the size distribution of income

Apart from tables and charts, two of the most widely used methods for measuring inequality are the *Lorenz curve* and the *Gini coefficient*.

Lorenz curve

Figure 11.2 shows the *Lorenz curve* for the UK based on pre-tax (but post-benefit) incomes.

The horizontal axis measures percentages of the population from the poorest to the richest. Thus the 40 per cent point represents the poorest 40 per cent of the population. The vertical axis measures the percentage of national income they receive.

The curve starts at the origin: zero people earn zero incomes. If income were distributed totally equally, the Lorenz curve would be a straight 45° line. The 'poorest' 20 per cent of the population would earn 20 per cent of national income; the 'poorest' 60 per cent would earn 60 per cent, and so on. The curve ends up at the top right-hand corner, with 100 per cent of the population earning 100 per cent of national income.

In practice, the Lorenz curve will 'hang below' the 45° line. Point *x*, for example, shows a country where the poorest 50 per cent of households receive only 24 per cent of national income. The further the curve drops below the 45° line, the greater will be the level of inequality.

The Lorenz curve is quite useful for showing the change in income distribution over time. From 1949 to 1979 the curve for the UK moved inwards towards the 45° line, suggesting a lessening of inequality. Then from 1979 to 1990 it moved downwards away from the 45° line, suggesting a deepening of inequality. Since 1990 it has remained approximately the same.

The problem with simply comparing Lorenz curves by eye is that it is imprecise. This problem is overcome by using Gini coefficients.

Gini coefficient

The *Gini coefficient* is a precise way of measuring the position of the Lorenz curve. It is the ratio of the area between the Lorenz curve and the 45° line to the whole area below the 45° line. In Figure 11.2 this is the ratio of the shaded area *A* to the whole area (*A* + *B*), sometimes expressed as a percentage.

If income is equally distributed so that the Lorenz curve follows the 45° line, area *A* disappears and the Gini coefficient is zero. As inequality increases, so does area *A*, and the Gini coefficient rises. In the extreme case of total inequality, where one person earns the whole of national income, area *B* would disappear and the Gini coefficient would be 1. Thus the Gini coefficient will be between 0 and 1. The higher the figure, the greater is the measure of inequality.

In 1979, the *gross income* (original income plus cash benefits) Gini coefficient in the UK was 0.30 (see Figure 11.3). With the growth in inequality during the 1980s, the

Figure 11.2 Lorenz curve

coefficient steadily increased and stood at 0.39 in 1990. Since then it has remained relatively stable (fluctuating between 0.35 and 0.39). The *post-tax* coefficient (gross income minus both direct and indirect taxes) rose even more dramatically – from 0.29 in 1979 to 0.41 in 1990. It was 0.35 in 2015/16 (see Figure 11.3). In terms of *disposable income* (gross income minus just direct taxes), a similar pattern emerged, but by excluding indirect taxes, which, as we have seen, are paid proportionately more by the poor, the Gini coefficient was lower in all years.

Figure 11.4 shows the Gini coefficients for a selection of countries for the latest year available from 2013 to 2015. These are based on *disposable income*: that is, income after the deduction of taxes and the receipt of cash benefits (transfers). They also include the value of goods produced for own consumption as an element of self-employed income. As you can see, Iceland had the lowest Gini coefficient (0.246) and hence was the most equal. Other Scandinavian countries were also relatively equal. The most unequal country in the sample was South Africa (0.620), followed by China (0.556). The average of the 34 developed countries that form the Organisation for Economic Co-operation and Development (OECD) was 0.333, more equal than both the USA (0.390) and the UK (0.360).

Gini coefficients have the advantage of being relatively simple to understand and use. They provide a clear way of comparing income distribution either in the same country at different times, or between different countries.

Definitions

Lorenz curve A curve showing the proportion of national income earned by any given percentage of the population (measured from the poorest upwards).

Gini coefficient The area between the Lorenz curve and the 45° line divided by the total area under the 45° line.

Figure 11.3 UK Gini coefficients: 1977 to 2015/16

Note: From 1994/5 the figures refer to financial years ending in the year shown.
 Source: *Household Disposable Income and Inequality* (ONS, 2017).

Figure 11.4 Gini coefficients for selected countries, based on disposable income: latest year, 2013–15

Source: Based on data in *Household Disposable Income and Inequality, financial year ending 2016* (ONS dataset, January 2017)

Figure 11.5 Lorenz curves for two countries with the same Gini coefficients

However, they cannot take into account all the features of inequality. Take the case of the two countries illustrated in Figure 11.5. If area X is equal to area Y, they will have the same Gini coefficient, and yet the pattern of their income distribution is quite different.

Also it is important to note what statistics are used in the calculation. Are they pre-tax or post-tax; do they include benefits; do they include non-monetary incomes (such as food grown for own consumption: a major item in many developing countries); are they based on individuals, households or tax units?

? In which country in Figure 11.5 would you expect to find the highest number of poor people? Describe how income is distributed in the two cases.

Ratios of the shares in national income of two quantile groups

This is a very simple method of measuring income distribution. A ratio quite commonly used is that of the share of national income of the *bottom 40 per cent* of the population to that of the *top 20 per cent*. Thus if the bottom 40 per cent earned 15 per cent of national income and the top 20 per cent earned 50 per cent of national income, the ratio would be $15/50 = 0.3$. The lower the ratio, therefore, the greater the inequality. Some figures are shown in Table 11.1.

As can be seen from the table, South Africa is the most unequal country with a ratio of just 0.10 (its Gini coefficient in 2011 was 0.634). Zambia and Brazil also have high levels of inequality. Some of the former communist countries such as Hungary and Romania have greater levels of equality. Generally, advanced countries are more equal than developing countries. Western European countries typically have a ratio of between 0.4 and 0.65. For example, the UK has a figure of 0.49. The USA, however, is less equal, with a ratio of around 0.33.

1. Why do you think that the ratios for developing countries are lower than those for developed countries?
2. Make a list of reasons why the ratios of the bottom 40 per cent to the top 20 per cent may not give an accurate account of relative levels of inequality between countries.
3. What would the ratio be if national income were absolutely equally distributed?

Do earnings statistics give a true representation of inequality?

Although the size distribution of income gives a good first indication of inequality, there are various factors that need to be taken into account when interpreting the statistics.

The first is the diminishing marginal utility of income. If a rich person spends twice as much as a poor person, does that mean that they get twice as much utility? The answer is probably no. The more you earn and spend, the less additional utility you will get for each extra amount spent (see page 131). Part of the reason is that you buy more luxurious versions of products. The argument here is that a car costing £40 000 will not give you four times as much utility as one costing £10 000.

The second factor concerns the interpretation of changes in inequality over time. The past 30 years have seen income increases skewed towards the rich, with the top 10 per cent of income earners getting a lot richer, while the incomes of the poor have risen very little. As we have seen, from 1979 to 2015/16 the Gini coefficient of post-tax income in the UK rose from 0.29 to 0.36.

Although it appears from these figures that inequality has grown rapidly, there may have been factors that mitigate against this. As people earn more, they spend proportionately more on services, such as childcare and personal trainers, and on luxury goods such as designer clothing and fast cars, and proportionately less on items such as basic foodstuffs and clothing. The argument here is that if the prices of these more luxurious goods and services rise faster than

Table 11.1

National income share of the poorest 40 per cent of the population as a proportion of the share of the richest 20 per cent

Country	Quantile ratio
South Africa	0.10
Zambia	0.17
Brazil	0.19
USA	0.33
India	0.46
UK	0.49
Hungary	0.55
Romania	0.62

Source: World Development Indicators: Distribution of Income or Consumption, Table 1.3 (The World Bank, various years).

those of more basic goods, the poor will experience a lower inflation rate than the rich. This is what happened over the period 1990–2005, meaning that inequality did not rise as fast as the simple statistics would suggest.

More recently, however, the inflation rate of the poor has overtaken that of the rich. Prices of food and energy have risen faster than those of luxury goods. This would suggest that more recent statistics may have *understated* the growth in inequality.

The third factor that needs to be taken into account when assessing inequality is the distribution of *wealth*. We consider this below (pages 325–6).

The functional distribution of income in the UK

Distribution of income by source

Figure 11.6 shows the sources of household incomes in 1977 and 2015/16. Wages and salaries constitute by far the largest element. However, their share fell from 73 per cent of national income between 1977 and 2015/16. Conversely, the share coming from total cash benefits and pensions rose from 16 per cent to 25 per cent, reflecting the growing proportion of the population past retirement age, the proportion of the population on low incomes and the stage of the economic cycle.

In contrast to wages and salaries, investment income (dividends, interest and rent) accounts for a relatively small percentage of household income – a mere 3 per cent in 2015/16. Nevertheless, some groups, typically elderly people, rely on savings interest as a key source of income. With policy makers reducing interest rates in 2008 in response to the credit crunch, many of these people suffered falls in their income. Nominal interest rates have remained at historically

low levels and for much of the 2009–17 period they have been below inflation. This has meant that for most savers real interest rates were negative. Conversely, those with large mortgages linked to the Bank of England's Bank Rate ('tracker mortgages'), found themselves with much smaller payments each month. There was thus a major redistributive effect away from net savers to net borrowers.

With the growth of small businesses and the increased numbers of people being 'employed' on a freelance basis, the proportion of incomes coming from self-employment has grown. It rose from 7 per cent in 1977 to 8 per cent in 2015, although this is lower than the 10 per cent seen in 2000/1.

The overall shares illustrated in Figure 11.6 hide the fact that the sources of income differ quite markedly between different income groups. These differences are shown in Table 11.2.

Column (1) shows that higher-income groups get a larger proportion of their income from wages and salaries than do lower-income groups. This can be largely explained by examining column (5). As would be expected, the poor tend to get a larger proportion of their incomes in cash benefits from the government than do people further up the income scale.

One feature to note is that the proportion of income coming from profits, rent and interest (column (3)) varies little between the income groups. In fact only for those people in the top 1 or 2 per cent is it significantly higher. The conclusion from this, plus the fact that investment incomes account for only 3 per cent of household incomes in total, is that incomes from capital and land are of only relatively minor significance in explaining income inequality.

The major cause of differences in incomes between individuals in employment is the differences in wages and salaries between different occupations.

Figure 11.6 Sources of UK household income as a percentage of gross household income

Source: Based on data in *Income and Source of Income for all UK Households*, Table 18 (National Statistics, 2017).

Table 11.2 Sources of UK household income as a percentage of total gross household income by quintile groups: 2015/16

Gross household weekly incomes (quintiles)	Wages and salaries (1)	Income from self-employment (2)	Income from investments (3)	Pensions and annuities (4)	Total cash benefits (5)	Other (6)	Total (7)
Lowest 20%	30	8	2	7	52	1	100
Next 20%	41	5	1	10	41	2	100
Middle 20%	60	7	1	10	20	2	100
Next 20%	69	7	2	11	10	1	100
Highest 20%	72	10	4	9	3	2	100
All households	63	8	3	10	15	1	100

Source: *Household Disposable Income and Inequality*, Table 2 (National Statistics, 2017).

Distribution of wages and salaries by occupation

Differences in full-time wages and salaries are illustrated in Figure 11.7. This shows the average gross weekly pay of full-time adult workers in selected occupations in 2016. As you can see, there are considerable differences in pay between different occupations. The causes of differences in wage rates from one occupation to another were examined in Chapter 10.

? If fringe benefits (such as long holidays, company cars and health insurance) were included, do you think the level of inequality would increase or decrease? Explain why.

Since the late 1970s, wage differentials have widened. Part of the explanation lies in a shift in the demand for labour. Many firms have adopted new techniques which require a more highly educated workforce. Wage rates in some of these skilled occupations have increased substantially.

At the same time, there has been a decline in the number of unskilled jobs in industry and, along with it, a decline in the power of unions to represent such people. Where low-skilled jobs remain, there will be pressure on employers to reduce wage costs if they are competing with companies based in developing countries, where wage rates are much lower.

Figure 11.7 Average gross weekly earnings (excluding overtime) of UK full-time adult employees (£): 2016

Source: Based on data in the *Annual Survey of Hours and Earnings*, Table 14.2a (National Statistics, 2016).

As prospects for unskilled people decline in industry, so people with few qualifications increasingly compete for low-paid, service-sector jobs (e.g. in supermarkets and fast-food outlets). The growth in people seeking part-time work has also kept wage rates down in this sector.

Other determinants of income inequality

Differences in household composition

Other things being equal, the more dependants there are in a household, the lower the income will be *per member* of that household. Figure 11.8 gives an extreme example of this. It shows the average household income in the UK in 2015/16 of four different categories of household.

Households containing one adult with children had slightly less gross income than households with only one adult. This means that they had a very much lower income *per member* of the household. This, however, was offset somewhat by the tax and benefits system, with the households with one adult and children having slightly more disposable income than households with just one adult. Disposable income *per member* of the household, however, was still considerably less.

There is a twin problem for many large households. Not only may there be relatively more children and elderly dependants, but also the total household income will be reduced if one of the adults stays at home to look after the family or works only part-time.

Differences by gender

Box 10.7 on pages 294–5 looked at some of the aspects of income inequality between the sexes. In 2016, the average gross weekly pay for full-time female employees was £562.10. For male employees it was £697.1. There are three important factors to note:

- Women are paid less than men in the same occupations. You will see this if you compare some of the occupations in Table (b) in Box 10.7.
- Women tend to be employed in lower-paid occupations than men.
- Women do less overtime than men (on average, 0.5 hours per week, compared with 1.5 for men).

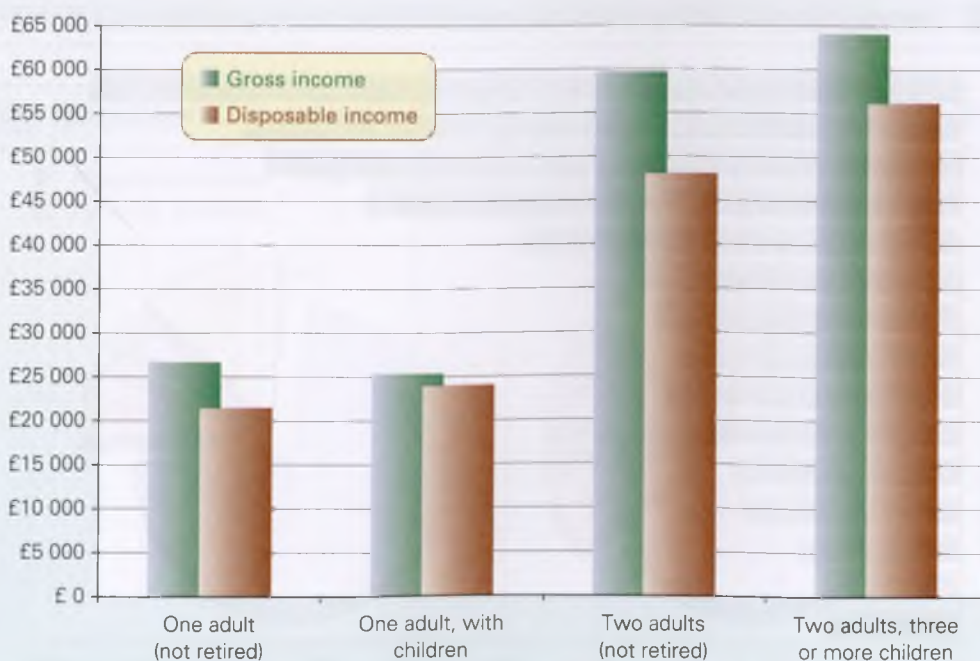

List the reasons for each of the three factors above. (Re-read section 10.2 and Box 10.7 if you need help.)

Differences in the geographical distribution of income

Figure 11.9 shows the gross yearly household incomes in different regions of the UK in 2014/15. Differences in incomes between the regions reflect regional differences in industrial structure, unemployment and the cost of living. As can be seen from the figure, average incomes are significantly lower in the North-East than in the South East of England and in London.

Figure 11.8 Yearly income for different types of UK households (£): financial year ending 2016

On a more local level, there are considerable differences in incomes between affluent areas and deprived areas. It is at this level that some of the most extreme examples of inequality can be observed, with 'leafy' affluent suburbs only a mile or two away from run-down estates. Regional inequality and local inequality are explored in Case Study 23.14 on the student website.

The distribution of wealth

Wealth is difficult to measure. Being a *stock* of assets (such as a house, land, furniture, personal possessions and investments), it has an easily measurable value only when it is sold. What is more, individuals are not required to keep any record of their assets. Only when people die and their assets are assessed for inheritance tax does a record become available. Official statistics are thus based on HMRC data of the assets of those who have died that year. These statistics are suspect for two reasons. First, the people who have died are unlikely to be a representative sample of the population. Second, many items are excluded, such as household and personal items, and items passed automatically to the surviving partner.

Figure 11.10 shows the composition of UK marketable wealth. Residential property is the largest component of wealth (51.7 per cent), followed by bank deposits and cash (15.7 per cent).

Inequality of wealth is far greater than inequality of income. The wealthiest 20 per cent of the adult population owned 64 per cent of aggregate total wealth in 2012–14 – 117

Figure 11.10 Composition of UK net personal wealth: average 2011–13

Source: Based on *UK Personal Wealth Statistics*, Table 13.1 (HMRC, September 2016).

times more than the least wealthy 20 per cent of households. The Gini coefficient for total wealth was 0.63 compared with a figure of 0.36 for post-tax income.

The four major causes of inequality in the distribution of wealth are as follows:

- **Inheritance.** This allows inequality to be perpetuated from one generation to another.
- **Income inequality.** People with higher incomes can save more.
- **Different propensities to save.** People who save a larger proportion of their income will build up a bigger stock of wealth.
- **Entrepreneurial and investment talent/luck.** Some people are successful in investing their wealth and making it grow rapidly.

Even though wealth is highly concentrated, there was a significant reduction in inequality of wealth up to the early 1990s. From 1971 to 1991 the Gini coefficient of wealth fell a full 16 percentage points from 0.80 to 0.64. A major reason for this was the increased taxation of inherited wealth. Since 1991, however, this reduction in inequality has been reversed somewhat. This can be explained by lower levels of inheritance tax and substantial rises in property prices and share values.

Causes of inequality

We turn now to identify the major causes of inequality. The problem has many dimensions and there are many factors that determine the pattern and depth of inequality. It is thus wrong to try to look for a single cause, or even the

major one. The following are possible determinants of inequality:

- **Inequality of wealth.** People with wealth are able to obtain an income other than from their own labour.
- **Differences in ability.** People differ in intelligence, strength, etc. Some of these differences are innate and some are acquired through the process of 'socialisation' – education, home environment, etc.
- **Differences in attitude.** Some people are adventurous, willing to take risks, willing to move for better jobs, keen to push themselves forward. Others are much more cautious.
- **Differences in qualifications.** These are reflections of a number of things: ability, attitudes towards study, access to good education, income of parents, etc.
- **Differences in hours worked.** Some people do a full-time job plus overtime, or a second job; others work only part-time.
- **Differences in job utility/disutility.** Other things being equal, unpleasant or dangerous jobs will need to pay higher wages.
- **Differences in power.** Monopoly power in the supply of factors or goods, and monopsony power in the demand for factors, is unequally distributed in the economy.
- **Differences in the demand for goods.** Factors employed in expanding industries will tend to have a higher marginal revenue product because their output has a higher market value.
- **Differences in household composition.** The greater the number of dependants relative to income earners, the poorer the average household member will be (other things being equal).

BOX 11.1

POVERTY IN THE PAST

CASE STUDIES AND APPLICATIONS

Consider from the following passage whether it is reasonable or even possible to compare poverty today with poverty in the 1800s.

Every great city has one or more slums, where the working class is crowded together. True, poverty often dwells in hidden alleys close to the palaces of the rich; but, in general, a separate territory has been assigned to it, where, removed from the sight of the happier classes, it may struggle along as it can.

The houses are occupied from cellar to garret, filthy within and without, and their appearance is such that no human being could possibly wish to live in them . . . the filth and tottering ruin surpass all description. Scarcely a whole window-pane can be found, the walls are crumbling, doorposts and window-frames loose and broken, doors of old boards nailed together, or altogether wanting in this thieves' quarter, where no doors are needed, there being nothing to steal. Heaps of garbage

and ashes lie in all directions, and the foul liquids emptied before the doors gather in stinking pools. Here live the poorest of the poor, the worst-paid workers with thieves and the victims of prostitution indiscriminately huddled together . . . and those who have not yet sunk in the whirlpool of moral ruin which surrounds them, sinking daily deeper, losing daily more and more of their power to resist the demoralising influence of want, filth, and evil surroundings.¹

1. *If we were to measure poverty today and in the nineteenth century in absolute terms, in which would there be the greater number of poor?*
2. *If we measure poverty in relative terms, must a society inevitably have a problem of poverty, however rich it is?*

1 F. Engels, *The Condition of the Working Class in England* (Progress Publishers, 1973), pp. 166–7.

- Discrimination by race, sex, age, social background, etc.
- Degree of government support. The greater the support for the poor, the less will be the level of inequality in the economy.
- Unemployment. When unemployment levels are high, this is one of the major causes of poverty.

Which of the above causes are reflected in differences in the marginal revenue product of factors?

Government attitudes towards inequality

Attitudes of the right. The political right sees inequality as having an important economic function. Factor price differences are an essential part of a dynamic market economy. They are the price signals that encourage resources to move to sectors of the economy where demand is growing, and away from sectors where demand is declining. If the government interferes with this process by taxing high incomes and subsidising low incomes, working people will not have the same incentive to gain better qualifications, to seek promotion, to do overtime, or to move for better jobs. Similarly, owners of capital will not have the same incentive to invest.

If inequality is to be reduced, claims the political right, it is better done by encouraging greater factor mobility. If factor supply curves are more elastic (greater mobility), then any shifts in demand will cause smaller changes in factor prices and thus less inequality. But how is greater mobility to be encouraged? The answer, they say, is to create a culture of self-help: where people are not too reliant on state support; where they will look for higher incomes of their own

volition. At the same time, they argue that the monopoly power of unions to interfere in labour markets should be curtailed. The net effect of these policies, they claim, would be to create a more competitive labour market which would help to reduce inequality as well as promoting economic growth and efficiency.

State support, say those on the right, should be confined to the relief of 'genuine' poverty. Benefits should be simply a minimum safety net for those who cannot work (e.g. the sick or disabled), or on a temporary basis for those who, through no fault of their own, have lost their jobs. Even at this basic level, however, the right argues that state support can discourage people from making more effort.

Attitudes of the centre and left. Although many in the political centre and on the left accept that there is a trade-off between equality and efficiency, they tend to see it as a far less serious problem. They claim that questions of efficiency and growth are best dealt with by encouraging investment. They argue that this can be achieved by creating an environment of industrial democracy where workers participate in investment decisions. This common purpose is in turn best achieved in a more equal and less individualistically competitive society. The left also sees a major role for government in providing support for investment: for example, through government-sponsored research, by investment grants or by encouraging firms to get together and plan a co-ordinated strategy.

These policies to achieve growth and efficiency, claims the left, will leave the government freer to pursue a much more active policy on redistribution.

Section summary

1. Inequality can be examined by looking at the size distribution of income, the functional distribution of income, the distribution of income by recipient, the distribution of wealth, or the extent and nature of poverty.
2. An analysis of the size distribution of income in the UK shows that inequality has grown over the past 30 to 40 years.
3. The size distribution of income can be illustrated by means of a Lorenz curve. The greater the inequality, the more bowed the curve will be towards the bottom right-hand corner.
4. Size distribution can also be measured by a Gini coefficient. This will give a figure between 0 (total equality) and 1 (total inequality). Income distribution can also be measured as the ratio of the share of national income of a given lower income quantile to that of a higher income quantile.
5. Wages and salaries constitute by far the largest source of income, and thus inequality can be explained mainly in terms of differences in wages and salaries. Nevertheless, state benefits are an important moderating influence on inequality and constitute the largest source of income for the poorest 20 per cent of households. Investment earnings are only a minor determinant of income except for the richest 1 or 2 per cent.
6. Other determinants of income inequality include differences in household composition, gender and where people live.
7. The distribution of wealth is less equal than the distribution of income.
8. Attitudes towards government redistribution of income vary among political parties. The political right stresses the danger that redistributive policies may destroy incentives. The best approach to inequality, according to the right, is to 'free up' markets so as to encourage greater mobility. The left, by contrast, sees fewer dangers in reducing incentives and stresses the moral and social importance of redistribution from rich to poor.

11.2 TAXES, BENEFITS AND THE REDISTRIBUTION OF INCOME

In this section, we will look at policies to redistribute incomes more equally, and in particular we will focus on the use of government expenditure and taxation. Redistribution is just one of three major roles for government expenditure and taxation. The second is to compensate for the failure of the market to allocate resources efficiently. We examine this role in the following three chapters. The third is to influence the overall level of activity in the economy. Adjusting government expenditure and/or taxation for this purpose is known as *fiscal policy* and is examined in Chapter 22.

TC 7
p81

The use of taxation and government expenditure to redistribute income

Taxation. If the rich are taxed proportionately more than the poor, the post-tax distribution of income will be more equal than the pre-tax distribution.

Subsidies. Subsidies are of two broad types. First, *cash benefits* can be seen as subsidies to people's incomes. They include such things as child benefit and old-age pensions. Second, *benefits in kind* provide subsidised goods and services, which may be provided free (e.g. education or bus travel) or at a reduced price (e.g. NHS dental treatment). Subsidies will lessen inequality if they account for a larger proportion of a poor person's income than a rich person's.

Although we shall focus mainly on the use of taxes and benefits, there are two other types of redistributive policy.

Legislation. Examples include minimum wage legislation (see Box 11.2) and anti-discrimination legislation.

Structural policies. These are policies where the government tries to alter those institutions and attitudes of society that increase or at least perpetuate inequalities. Examples of such policies include removing privileges, encouraging widening participation in higher education, promoting worker share ownership, encouraging industries to move to areas of high unemployment and encouraging the provision of crèche facilities at work.

Before we turn to look at the use of taxation and government expenditure to redistribute incomes, we must first look at what taxes are available to a government and what are the requirements of a good tax system.

The requirements of a good tax system

Whatever the purpose of taxation, when it comes to devising and administering particular taxes there are various principles that many people argue should be observed.

Horizontal equity. According to the principle of *horizontal equity*, people in the *same circumstances* should be taxed

equally. In other words, taxes should be levied impartially. For example, people earning the same level of income and with the same personal circumstances (e.g. number and type of dependants, size of mortgage, etc.) should pay the same level of income tax.

Is it horizontally equitable for smokers and drinkers to pay more tax than non-smokers and non-drinkers?

Vertical equity. According to the principle of *vertical equity*, taxes should be 'fairly' apportioned between rich and poor. What constitutes fairness here is highly subjective. No one likes paying taxes and thus a rich person's concept of a fair tax is unlikely to be the same as a poor person's. This whole question of using taxes as a means of redistributing incomes will be examined in detail below.

Equity between recipients of benefits. Under the *benefit principle*, it is argued that those who receive the most benefits from government expenditure ought to pay the most in taxes. For example, it can be argued that roads should be paid for from fuel tax. That way those who use the roads the most will pay the most towards their construction and maintenance.

1. *Does the benefit principle conflict with either vertical or horizontal equity?*
2. *Would this be a good principle to apply in the case of health care?*

In most cases, the benefits principle would be difficult to put into practice. There are two reasons why. First, a specific tax would have to be devised for each particular good and service provided by the state. Second, in the case of many goods and services provided by the state, it would be difficult to identify the amount of benefit received by each individual. Just how much benefit (in money terms) do you derive from street lighting, from the police, from clean air, etc.?

Cheapness of collection. Taxes cost money to collect. These costs should be kept to a minimum relative to the revenue they yield.

Definitions

Horizontal equity The equal treatment of people in the same situation.

Vertical equity The redistribution from the better off to the worse off. In the case of taxes, this means the rich paying proportionately more taxes than the poor.

Benefit principle of taxation The principle that people ought to pay taxes in proportion to the amount that they use government services.

Difficulty of evasion. If it is desirable to have a given tax, people should not be able to escape paying. A distinction is made between **tax evasion** and **tax avoidance**:

- Tax evasion is illegal. This is where, for example, people do not declare income to the tax authorities.
- Tax avoidance is legal, albeit from the government's point of view undesirable. This is where people try to find ways of managing their affairs so as to reduce their tax liability.

Measuring the extent of evasion and avoidance is inherently tricky, but every year HMRC publishes a figure for the 'tax gap'. In 2014/15 this was estimated at £36 billion or 6.5 per cent of tax revenues.

Tax avoidance is more likely to be practised by the rich than the poor – in part because they stand to gain more; in part because they can afford to pay for the specialist advice required. In a period of public-sector cuts, a great deal of attention has been focused on tax avoidance by large companies such as Google and Starbucks.

Non-distortion. Taxes alter market signals: taxes on goods and services alter market prices; taxes on income alter wages. They should not do this in an undesirable direction.

If prices are not distorted in the first place, it is best to use taxes that have the same percentage effect on prices of all goods and services. That way *relative* prices remain the same. For example, VAT in the UK is levied on most goods and services at a single rate of 20 per cent, increased in 2011 from the previous rate of 17.5 per cent. (There was a temporary cut to 15 per cent in 2009). If goods were taxed at different rates, this would create distortions, switching consumption and production from goods with high taxes to goods with low taxes.

If, however, the government feels that market prices are distorted in the first place, taxes can be used to alter price signals in the desired direction.

? *How can the market distortions argument be used to justify putting excise duties on specific goods such as petrol, alcohol and tobacco? Is this the only reason why excise duties are put on these particular products?*

Convenience to the taxpayer. Taxes should be *certain* and *clearly understood* by taxpayers so that they can calculate their tax liabilities. The method of payment should be *straightforward*.

Convenience to the government. Governments use tax changes as an instrument for managing the economy. Tax rates should thus be *simple to adjust*. Also, the government will need to be able to *calculate* as accurately as possible the effects of tax changes, both on the total tax yield and on the distribution of the burden between taxpayers.

Minimal disincentive effects. Taxes may discourage people from working longer or harder, from saving, from investing or from taking initiative. For example, a high rate of income tax may discourage people from seeking promotion or from doing overtime. 'What is the point', they may say, 'if a large proportion of my extra income is taken away in taxes?' It is desirable that these disincentives should be kept to a minimum.

Of course, not all these requirements can be met at the same time. There is no perfect tax. The government thus has to seek a compromise when there is a conflict between any of the requirements. One of the most serious conflicts is between vertical equity and the need to keep disincentives to a minimum. The more steeply the rich are taxed, it is argued, the more serious are the disincentive effects on them likely to be. This particular conflict is examined below.

Types of tax

Taxes can be divided into two broad categories. **Direct taxes** are paid directly by the taxpayer to the tax authorities. Such taxes include personal income tax, tax on companies' income and tax on capital and wealth. **Indirect taxes**, on the other hand, are paid via a middle person. For example, value added tax (VAT) is designed to be a tax on consumption. But you the consumer do not pay it to the authorities: it is paid by firms, which then pass it on to consumers in higher prices (see section 3.2). You are thus taxed indirectly when you buy goods and services.

Direct taxes

Personal income tax. All types of income are included – wages, salaries, interest, dividends and rent. In most countries, people can earn a certain amount of income free of tax: this is known as their personal **tax allowance**. In many countries, employees' income tax is paid directly on their behalf by their employers. In the UK this is known as the pay-as-you-earn scheme (PAYE).

Definitions

Tax evasion The illegal non-payment of taxes (e.g. by not declaring income earned).

Tax avoidance The rearrangement of one's affairs so as to reduce one's tax liability.

Direct taxes Taxes on income and wealth. Paid directly to the tax authorities on that income or wealth.

Indirect taxes Taxes on expenditure. Paid to the tax authorities not by the consumer, but indirectly by the suppliers of the goods or services.

Tax allowance An amount of income that can be earned tax-free. Tax allowances vary according to a person's circumstances.

BOX 11.2 MINIMUM WAGE LEGISLATION

A way of helping the poor?

The Labour government introduced a statutory UK minimum wage in April 1999. The rate was set at £3.60 per hour for those aged 22 and over, and £3.00 for those between 18 and 21. In 2004, an additional rate was introduced for 16 and 17 year-olds and in 2010 for apprentices aged 16–18 and those aged 19 in the first year of their apprenticeship. In 2015, George Osborne announced that a new statutory 'national living wage' would be introduced in April 2016. This is effectively a new higher minimum wage for those workers aged 25 and above.

The rates are increased every year and were set at the following levels for 2017/18.

• 25 and over	£7.50
• 21 to 24	£7.05
• 18 to 20	£5.60
• Under 18	£4.05
• Apprentice	£3.50

As of January 2017, 22 of out the 28 EU member countries had a national minimum wage. The rates vary among the member states from €2.19 in Latvia to €11.53 in Luxembourg. Once adjustments have been made to take account of the different price levels, the ratio between the highest and lowest rates falls from 8.5:1 to 3.3:1. The UK has the seventh highest figure.

The call for a minimum wage in the UK grew during the 1990s as the number of low-paid workers increased. There were many people working as cleaners, security guards and shop assistants who were receiving very low rates of pay, sometimes less than £2 per hour. Several factors explain the growth in the size of the low-pay sector.

Lower demand for unskilled labour. Increased unemployment since the early 1980s had shifted the balance of power from

workers to employers. Employers were able to force many wage rates downwards, especially those of unskilled workers.

Growth in part-time employment. Changes in the structure of the UK economy, particularly the growth in the service sector and the growing proportion of women seeking work, had led to an increase in part-time employment and zero hours contracts, with many part-time workers not receiving the same rights and hourly pay as their full-time equivalents until 2000.

Changes in labour laws. The abolition of 'wages councils' in 1993, which had set legally enforceable minimum hourly rates in various low-paid industries, and the introduction of various new laws to reduce the power of labour (see page 290) had left low-paid workers with little protection.

Assessing the arguments

The principal argument against imposing a national minimum wage concerns its impact on employment. If you raise wage rates above the equilibrium level, there will be surplus labour: i.e. unemployment (see Figure 10.9 on page 289). However, the impact of a national minimum wage on employment is not so simple.

In the case of a firm operating in competitive labour and goods markets, the demand for low-skilled workers is relatively wage sensitive. Any rise in wage rates, and hence prices, by this firm alone would lead to a large fall in sales and hence in employment. But given that all firms face the minimum wage, individual employers are more able to pass on higher wages in higher prices, knowing that their competitors are doing the same.

When employers have a degree of monopsony power, however, it is not even certain that they would want to reduce

The marginal rate of income tax is the rate that people pay on additional income. In most countries, the marginal rate increases in bands as people earn more. In many countries, there is a main marginal rate of tax that most people pay. This is known as the standard or *basic rate of tax*.

The *average* rate is a person's total income tax as a fraction of total income. This will always be less than the marginal rate, since part of a person's income will be tax-free; and for higher tax rate payers, part will be taxed at lower rates.

Definition

Basic rate of tax The main marginal rate of tax, applying to most people's incomes.

Individuals' social security contributions. In the UK these are known as national insurance contributions (NICs). These are like income taxes in that they are generally charged as a percentage of a person's income, the marginal rate varying with income. Unlike other taxes, which are paid into a common fund to finance government expenditure, they are used to finance *specific* expenditure: namely, pensions and social security. Although they do not officially count as 'taxes', to all intents and purposes they are so.

Table 11.3 and Figure 11.11 show the marginal and average rates of income tax and social security contributions in England, Wales and Northern Ireland in 2017/18. Notice that above £100 000, the personal allowance is reduced by £1 for each £2 earned. This is equivalent to an extra 20 per cent for the next £23 000 (i.e. $£11500 \times 2$).

employment. Remember what we argued in Figure 10.10 (on page 289) when we were examining the effects of unions driving up wages. The argument is the same with a minimum wage. The minimum wage can be as high as W_2 and the firm will still want to employ as many workers as at W_1 . The point is that the firm can no longer drive down the wage rate by employing fewer workers, so the incentive to cut its workforce has been removed.

In the long run, the effect on unemployment will depend on the extent to which the higher wages are compensated by higher labour productivity.

Evidence from the USA and other countries suggested that modest increases in the minimum wage had a neutral effect upon employment. Similarly in the UK, there is little evidence to suggest that from 1999 employers responded by employing fewer workers. In fact, until 2008, unemployment rates fell every year, due to the buoyant economy and increasing labour market flexibility (see Box 10.8).

Whether there would continue to be little effect if the minimum wage were to rise substantially is another matter. The question for policy makers, then, seems to be how high the minimum wage can be set before unemployment begins to rise.

Impact of the minimum wage in the UK

The Low Pay Commission estimated that 2.3 million people (8.5 per cent of workers) would be on one of the minimum wage rates from April 2017. This figure was below 500 000 in 2001. If the increases in the NLW are introduced as planned, then by 2020 3.3 million workers will be covered. Evidence suggests that there is also a *ripple effect* on workers earning just above the minimum wage rates. The growth in pay in 2015/16 for those in the bottom quarter of the pay

distribution (i.e. earning up to £9 per hour) was greater than the average.

There has been criticism of the UK government for ‘hijacking’ the term ‘National Living Wage’. The term ‘living wage’ has been used for several years by the Living Wage Foundation. It is independently calculated each year by the Resolution Foundation ‘based on what employees and their families need to live’. In 2017, it was £9.75 in London and £8.45 in other parts of the UK for all workers over 18.

One concern for economists, when assessing the national minimum wage, is that living costs, and particularly housing costs, vary substantially across the economy. For example, 22 per cent of workers in the local authority of West Somerset are covered by the latest rates, whereas the figure for Westminster is just 3 per cent. There have been suggestions that *local* minimum wages rates should be set to ensure both a fairer and a more efficient allocation of resources.

Of course, a weakness of using a minimum wage as a means of relieving poverty is that it only affects the employed; yet one of the main causes of poverty is unemployment. This, in part, explains the focus on getting adults into work as the major plank of poverty relief policy in the UK. It is apparent that a minimum wage rate cannot be the sole answer to poverty and must be considered in conjunction with benefits.

1. If an increase in wage rates for low-paid workers leads to their being more motivated, how would this affect the marginal revenue product and the demand for such workers? What implications does your answer have for the effect on employment in such cases? (See page 291 on the efficiency wage hypothesis.)
2. If a rise in the minimum wage encourages employers to substitute machines for workers, will this necessarily lead to higher long-term unemployment in (a) that industry and (b) the economy in general?

Table 11.3 UK¹ marginal income tax and national insurance rates: 2017/18

Income per annum (£)	Marginal income tax rate (%)	Marginal NIC rate (%)	Marginal income tax plus NIC rate (%)
0–8164	0	0	0
8165–11 500	0	12	12
11 501–45 000	20	12	32
45 001–100 000	40	2	42
100 001–123 000	40 + 20	2	62
123 001–150 000	40	2	42
Above 150 000	45	2	47

¹ The structure is very similar in Scotland but the Scottish Government used its devolved powers to leave the income threshold at which people pay 40 per cent income tax at £43 000 in 2017/18.

Employers’ social security contributions. Employers also have to pay social security contributions on behalf of their employees. These are paid per employee. In some countries, small firms pay reduced rates.

Tax on corporate income. In the UK this is known as corporation tax. It is a tax on the profits of limited companies. In most countries, there are lower rates for small companies. Profits can usually be offset against capital expenditure and interest payments when working out the tax liability. This effectively means that profits that are reinvested are not taxed.

Tax on capital gains. This is a tax payable when a person sells assets, such as property or shares. It is payable on the gain in value of these assets since a set date in the past, or since they were purchased if this was after the set date.

Figure 11.11 UK² marginal and average rates of income tax plus national insurance contributions, 2017/18

²The threshold at which people pay 40 per cent income tax in Scotland is £43 000 in 2017/18

Taxes on wealth. These are taxes on assets held or acquired by individuals. One form of wealth tax in most countries is that on inherited assets or assets transferred before a person's death. Another is taxes based on the value of a person's property. This is a particularly common form of local taxation (the others being local income tax, local business tax and local sales tax).

Poll taxes. These are fixed-sum charges per head of the population, irrespective of the person's income. Very few countries use such taxes as they are regarded as unfair. A poll tax (or 'community charge') was introduced in Scotland in 1989 and in England and Wales in 1990 as the new form of local tax, replacing the property tax called 'rates', which was based on property values. But it was massively unpopular with the electorate, leading to demonstrations and riots, and was replaced by 'council tax' (again based on property values) in 1993.

Indirect taxes

There are three main types of indirect tax, all of which are taxes on *expenditure*.

General expenditure taxes. An example of this is **value added tax (VAT)**. This is the main indirect tax throughout the EU. VAT is paid on the value that firms add to goods and services at each stage of their production and distribution. For example, if a firm purchases supplies costing £10 000 and

with them produces goods that it sells for £15 000 (before VAT), it is liable to pay VAT on the £15 000 minus £10 000: in other words, on the £5000 value it has added. Suppliers must provide invoices to show that the VAT has already been paid on all the inputs.

The example in Table 11.4 can be used to show how the tax eventually gets passed on to the consumer. For simplicity's sake, assume that the rate of VAT is 20 per cent and that each firm uses only one supplier.

The value added at each stage plus VAT adds up to the total amount paid by the consumer: £48 000 in this case. The total VAT paid, therefore, amounts to a tax on the consumer. In the example, the £8000 VAT is 20 per cent of the (pre-tax) consumer price of £40 000.

The rates of VAT in the various EU countries are considered in Box 24.10. Each country has a standard rate and up to two lower rates for basic goods and services. Standard rates vary between 15 and 27 per cent, but are typically between 20 and 25 per cent.

Definition

Value added tax (VAT) A tax on goods and services, charged at each stage of production as a percentage of the value added at that stage.

Table 11.4 Calculating VAT: an example where the rate of VAT is 20%

	Value added	VAT	Value added plus VAT	Price sold to next stage
	(1)	(2)	(3)	(4)
Firm A sells raw materials to firm B for £12 000	£10 000	£2000	£12 000	£12 000
Firm B processes them and sells them to a manufacturer, firm C, for £21 600	£8 000	£1600	£9 600	£21 600
Firm C sells the manufactured goods to a wholesaler, firm D, for £30 000	£7 000	£1400	£8 400	£30 000
Firm D sells them to a retailer, firm E, for £36 000	£5 000	£1000	£6 000	£36 000
Firm E sells them to consumers for £48 000	£10 000	£2000	£12 000	£48 000
	£40 000	£8000	£48 000	

Many other countries levy general expenditure taxes at a single stage (either wholesale or retail). These taxes are called *purchase taxes* and will normally be a percentage of the price of the good at that stage.

Excise duties. These are taxes on particular goods and services: for example, petrol and diesel, alcoholic drinks, tobacco products and gambling. They are a single-stage tax levied on the manufacturer. For example, duty on beer in the UK depends on its alcoholic strength measured as alcohol by volume (ABV). If the ABV of the beer is between 2.8 per cent and 7.5 per cent then the rate of duty in 2017/18 is 19.08 pence per litre for each 1 per cent of ABV. This means that the duty paid on a 5 per cent ABV pint of beer would be 54p. Duty is paid in addition to VAT.

VAT is an *ad valorem tax*. This means that the tax is levied at a *percentage* of the value of the good. The higher the value of the good, the higher the tax paid. Excise duties, by contrast, are a *specific tax*. This means that they are levied at a *fixed amount*, irrespective of the value of the good. Thus the duty on a litre of unleaded petrol is the same for a cut-price filling station as for a full-price one.

Customs duties. Economists normally refer to these as *tariffs*. They are duties on goods imported from outside the country.

To what extent do (a) income tax, (b) VAT and (c) a poll tax meet the various requirements for a good tax system on pages 328–9 above? (Some of the answers to this question are given below.)

Details of tax rates in the UK are given in Case Study 11.3 on the student website. This case study also examines how progressive or regressive the various types of tax are.

The balance of taxation

Table 11.5 shows the balance of the different types of tax in selected countries. Some striking differences can be seen between the countries. In France, income and capital gains

Definition

Ad valorem tax A tax on a good levied as a percentage of its value. It can be a single-stage tax or a multi-stage tax (as with VAT).

Specific tax A tax on a good levied at a fixed amount per unit of the good, irrespective of the price of that unit.

Tariff A tax on imported goods.

Table 11.5 Balance of taxation in selected countries (2015)

Types of tax as percentage of GDP	France	Germany	Japan	Sweden	UK	USA
Personal income tax and capital gains tax	8.6	9.9	6.1	12.5	9.1	10.7
Social security: employee and self-employed contributions	5.6	7.4	6.9 ¹	2.7	2.5	3.2
Social security: employer contributions	11.3	6.6	5.8 ¹	7.0	3.5	3.1
Corporate taxes	2.1	1.7	4.3	3.0	2.5	2.2

¹ 2014.

Source: Extracted from Revenue statistics tables in *StatExtracts* (OECD).

taxes account for only 18.9 per cent of tax revenue, whereas in the USA they account for 40.5 per cent. In the UK, social security contributions (national insurance) are a lower percentage of total taxes than in other countries, whereas taxes on property (mainly the council tax) are a higher percentage of total taxes.

There is also a big difference between countries in the proportion of taxes paid by companies and that paid by individuals. Corporate taxes, payroll taxes and employer social security contributions account for 33.0 per cent of taxes and 15.0 per cent of GDP³ in France. In the USA they account for only 20.1 per cent of taxes and just 5.3 per cent of GDP.

In terms of total taxes, again there are large differences between countries. In France 45.5 per cent of GDP is paid in tax whereas in the USA the figure is only 26.4 per cent.

Taxes as a means of redistributing income

If taxes are to be used as a means of achieving greater equality, the rich must be taxed proportionately more than the poor. The degree of redistribution will depend on the degree of 'progressiveness' of the tax. In this context, taxes may be classified as follows:

- **Progressive tax.** As people's income (Y) rises, the percentage of their income paid in the tax (T) rises. In other words, the *average* rate of tax (T/Y) rises.
- **Regressive tax.** As people's income rises, the percentage of their income paid in the tax falls: T/Y falls.
- **Proportional tax.** As people's income rises, the percentage of their income paid in the tax stays the same: T/Y is constant.

In other words, progressiveness is defined in terms of what happens to the average rate of tax as incomes rise. (Note that it is not defined in terms of the *marginal* rate of tax.)

1. If a person earning £10 000 per year pays £1000 in a given tax and a person earning £20 000 per year pays £1600, is the tax progressive or regressive?
2. A proportional tax will leave the distribution of income unaffected. Why should this be so, given that a rich person will pay a larger absolute amount than a poor person?

An extreme form of regressive tax is a lump-sum tax (e.g. a poll tax). This is levied at a fixed *amount* (not rate) irrespective of income.

Figure 11.12 illustrates these different categories of tax. Diagram (a) shows the total amount of tax that a person pays. With a progressive tax, the curve gets progressively steeper, showing that the average rate of tax (T/Y) rises. The marginal rate of tax ($\Delta T/\Delta Y$) is given by the slope. Thus between points x and y the marginal tax rate is 40 per cent.

Diagram (b) shows the average rates. With a proportional tax, a person pays the same amount of tax on each pound earned. With a progressive tax, a larger proportion is paid by a rich person than by a poor person, and vice versa with a regressive tax.

The more steeply upward sloping the average tax curve, the more progressive is the tax, and the more equal will be the post-tax incomes of the population.

Definition

Progressive tax A tax whose average rate with respect to income rises as income rises.

Regressive tax A tax whose average rate with respect to income falls as income rises.

Proportional tax A tax whose average rate with respect to income stays the same as income rises.

Figure 11.12 Different categories of tax

³ GDP is a measure of the nation's income: we will be examining how it is measured in the appendix to Chapter 15.

Problems with using taxes to redistribute incomes

How successfully can taxes redistribute income, and at what economic cost?

Problems in achieving redistribution

How to help the very poor. Taxation takes away income. It can thus reduce the incomes of the rich. But no taxes, however progressive, can *increase* the incomes of the poor. This will require subsidies (i.e. benefits).

But what about tax cuts? Can bigger tax cuts not be given to the poor? This is possible only if the poor are already paying taxes in the first place. Take the two cases of income tax and taxes on goods and services.

- **Income tax.** If the government cuts income tax, then anyone currently paying it will benefit. A cut in tax *rates* will give proportionately more to the rich, since they have a larger proportion of taxable income relative to total income. An increase in personal *allowances*, on the other hand, will give the same *absolute* amounts to everyone above the new tax threshold. This will therefore represent a smaller proportionate gain to the rich. In either case, however, there will be no gain at all to those people below the tax threshold. They paid no income tax in the first place and gain nothing at all from income tax cuts.
- **Taxes on goods and services.** Since these taxes are generally regressive, any cut in their rate will benefit the poor proportionately more than the rich. A more dramatic effect would be obtained by cutting the rate most on those goods consumed relatively more by the poor.

The government may not wish to cut the overall level of taxation, given its expenditure commitments. In this case, it can switch the burden from regressive to progressive taxes, if it wishes to benefit the very poor.

Tax evasion and tax avoidance. The higher the rates of tax, the more likely are people to try to escape paying some of their taxes.

People who are subject to higher rates of income tax will be more tempted not to declare all their income. This tax *evasion* will be much easier for people not paying all their taxes through a pay-as-you-earn (PAYE) scheme. This will include the self-employed and people doing casual work on top of their normal job ('moonlighting'). Furthermore, richer people can often reduce their tax liability – engage in *tax avoidance* – by a careful use of various legal devices such as trusts and tax loopholes such as being allowed to offset 'business expenses' against income.

Part of the government's justification for abolishing income tax rates above 40 per cent in 1988 was that many people escaped paying these higher taxes. Nevertheless, in 2009 the Labour Chancellor, Alistair Darling, announced that a new top rate of 50 per cent would be introduced in 2010/11. He forecast that this would bring an extra £3 billion

per year in tax revenues. However, in 2011, the Office for Budget Responsibility suggested that the overall increases were likely to be much lower than this and HMRC figures suggested that £100 million a year would be lost in avoidance.

In 2013, the Coalition reduced the top rate to 45 per cent. It is difficult, if not impossible, to calculate the exact effect of these marginal changes.

Why may a steeply progressive income tax which is designed to achieve greater vertical equity lead to a reduction in horizontal equity?

Undesired incidence of tax. High rates of income tax on high wage earners may simply encourage employers to pay them higher wages. At the other end of the scale, tax cuts for low-paid workers may simply allow employers to cut wages. In other words, part of the incidence of income taxes will be borne by the employer and only part by the employee. Thus attempting to make taxes more 'progressive' will fail if employers simply adjust wages to compensate.

The incidence of income tax is determined by the elasticity of supply and demand for labour. In Figure 11.13, the initial supply and demand curves for labour (before the imposition of the tax) intersect at point (1), giving Q_1 labour employed at a wage of W_1 . Now an income tax is imposed. This shifts the labour supply curve vertically upwards by the amount of the tax, giving the new labour supply curve, $S + \text{tax}$. The new equilibrium is reached at point (2) with Q_2 labour employed at a (gross) wage of W_2 .

The incidence of the tax is as follows:

- The total tax revenue for the government is shown by the total shaded area.
- Workers' take-home pay is cut from W_1 to $W_2 - \text{tax}$. Their share of the tax is thus area A .
- Employers have to pay workers a rise of $W_2 - W_1$. They pay area B .

If the supply curve of labour of well-paid workers is relatively elastic, as shown in Figure 11.13, there will only be a

Figure 11.13 The incidence of an income tax: elastic supply of labour

relatively slight fall in take-home pay (the workers' share of the tax is relatively small). The tax will, therefore, have only a relatively slight redistributive effect away from this group of workers.

1. Do poor people gain more from a cut in income tax with an elastic or an inelastic supply of labour? Is the supply of unskilled workers likely to be elastic or inelastic?
2. Draw two diagrams like Figure 11.13, one with a steep demand curve and one with a shallow demand curve. How does the elasticity of demand affect the incidence of the income tax?

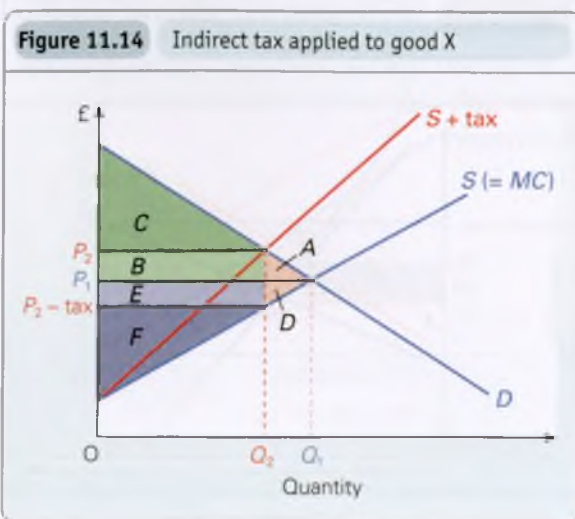

Of course, income taxes are not imposed on workers in one industry alone. People therefore cannot move to another industry to avoid paying taxes. This fact will cause a relatively inelastic supply response to any rise in income tax, since the only alternative to paying the income tax is to work less. The less elastic this response, the more will the burden of the tax fall on the taxpayer and the more effectively can income taxes be used to redistribute incomes.

The economic costs of redistribution

If redistribution is to be achieved through *indirect* taxes, this can lead to market distortions.

Take first the case of an indirect tax applied to one good only. Assume for simplicity that there is universal perfect competition. Raising the price of this good relative to other goods will introduce a market distortion. Consumption will shift away from this good towards other goods that people preferred less at the original prices. What is more, the loss to consumers and producers (other things being equal) will be greater than the gain to the community from the tax revenue. This is illustrated in Figure 11.14.

With no tax, price will be at P_1 and output at Q_1 , where demand equals supply. By imposing a tax on the good, the supply curve shifts upwards to $S + \text{tax}$. Price rises to P_2 and output falls to Q_2 . Producers are left with $P_2 - \text{tax}$. What are the various losses and gains?

Consumers, by having to pay a higher price, lose consumer surplus (see section 4.1). Originally their consumer surplus was areas $A + B + C$. With the price now at P_2 , the consumer surplus falls to area C alone. The loss to consumers is areas $A + B$.

Producers, by receiving a lower price after tax and selling fewer units, lose profits. In the simple case where there are no fixed costs of production, total profits are simply the sum of all the marginal profits ($P (= MR) - MC$) on each of the units sold. Thus before the tax is imposed, firms receive total profits of areas $D + E + F$. After the tax is imposed, they receive a profit of area F alone. The loss in profits to producers is therefore areas $D + E$.

The total loss to consumers and producers is areas $A + B + D + E$. The gain to the government in tax revenue is areas $B + E$: the tax rate times the number of units sold (Q_2). There is thus a net loss to the community of areas $A + D$. This is known as the **deadweight loss of the tax**.

However, if the money raised from the tax is redistributed to the poor, their gain in welfare is likely to exceed the loss in welfare from the higher tax. The reason is that a pound sacrificed by the average consumer is probably of less value to them than a pound gained by a poor person.

What is more, if the tax is applied at a uniform rate to *all* goods, there is no distortion resulting from reallocation between goods. This is one of the major justifications for having a single rate of VAT.

Of course, in the real world, markets are highly imperfect and there is no reason why taxes will necessarily make these imperfections worse. In fact, it might be desirable on efficiency grounds to tax certain goods and services, such as cigarettes, alcohol, petrol and gambling, at higher rates than other goods and services. We will examine these arguments in the next chapter.

Although there are costs of redistribution, there are also benefits extending beyond those to whom income is redistributed. If redistribution to the poor reduces crime, vandalism and urban squalor, then it is not just the poor who gain: it is everyone, both financially in terms of reduced policing and social work costs, and more generally in terms of living in a happier and less divided society.

Taxation and incentives

Another possible economic cost of high tax rates is that they may act as a disincentive to work, thereby reducing national output and consumption. This whole question of incentives is highly charged politically. According to the political

Definition

Deadweight loss of an indirect tax The net loss of consumer plus producer surplus (after adding in the tax revenue) from the imposition of an indirect tax.

right, there is a trade-off between output and equity. High and progressive income taxes can lead to a more equal distribution of income, but a smaller national output. Alternatively, if taxes are cut there will be a bigger national output, but less equally divided. If many on the left are correct, however, we can have both a more equal society *and* a bigger national output: there is no trade-off.

The key to analysing these arguments is to distinguish between the *income effect* and the *substitution effect* of a tax rise. Raising taxes does two things:

- It reduces incomes. People may therefore work *more* in an attempt to maintain their consumption of goods and services. This is the *income effect*.
- It reduces the opportunity cost of leisure. An extra hour taken in leisure now involves a smaller sacrifice in consumption, since each hour less worked involves less sacrifice in after-tax income. Thus people may substitute leisure for consumption, and work *less*. This is the *substitution effect*.

The relative size of the income and substitution effects is likely to differ for different types of people and different types of tax change.

Different types of people

The *income effect* is likely to dominate for people with long-term commitments: for example, those with families, or those with mortgages and other debts. They may feel forced to work *more* to maintain their disposable income. Clearly for such people, higher taxes are *not* a disincentive to work. The income effect is also likely to be relatively large for people on higher incomes, for whom an increase in tax rates represents a substantial cut in income.

The *substitution effect* is likely to dominate for those with few commitments: those whose families have left home, the single and second income earners in families where that second income is not relied on for 'essential' consumption. A rise in tax rates for these people is likely to encourage them to work less.

Definitions

Income effect of a tax rise Tax increases reduce people's incomes and thus encourage people to work more.

Substitution effect of a tax rise Tax increases reduce the opportunity cost of leisure and thus encourage people to work less.

BOX 11.3 THE LAFFER CURVE

EXPLORING ECONOMICS

Having your cake and eating it

Professor Art Laffer was one of President Reagan's advisers during his first administration (1981–4). He was a strong advocate of income tax cuts, arguing that substantial increases in output would result.

He went further than this. He argued that tax cuts would actually increase the amount of tax revenue that the government earned.

If tax cuts cause income to rise (due to incentives) proportionately more than the tax rate has fallen, then tax revenues will increase. These effects are illustrated by the now famous 'Laffer' curve.

If the average tax rate were zero, no revenue would be raised. As the tax rate is raised above zero, tax revenues will increase. The curve will be upward sloping. Eventually, however, the curve will peak (at tax rate t_1). Thereafter tax rates become so high that the resulting fall in output more than offsets the rise in tax rate. When the tax rate reaches 100 per cent, the revenue will once more fall to zero, since no one will bother to work.

The curve may not be symmetrical. It may peak at a 40 per cent, 50 per cent, 60 per cent or even 90 per cent rate. Nevertheless, Laffer and others on the political right argued that tax rates were above t_1 . In fact, most evidence suggests that tax rates in most countries were well below t_1 in the 1980s and certainly are now, given the cuts in

income tax rates that have been made around the world over the past 20 years.

1. What is the elasticity of supply of output with respect to changes in tax rates at a tax rate of t_1 ? What is it below t_1 ? What is it above t_1 ?
2. If the substitution effect of a tax cut outweighs the income effect, does this necessarily mean that the economy is to the right of point t_1 ?

Total tax revenue

Although high income earners may work more when there is a tax *rise*, they may still be discouraged by a steeply progressive tax *structure*. If they have to pay very high marginal rates of tax, it may simply not be worth their while seeking promotion or working harder (see Boxes 11.3 and 11.4).

1. Who is likely to work harder as a result of a cut in income tax rates, a rich person or a poor person? Why? Would your answer be different if personal allowances were zero?
2. How will tax cuts affect the willingness of women to return to employment after having brought up a family?

Different types of tax change

A government may wish to raise income taxes in order to redistribute incomes through higher benefits. There are three main ways it can do so: raising the higher rates of tax; raising the basic rate; and reducing tax allowances.

Raising the higher rates of tax. This may seem the most effective way of redistributing incomes: after all, it is only the rich who will suffer. There are, however, serious problems:

- The income effect will be relatively small, since it is only that part of incomes subject to the higher rates that will be affected. The substitution effect, however, could be relatively high. Rich people are likely to put a higher premium on leisure, and may well feel that it is not worth working so hard if a larger proportion of any increase in income is taken in taxes.
- It may discourage risk-taking by businesspeople.
- The rich may be more mobile internationally, so there may be a 'brain drain'. This criticism was made by the then Mayor of London, Boris Johnson, when discussing the effect of a 50 per cent tax rate on the financial sector.

Raising the basic rate of tax. As we have seen, the income effect is likely to be relatively large for those with higher incomes, especially if they have substantial commitments like a large mortgage. For such people, a rise in tax rates is likely to act as an incentive.

For those just above the tax threshold, there will be very little extra to pay on *existing* income, since most of it is tax-free. However, each *extra* pound earned will be taxed at the new higher rate. The substitution effect, therefore, is likely to outweigh the income effect. For these people, a rise in tax rates will act as a disincentive.

For those below the tax threshold, the marginal rate remains at zero. A rise in the basic rate might nevertheless deter them from undertaking training in order to get a better wage.

For those people who are not employed, a rise in tax rates may make them feel that it is no longer worth looking for a job.

Reducing tax allowances. For all those above the old tax threshold, there is no *substitution* effect at all. The rate of tax has not changed. However, there is an *income* effect. The effect is like a lump-sum tax. Everyone's take-home pay is cut by a fixed sum, and people will need to work harder to

make up some of the shortfall. This type of tax change, however, is highly regressive. If everyone pays the same *amount* of extra tax, this represents a bigger percentage for poorer people than richer people. In other words, there may be no negative incentive effects, but it is not suitable as part of a policy to redistribute incomes more equally!

The conclusion from the theoretical arguments is that tax changes will have very different effects depending on (a) whom they affect and (b) the nature of the change.

1. A key policy of the UK Coalition government, achieved in April 2014, was to raise the personal income tax allowance to £10 000. This was accompanied by the gradual removal of the same allowance from those earning over £100 000 (see Table 11.3 on page 331). Evaluate these policies.
2. What would the effects be of cuts in (i) the basic rate of tax (ii) the top rate of tax?
3. What tax changes (whether up or down) will have a positive incentive effect and also redistribute incomes more equally?

One final point should be stressed. For many people, there is no choice in the amount they work. The job they do dictates the number of hours worked, irrespective of changes in taxation.

Evidence

All the available evidence suggests that the effects of tax changes on output are relatively small. Labour supply curves seem highly inelastic to tax changes.

Benefits

Benefits can be either cash benefits or benefits in kind.

Cash benefits

Means-tested benefits. **Means-tested benefits** are available only to those whose income (and savings in some instances) fall below a certain level. To obtain such benefits, therefore, people must apply for them and declare their personal circumstances to the authorities. Examples include housing benefit and income support, the safety net that exists for all in the UK.

The benefits could be given as grants or merely as loans. They could be provided as general income support or for the meeting of specific needs, such as rents, fuel bills and household items.

Universal benefits. **Universal benefits** are those that everyone is entitled to, irrespective of their income, if they fall

Definitions

Means-tested benefits Benefits whose amount depends on the recipient's income or assets.

Universal benefits Benefits paid to everyone in a certain category irrespective of their income or assets.

BOX 11.4 TAX CUTS AND INCENTIVES
EXPLORING ECONOMICS
An application of indifference curve analysis¹

Will tax cuts provide an incentive for people to work more? This question can be analysed using indifference curves (see section 4.3). The analysis is similar to that developed in Box 10.2. It is assumed that individuals can choose how many hours a day to work.

The position with no income tax

Diagram (a) shows the situation without income tax.

The budget line shows the various combinations of leisure and income open to an individual at a given wage rate.

? Why is the budget line straight? What would it look like if overtime were paid at higher rates per hour?

The indifference curves show all the combinations of income and leisure that give the person equal satisfaction. The optimum combination of income and leisure is at Y^* and L^* where the individual is on the highest possible indifference curve: point a .

The position with income tax

Now let us introduce a system of income taxes. This is illustrated in diagram (b).

Assume that the tax has the following features:

- Up to an income of Y_1 no tax is paid: Y_1 is the individual's personal allowance.
- From Y_1 to Y_2 the basic rate of tax is paid. The budget line is flatter, since less extra income is earned for each extra hour of leisure sacrificed.
- Above Y_2 the higher rate of tax is paid. The budget line becomes flatter still.

The individual illustrated in the diagram will now choose to earn a take-home pay of Y^{**} and have L^{**} hours of leisure: point b . Note that this is more leisure than in the no-tax situation (point a). In this diagram, then, the tax has acted as a disincentive. The substitution effect has outweighed the income effect.

Redraw diagram (b), but in such a way that the income effect outweighs the substitution effect.

A cut in the basic tax rate

We can now analyse the effects of tax cuts. A cut in the basic rate is shown in diagram (c).

The tax cut makes the budget line steeper above point q (the tax threshold).

For people on the tax threshold – like person X – the cut in the basic rate makes no difference. Person X was originally taking L_x hours of leisure (point q) and will continue to do so.

For people above the tax threshold – like person W – the tax cut will enable them to move to a higher indifference curve. Person W will move from point r to point s . The way this diagram is drawn, point s is to the left of point r . This means that person W will work more: the substitution effect is greater than the income effect.

Try drawing two or three diagrams like diagram (c), with the tangency point at different points along the budget line to the left of q . You will find that the further to the left you move, the less likely is the substitution effect to outweigh the income effect: i.e. the more likely are people to work less when given a tax cut.

¹ This box is based on D. Ulph, 'Tax cuts: will they work?', *Economic Review*, March 1987.

A rise in the tax threshold

Diagram (d) shows a rise in personal allowances while the tax rates stay the same.

The point at which people start paying taxes rises from point t to point u . The slope of the budget line remains the same, however, since the tax rates have not changed.

For people paying taxes, the increase in allowances represents a lump-sum increase in income: there will thus be an income effect. But since tax rates have not changed, there is no substitution effect. People therefore work less. The person in the diagram moves from point m to point n , taking L_2 rather than L_1 hours in leisure.

? Will people actually on the old tax threshold (i.e. those whose indifference curve/budget line tangency point is at t) work more or less? Try drawing it.

A cut in the higher rate of tax

It is likely that the income effect of this will be quite small except for those on very high incomes. The substitution effect is therefore likely to outweigh the income effect, causing people to work more.

? All the above analysis assumes that taxes will not affect people's gross wage rates. If part of the incidence of taxes is borne by the employer, so that gross wages fall, after-tax wages will fall less. There will therefore be a smaller shift in the budget line. How will this affect the argument for tax cuts?

into a certain category or fulfil certain conditions (these conditions might include a contributions record). Examples include state pensions, and certain unemployment, sickness and invalidity benefits.

Benefits in kind

Individuals receive other forms of benefit from the state, not as direct monetary payments, but in the form of the provision of free or subsidised goods or services. These are known as **benefits in kind**. The two largest items in most countries are health care and education. They are distributed very unevenly, however, largely due to the age factor. Old people use a large proportion of health services, but virtually no education services.

Benefits in kind tend to be consumed roughly equally by the different income groups. Nevertheless they still have some equalising effect, since they represent a much larger proportion of poor people's income than rich people's. They still have a far smaller redistributive effect, however, than cash benefits.

Figure 11.15 shows the expenditure on social protection benefits in selected European countries. These include unemployment, sickness, invalidity, maternity, family, survivors' and housing benefits and state pensions. They are mainly cash benefits, but do include some benefits in kind. They exclude health and education.

As you can see, the benefits vary significantly from one country to another. Part of the reason for this is that countries differ in their rates of unemployment and in the age structure of their population. Thus Ireland has a very low percentage of people over 65, compared with other countries

in the EU and the smallest share of benefits devoted to pensions. Despite this, however, the generosity and coverage of benefits varies considerably from country to country, reflecting, in part, the level of income per head.

Also, you will see from chart (b) that benefits were generally greater in 2013 than in 1990. This is a largely a reflection of the higher rates of unemployment in 2013, and hence more people in receipt of unemployment benefits.

The system of benefits in the UK and their redistributive effects are examined in Case Study 11.5 on the student website.

Benefits and the redistribution of income

It might seem that means-tested benefits are a much more efficient system for redistributing income from the rich to the poor: the money is directed to those most in need. With universal benefits, by contrast, many people may receive them who have little need for them. Do families with very high incomes need child benefit? Would it not be better for the government to redirect the money to those who are genuinely in need? In the UK, from 2012, families with at

Definition

Benefits in kind Goods or services that the state provides directly to the recipient at no charge or at a subsidised price. Alternatively, the state can subsidise the private sector to provide them.

Figure 11.15 Social protection benefits in various European countries

(a) € per head (2014)

(b) % of GDP

Source: Based on data in *Social Protection Tables* (Eurostat, 2017).

least one higher-rate taxpayer were no longer eligible for child benefit (see Box 11.5 for more on this).

There are, however, serious problems in attempting to redistribute incomes by the use of means-tested benefits:

- Not everyone entitled to means-tested benefits applies for them, whether from ignorance of what is available, from the complexities of claiming or from reluctance to reveal personal circumstances or from a feeling that it is demeaning to claim. Thus some of the poorest families receive no support. This is a particular issue with pensioners living in poverty.
- The level of income above which people become ineligible for benefits may be set too low. Even if it were raised, there will always be some people just above the level who will still find difficulties.
- Means tests based purely on *income* (or even universal benefits based on broad categories) ignore the very special needs of many poor people. A person earning £120 a week and living in a small, well-appointed flat with a low rent and an allotment to grow vegetables will have less need

of assistance than another person who also earns £120 per week but lives in a cold, draughty and damp house with large bills to meet and no means of growing their own food. If means tests are to be really fair, *all* of a person's circumstances would need to be taken into account.

The tax/benefit system and the problem of disincentives: the poverty trap

When means-tested benefits are combined with a progressive income tax system, there can be a serious problem of disincentives. As poor people earn more money, not only will they start paying income taxes and national insurance, but also they will begin losing means-tested benefits. Theoretically, it is possible to have a marginal tax-plus-lost-benefit rate in excess of 100 per cent. In other words, for every extra £1 earned, taxes and lost benefits add up to more than £1. High marginal tax-plus-lost-benefit rates obviously act as a serious disincentive. What is the point of getting a job or trying to earn more money if you end up earning little more or even losing money?

BOX 11.5

UK TAX CREDITS

An escape from the poverty trap?

Tax credits (which share characteristics with negative income taxes) were first introduced in the UK in 1999 in the form of Working Families Tax Credit (WFTC). In many ways, the label 'tax credit' is misleading as people do not need to be paying tax in order to receive the benefit. Tax credits are not the same thing as tax relief.

WFTC was replaced in 2003 by Working Tax Credit (WTC) and Child Tax Credit (CTC). WTC provides support for working people on low incomes. To be eligible for the basic amount (£1960 in 2017/18), people without children must be aged 25 or over and work at least 30 hours per week. People with children, the over-50s returning to work, the over-60s and the disabled must work at least 16 hours per week. Couples and lone parents receive an additional amount (£2010 in 2017/18). There is a further additional payment (£810 in 2017/18) for a single parent who works at least 30 hours per week, or for couples who jointly work at least 30 hours per week.

The payment provides an incentive for people to move from part-time to full-time work. Recipients of WTC also get paid 70 per cent of eligible childcare costs up to £175 per week for one child and £300 for two or more children (2017/18). For each pound earned above a threshold amount (£6420 in 2017/18), the benefit is reduced by 41p. This is known as the taper.

Child Tax Credit provides support to families with children. Unlike WTC, eligibility is not dependent on someone in the family working. It is paid in addition to WTC and child benefit. In 2017/18, for families with children born before 6 April 2017, £3325 per year was paid for their first child and £2780 for each subsequent child. For families with the first child born after 5 April 2017, payment for that child was reduced to £2780. For families with the third or subsequent child born after 5 April 2017, there was no WTC paid at all for these children. Such families thus received a maximum of £5560 no matter how many children they have.

In 2014/15, 872 000 families with more than two children claimed tax credits. Some campaign groups argued that the

restriction of Child Tax Credit could push 200 000 more children into poverty. The Office for Budget Responsibility estimates that the cuts will save the Treasury some £70 million per year by 2020/21. In 2015/16, approximately 4.4 million families with 7.4 million children received tax credits. The cost to the government was over £27.5 billion.

Tax credits and incentives

Tax credits were designed to improve incentives to work, by reducing the poverty trap (see above). In other words, the aim was to reduce the financial penalties for parents working by tapering off more slowly the rate at which benefits are lost. With a taper rate of 41 per cent, the combined marginal tax-plus-lost-benefit rate (the 'marginal deduction rate') is typically 73 per cent (20% income tax + 12% national insurance + 41% lost benefit)

Although the introduction of tax credits did reduce the marginal deduction rate, it remains relatively high. For many poor parents, therefore, the incentive to work is still low. What is more, a lower taper rate means that *more* families with higher incomes become eligible to receive payments. While this is good, in terms of providing support for them, the result is more of a disincentive for parents in such families to work extra hours, or to take a better job, since their marginal deduction rate is now higher. In other words, although they are better off, they will take home less for each extra hour worked.

WTC and CTC illustrate the general problem of providing support to poor people which is affordable for taxpayers without creating disincentives to work. The more gently the support tapers off (and hence the less the disincentive to earn extra money), the more costly it is to finance, and hence higher tax rates are needed elsewhere. The problems with using negative income taxes are explored in Case Study 11.6 on the student website.

A major criticism of tax credits lies in the complexity of the system. This has two consequences: first, it is estimated that of the 7 million households eligible for the benefits, over 2 million

This situation is known as the **poverty trap**. People are trapped on low incomes with no realistic means of bettering their position.

The problem of the poverty trap could be overcome by switching to a system of universal benefits unrelated to income. For example, *everyone* could receive a flat payment from the state fixed at a sufficiently high level to cover their basic needs. There would still be *some* disincentive, but this would be confined to an income effect: people would not have the same need to work if the state provided a basic income. But there would no longer be the disincentive to work caused by a resulting *loss* of benefits (a substitution effect). In addition, a system of universal benefits is relatively cheap to administer, avoiding the need for costly means-testing.

The big drawback with universal benefits, however, is their cost. If they were given to everyone and were large enough to help the poor, their cost would be enormous. Thus, although the benefits themselves would not create much disincentive effect, the necessary taxation to fund them probably would.

There is no ideal solution to this conundrum. On the one hand, the more narrowly benefits are targeted on the poor, the greater is the problem of the poverty trap. On the other hand, the more widely they are spread, the greater is the cost of providing any given level of support to individuals. One compromise proposal is that of a **negative income tax**. This is examined in Case Study 11.6 on the student website. Box 11.5 examines the use of tax credits – which have similarities with a negative income tax – in the UK.

Definitions

Poverty trap Where poor people are discouraged from working or getting a better job because any extra income they earn will be largely or entirely taken away in taxes and lost benefits.

Negative income tax A combined system of tax and benefits. As people earn more, they gradually lose their benefits until beyond a certain level they begin paying taxes.

fail to claim them; second, the system is administratively costly and prone to errors.

A universal approach

In 2011, Iain Duncan Smith, the then Secretary of State for Work and Pensions, announced plans to make fundamental reforms to the benefit system by introducing a new Universal Credit (UC).

His intention was to 'simplify the system to make work pay and combat worklessness and poverty'.¹ The new credit was described as an integrated working-age credit providing a basic allowance with additional elements for children, disability, housing and caring. It differs from the system that it is gradually replacing, in that it supports people both in and out of work, replacing Working Tax Credit, Child Tax Credit, Housing Benefit, Income Support, income-based Jobseeker's Allowance and income-related Employment and Support Allowance. (Note that although it is called Universal Credit, it is not a universal benefit and is means-tested.)

The design of UC is intended to address concerns raised about tax credits by:

- Introducing smoother taper rates and so lessening the impact of the poverty trap.
- Removing the distortions that over-reward individuals working a certain number of hours, notably 16 or 30 hours with Working Tax Credits.
- Bringing together in-work and out-of-work benefits, and reducing the risks and transactions costs for those moving into work.
- Reducing administrative costs, with benefits being overseen by a single body, the Department for Work and Pensions.

Although UC originally offered higher levels of support, cuts announced in the July 2015 budget make the payments

far less generous. The government is also applying stronger levels of conditionality on claimants.

Unfortunately, achieving simplicity in a benefit system has proved more complex than Iain Duncan Smith had anticipated. There have been numerous setbacks in the implementation of the new system, which has been dogged by design errors, problems with IT systems and cost over-runs. It is gradually being introduced into different areas of the country and by December 2016, 430 000 people were receiving UC. When the scheme finally becomes fully operational, this number will increase to approximately 7 million. In July 2016, the government announced that, due to further delays, the scheme would not be fully implemented until 2022 – five years later than originally planned.

A number of people receiving UC have suffered considerable hardship. Claimants have to wait six weeks for their first payment and some families have found it difficult to cope with this delay. According to evidence presented to the Work and Pensions Select Committee, 920 out of 1058 housing association tenants in Halton Merseyside who had been moved onto UC had rent arrears averaging £600.

1. *Economists sometimes refer to an 'unemployment trap'. People are discouraged from taking work in the first place. Explain how such a 'trap' arises. Will the Universal Credit create an unemployment trap? What are the best ways of eliminating, or at least reducing, the unemployment trap?*
2. *Universal Credit involves a single monthly payment direct to the claimant's bank account. This replaces fortnightly payments, some in the form of cashable cheques, and rent payments direct to landlords. What additional support do you anticipate claimants would need?*

¹ White Paper Universal Credit: Welfare that Works, www.gov.uk/government/publications/universal-credit-welfare-that-works

Conclusions

Redistribution is not costless. Whether it takes place through taxes or benefits or both, it can pose a problem of disincentives. The size of the disincentive problem varies from one tax to another and from one benefit to another, and in some cases there may even be an incentive effect: for example, when the income effect of a tax outweighs the substitution effect. It is therefore important to estimate the particular effects of each type of proposal not only on income distribution itself, but also on economic efficiency.

Ultimately, the questions of how much income should be redistributed, and whether the costs are worth bearing,

are normative questions, and ones that an economist cannot answer. They are moral and political questions. Unfortunately there is no mechanism for measuring the 'utility' gained by the poor and lost by the rich so that any net gain from redistribution can be weighed up against lost output. For example, the benefit that a person receives from a cooker or an electric fire cannot be measured in 'utils' or any other 'psychic unit'. What people are prepared to pay for the items is no guide either, since a poor person obviously cannot afford to pay nearly as much as a rich person, and yet will probably get the same if not more personal benefit from them.

Section summary

1. Government intervention in the economy through taxation and government expenditure has a number of purposes including redistribution, the correction of market distortions and macroeconomic stabilisation.
2. There are various requirements of a good tax system, including horizontal and vertical equity; payment according to the amount of benefit received; being cheap to collect, difficult to evade, non-distortionary and convenient to the taxpayer and the government; and having the minimum disincentive effects.
3. Taxes can be divided into those paid directly to the authorities (direct taxes: e.g. income tax) and those paid via a middle person (indirect taxes: e.g. VAT).
4. Taxes can be categorised as progressive, regressive or proportional. Progressive taxes have the effect of reducing inequality. The more steeply progressive they are, the bigger is the reduction in inequality.
5. There are various limitations to using taxes to redistribute incomes. First, they cannot on their own increase the incomes of the poor. (Cutting taxes, however, can help the poor if the cuts are carefully targeted.) Second, high taxes on the rich may encourage evasion or avoidance. Third, higher income taxes on the rich will probably lead to their employers paying higher (gross) wages.
6. Using indirect taxes to redistribute incomes involves costs of resource reallocation.
7. Raising taxes has two effects on the amount that people wish to work. On the one hand, people will be encouraged to work more in order to maintain their incomes. This is the income effect. On the other hand, they will be encouraged to substitute leisure for income (i.e. to work less), since an hour's leisure now costs less in forgone income. This is the substitution effect. The relative size of the income and substitution effects will depend on the nature of the tax change. The substitution effect of a tax rise is more likely to outweigh the income effect for those with few commitments, for people just above the tax threshold and in cases where the highest rates of tax are increased.
8. Benefits can be cash benefits or benefits in kind. Means-tested cash benefits include support for poor families and for low-paid people. Universal benefits include state pensions and child benefit. Benefits in kind include health care, education and free school meals.
9. Means-tested benefits can be specifically targeted to those in need and are thus more 'cost effective'. However, there can be serious problems with such benefits, including limited take-up, some relatively needy people falling just outside the qualifying limit, and inadequate account being taken of all relevant circumstances affecting a person's needs.
10. The poverty trap occurs when the combination of increased taxes and reduced benefits removes the incentive for poor people to earn more. The more steeply progressive this combined system is at low incomes, the bigger is the disincentive effect.

BOX 11.6

WHAT THE FUTURE HOLDS

CASE STUDIES AND APPLICATIONS

Approaches to pensioner poverty in the UK

While much of the focus since 1997 has been on child poverty, politicians have also been concerned about the plight of pensioners. After all, unlike children, they have the vote. And with an ageing population, the numbers of pensioners are increasing.

For most of the first decade of this century, the analysis was relatively simple: many pensioners are poor and pensioner poverty needs to be addressed. Pensioner incomes had fallen relative to those of the working population, as pensions were up-rated in line with prices rather than wages. Increasing life expectancy and changing labour markets combined to leave nearly three million pensioners living in poverty by 1998.

Policy responses included more generous means-tested benefits and the introduction of a number of universal benefits for pensioners, such as free bus travel and winter fuel allowances. The result was that by 2009 the number of pensioners living in poverty had fallen by one-third to around two million.

Intergenerational equity

More recently, the focus has moved to looking at the question of equity between different generations. With many reliant on incomes from savings and personal pensions, older people have suffered from low or even negative real interest rates since 2008. Younger people with mortgages and other debts, by contrast, have benefited from these low real interest rates. Then there is the question of the fruits of economic growth. Should only companies and wage earners benefit from economic growth, or should the retired benefit too?

Many people, however, are concerned that pensioners as a group are getting more than their fair share of national income. They argue that it is those under 30 who are worst off. Those born between the 1940s and mid-1960s have benefited from a range of financial and social factors, including free higher education and generous final salary pension schemes. Many have built up substantial wealth in the form of housing equity, buying initially when prices were very low. This will enable them to have a comfortable retirement.

The situation is very different for the young, who face higher education fees of up to £9250 per annum, high house prices so they remain unaffordable for many, final salary pension schemes closed and retirement ages likely to increase beyond 70. What is more, they face higher taxes to pay for past spending, for the costs of the bank bailouts in 2008 and for the effects of climate change.

UK government policy

One of the most important elements of recent government policy has been the so-called 'triple lock'. Introduced in 2012, this guarantees that the annual increase in the state pension is by whichever one of the following is greatest – the increase in average earnings, the increases in the consumer price index, or 2.5 per cent. Research by the Institute for Fiscal Studies¹ indicated that between 2010 and 2016 the state pension increased by 22.2 per cent. During the same period, average earnings increased by 7.6 per cent and prices increased by 12.3 per cent. The current government is committed to the policy until 2020, although a number of people have argued that its cost is unsustainable. The Government's Actuary Department estimates that the triple lock increases the cost of the state pension by approximately £6 billion per year.

Rather than focusing on just those who are already pensioners, the government has also introduced policies to encourage those of working age to save more for their future retirement. In particular, the government has introduced an auto-enrolment programme. This aims to make sure that people have a retirement savings policy to top up their state pension. Every employer with at least one employee now has to enrol them automatically into a low-cost workplace pension scheme if they meet certain requirements – they must be over the age of 22 and earn at least £10 000 per year. The minimum contribution rate into the pension scheme is 2 per cent with at least 1 per cent paid by the employer. This increases to 5 per cent in April 2018 with a minimum of 2 per cent paid by the employer. The government has also introduced greater flexibility into how people can use their pension savings as they approach retirement.

Despite these measures, the amounts being saved by many people are still well below the levels required to provide a decent retirement income.

1. Why has the government legislated for the new national pension scheme to involve auto-enrolment? (Hint, think back to section 5.2 page 144)
2. The last two governments have used universal benefits, such as winter fuel allowances and free bus travel, as part of their approach to eliminating pensioner poverty. What are the advantages (and disadvantages) of this approach?
3. If you could find out, with some associated probability, when you might die, would you choose to find out? How might the answer affect the way you live today?

¹ *Would You Rather? Further Increases in the State Pension Age v Abandoning the Triple Lock* (IFS, February 2017).

END OF CHAPTER QUESTIONS

- Using the data shown on the pie charts in Figure 11.1, construct two Lorenz curves (on the same diagram), corresponding to the before- and after-tax income figures. Interpret and comment on the diagram you have drawn.
- Can taxes be used to relieve poverty?
- In what ways might the views of different politicians on what constitutes a 'good' tax system conflict?
- Distinguish between proportional, progressive and regressive taxation. Could a progressive tax have a constant marginal rate?
- Consider the cases for and against a poll tax.
- Under what circumstances would a rise in income tax act as (a) a disincentive and (b) an incentive to effort?
- What is meant by the poverty trap? What design of benefit system would offer the best solution to the problem of the poverty trap?
- How would you go about deciding whether person A or person B gets more personal benefit from each of the following: (a) an electric fire; (b) a clothing allowance of £x; (c) free higher education; (d) child benefit? Do your answers help you in deciding how best to allocate benefits?
- Just under two million pensioners were identified as living in poverty in the UK in 2016. In the same year it was estimated that the total property wealth of pensioner households had grown to a record high of £1.031 trillion. What does this imply about inequality and poverty?

Advantages of the free market	387
Should there be more or less intervention in the market?	387

In Chapter 11 we examined the problem of inequality. In this chapter we turn to examine another major area of concern. This is the question of the efficiency (or inefficiency) of markets in allocating resources.

First we show how a perfect market economy could under certain conditions lead to 'social efficiency'. In section 12.2 we examine the real world and show how real-world markets fail to meet social goals. These failures provide the major arguments in favour of government intervention in a market economy. We then turn to discuss the alternative ways in which a government can intervene to correct these various market failings.

If the government is to replace the market and provide goods and services directly, it will need some way of establishing their costs and benefits. Section 12.4 looks at 'cost-benefit analysis'. This is a means of establishing the desirability of a public project such as a new motorway or a new hospital. Finally, in section 12.5, we look at the case for restricting government intervention. We examine the advantages of real-world markets and the drawbacks of government intervention.

12.1 EFFICIENCY UNDER PERFECT COMPETITION

Perfect competition has been used by many economists and policy makers as an ideal against which to compare the benefits and shortcomings of real-world markets.

As was shown in Chapter 7, perfect competition has various advantages for society. Under perfect competition, firms' supernormal profits are competed away in the long run by the entry of new competitors. As a result, firms are forced to produce at the bottom of their average cost curves. What is more, the fear of being driven out of business by the entry of new firms forces existing firms to try to find lower-cost methods of production, thus shifting their *AC* curves downwards.

Perhaps the most wide-reaching claim for perfect competition is that under certain conditions it will lead to a *socially efficient* use of a nation's resources.

Social efficiency: 'Pareto optimality'

If it were possible to make changes in the economy – changes in the combination of goods produced or consumed, or changes in the combination of inputs used – and if these changes benefited some people without anyone else being made worse off, economists would describe this as an *improvement in social efficiency*, or a *Pareto improvement*, after Vilfredo Pareto, the Italian social scientist (see Case Study 12.1 on the student website).

? *Do you agree that, if some people gain and if no one loses, then this constitutes an 'improvement' in the well-being of society? Does it depend who gains? Would it be possible to improve the well-being of society without a Pareto improvement?*

When all Pareto improvements have been made – in other words, when any additional changes in the economy would benefit some people only by making others worse off – the economy is said to be *socially efficient*, or Pareto optimal. What we shall show is that under certain conditions a perfect market will lead to *Pareto optimality*.

But a word of caution. Just because social efficiency is achieved in a particular market environment, it does not necessarily make that environment *ideal*. It may be a *necessary* condition for an ideal allocation of resources that all Pareto improvements are made. It is not *sufficient*, however. If, for example, the government redistributed income from the rich to the poor, there would be no Pareto improvement, since the rich would lose. Thus both an equal and a highly unequal distribution of income could be Pareto optimal, and yet it could be argued that a more equal distribution is socially more desirable. For the moment, however, we will ignore questions of fairness and just focus on social efficiency.

So why may a perfect market lead to social efficiency? The following sections explain.

The simple analysis of social efficiency: marginal benefit and marginal cost

Remember how we defined 'rational' choices. A rational person will choose to do an activity if the gain from so doing exceeds any sacrifice involved. In other words, whether as a producer, a consumer or a worker, a person will gain by expanding any activity whose marginal benefit (*MB*) exceeds its marginal cost (*MC*) and by contracting any activity whose marginal cost exceeds its marginal benefit. Remember that when economists use the term 'cost', they are referring to 'opportunity cost': in other words, the *sacrifice* of alternatives. Thus when we say that the marginal benefit of an activity is greater than its marginal cost, we mean that the additional benefit gained exceeds any sacrifice in terms of alternatives forgone.

Thus the economist's rule for *rational economic behaviour* is that a person should expand or contract the level of any activity until its marginal benefit is equal to its marginal cost. At that point, the person will be acting efficiently in his or her own private interest. Only when $MB = MC$ can no further gain be made. This is known as a situation of *private efficiency*.

By analogy, *social efficiency* will be achieved where, for any activity, the marginal benefit to *society* (*MSB*) is equal to the marginal (opportunity) cost to *society* (*MSC*).

$$MSB = MSC$$

Allocative efficiency (simple formulation) in any activity is achieved where marginal benefit equals marginal cost. Private efficiency is achieved where marginal private benefit equals marginal private cost ($MB = MC$). Social efficiency is achieved where marginal social benefit equals marginal social cost ($MSB = MSC$).

Definitions

Pareto improvement Where changes in production or consumption can make at least one person better off without making anyone worse off.

Social efficiency A situation of Pareto optimality.

Pareto optimality Where all possible Pareto improvements have been made: where, therefore, it is impossible to make anyone better off without making someone else worse off.

Rational economic behaviour Doing more of those activities whose marginal benefit exceeds their marginal cost and doing less of those activities whose marginal cost exceeds their marginal benefit.

Private efficiency Where a person's marginal benefit from a given activity equals the marginal cost.

But why is social efficiency (i.e. Pareto optimality) achieved at this point? If MSB were greater than MSC , there would be a Pareto improvement if there were an increase in the activity. For example, if the benefits to consumers from additional production of a good exceed the cost to producers, the consumers could fully meet the cost of production in the price they pay, and so no producer loses, and yet there would still be a net gain to consumers. Thus society has gained. Likewise if MSC were greater than MSB , society would gain from a decrease in production.

Economists argue that under certain circumstances the achievement of *private* efficiency will result in *social* efficiency also. Two major conditions have to be fulfilled, however:

- There must be *perfect competition* throughout the economy. This is examined in the following sections.
- There must be *no externalities*. Externalities are additional costs or benefits of production or consumption experienced by people other than the producers and consumers directly involved in the transaction. They are sometimes referred to as spillover or third-party costs or benefits. Pollution is an example. It is a cost that society experiences from production, but it is not a cost that the individual producer has to pay. In the *absence* of externalities, the only costs or benefits to society are the ones that the individual producer or consumer experiences: i.e. marginal social benefit (MSB) is the same as marginal private benefit (MB), and marginal social cost (MSC) is the same as marginal private cost (MC).

To understand just how social efficiency is achieved, we must look at how people maximise their interests through the market.

Achieving social efficiency through the market

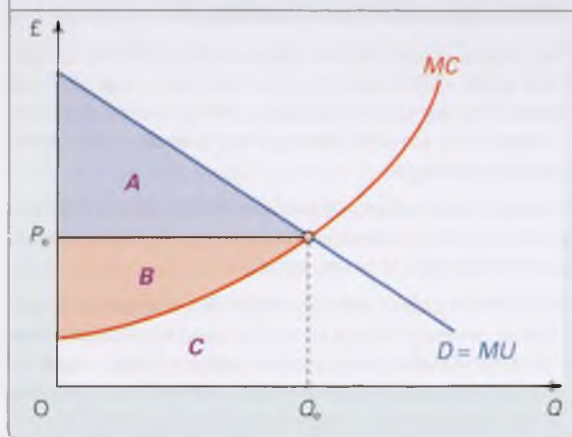

Consumption: $MU = P$

The marginal benefit to a consumer from the consumption of any good is its marginal utility. The marginal cost is the price the consumer has to pay.

As demonstrated in section 4.1, the 'rational' consumer will maximise consumer surplus where $MU = P$: in other words, where the marginal benefit from consumption is equal to the marginal cost of consumption. Do you remember the case of Tanya and her purchases of petrol? (See page 108.) She goes on making additional journeys and hence buying extra petrol as long as she feels that the journeys are worth the money she has to spend: in other words, as long as the marginal benefit she gets from buying extra petrol (its marginal utility to her) exceeds its marginal cost (its price). She will stop buying extra petrol when its marginal utility has fallen (the law of diminishing marginal utility) to equal its price. At that point, her consumer surplus is maximised: she has an 'efficient' level of consumption.

? Assume that the price of a good falls. How will an 'efficient' level of consumption be restored?

Figure 12.1 Maximum total surplus under perfect competition

As we have seen, an individual's consumer surplus is maximised at the output where $MU = P$. With all consumers doing this, and all facing the same market price, their collective consumer surplus will be maximised. This is illustrated in Figure 12.1. Consumers' total utility is given by the area under the demand (MU) curve (areas $A + B + C$). Consumers' total expenditure is $P \times Q$ (areas $B + C$). Consumer surplus is the difference between total utility and total expenditure: in other words, the area between the price and the demand curve (area A).

Production: $P = MC$

The marginal benefit to a producer from the production of any good is its marginal revenue (which under perfect competition will be the same as the price of the good). As demonstrated in section 6.6, the 'rational' firm will maximise its profit where its marginal revenue (i.e. the price under conditions of perfect competition) is equal to its marginal cost of production. This is the same thing as saying that it will produce where the marginal benefit from production is equal to the marginal cost from production.

Profit is the excess of total revenue over total costs. A related concept is that of **total producer surplus** (TPS). This is the excess of total revenue over total *variable* costs: $TPS = TR - TVC$. In other words, total producer surplus is total profit plus fixed costs: $TPS = \pi + TFC$. But since there are no marginal fixed costs (by definition), both producer surplus and profit will be maximised at the same output.

Definitions

Externalities Costs or benefits of production or consumption experienced by people *other* than the producers and consumers directly involved in the transaction. They are sometimes referred to as 'spillover' or 'third-party' costs or benefits.

Total producer surplus Total revenue minus total variable costs ($TR - TVC$): in other words, total profit plus total fixed costs ($\pi + TFC$).

THRESHOLD CONCEPT 10

GENERAL EQUILIBRIUM

THINKING LIKE AN
ECONOMIST

When all markets are in balance

In previous chapters we have been looking at individual markets: goods markets and factor markets. But any change in one market is likely to have repercussions in other markets. And changes in these other markets will probably affect other markets, and so on.

The point about a market economy is that it is like an interconnected web. Understanding these connections helps us understand the concept of an 'economy'.

If we started with an economy where all markets were in equilibrium, we would have a state of **general equilibrium**. Then let's assume that a change occurs in just one market – say a rise in oil prices resulting from increased demand from China and other rapidly growing newly industrialised countries. This will have knock-on effects throughout the economy. Costs, and hence prices, will rise in oil-consuming industries. Consumption will fall for the products of these industries and rise for substitute products which do not use oil, or use less of it. Some motorists will be encouraged to use public transport or cycle. This could have knock-on effects on the demand for houses, with people choosing to live nearer to their work. This could then have effects on the various parts of the construction industry. You can work out some of these effects for yourself.

You will quickly see that a single change in one industry can set off a chain reaction throughout the economy. If there is just the one initial change, things will settle to a new general equilibrium where all markets are back in balance with demand equal to supply. In practice, of course, economic 'shocks' are occurring all the time and thus the economy is in a constant state of flux with no stable general equilibrium.

The concept of general equilibrium is a *threshold concept* because it gives us an insight into how market forces apply to a *whole* economy, and not just to its individual parts. It is about seeing how the whole jigsaw fits together and how changes ripple throughout the economy.

Many other subjects use the concept of general equilibrium. Take meteorology. We could study a single weather system, such as a low pressure area or a cold front. But, to make sense of the development and movement of such systems, we need to see them as part of a bigger picture: as part of the whole world's weather system, which at any time is moving towards a general equilibrium in response to various changes.

For instance, in the short term, we can see how weather systems respond to the changing seasons: for example, how pressure systems move northwards in the northern hemisphere summer. In the longer term, we could model how world weather systems will respond to climate change. Will the resulting general equilibrium be one where sea levels rise; where the Gulf Stream is turned off, with much of north-western Europe becoming colder; where the deserts of north Africa spread to southern Europe; and so on?

But in economics, understanding general equilibrium is not just about understanding and predicting the output of the various industries that make up the economy. It can help us make value judgements and formulate policy. As we shall see in Threshold Concept 11 (see page 353), under certain conditions, general equilibrium can be seen as *socially efficient*. These conditions are (a) perfect competition and (b) an absence of externalities.

If social efficiency is seen as desirable, then one policy implication might be to try to make markets as perfect as possible and to 'internalise' externalities. In this chapter we examine whether such policies should be adopted and, if so, what form should they take?

1. If general equilibrium is achieved when all markets have responded to a change and its knock-on effects, and if such changes are constantly occurring, will general equilibrium actually be achieved? Does your answer have any implications for policy?
2. If social efficiency is seen as desirable (a normative issue), should policy always be geared to achieving this?

Total producer surplus for all firms in the market is shown in Figure 12.1. Total revenue (i.e. total expenditure) is $P \times Q$ (areas $B + C$). Total variable cost is the area under the MC curve (area C): i.e. it is the sum of all the marginal costs of each unit produced. Producer surplus is thus the area between the price and the MC curve (area B).

Private efficiency in the market: $MU = MC$

In Figure 12.1, both consumer surplus and producer surplus are maximised at output Q_e . This is the equilibrium output under perfect competition. Thus, under perfect competition, the market will ensure that **total surplus** (areas $A + B$), sometimes called **total private surplus**, is maximised. At this output, $MU = P = MC$.

At any output other than Q_e total surplus will be less. If output were below Q_e , then MU would be above MC : total surplus would be increased by producing more. If output

were above Q_e , then MU would be below MC : total surplus would be increased by producing less.

Social efficiency in the market: $MSB = MSC$

Provided the two conditions of (a) perfect competition and (b) the absence of externalities are fulfilled, Pareto optimality (i.e. social efficiency) will be achieved. Let us take each condition in turn.

Definition

General equilibrium Where all the millions of markets throughout the economy are in a simultaneous state of equilibrium.

Total (private) surplus Total consumer surplus ($TU - TE$) plus total producer surplus ($TR - TVC$).

Perfect competition. Perfect competition will ensure that private efficiency is achieved:

$$MU = MC \text{ (for all producers and all consumers)}$$

No externalities. In the absence of externalities, $MSB = MU$ (i.e. the benefits of consumption within society are confined to the direct consumers) and $MSC = MC$ (i.e. the costs of production to society are simply the costs paid by the producers). Thus

$$MSB = MU = P = MC = MSC$$

i.e.

$$MSB = MSC$$

With no externalities, the total surplus shown in Figure 12.1 will represent **total social surplus**.

Inefficiency would arise if (a) competition were not perfect and so marginal revenue were *not* equal to price and as a result marginal cost were not equal to price; or (b) there were externalities and hence either marginal social benefit were different from marginal utility (i.e. marginal *private* benefit) or marginal social cost were different from marginal (private) cost. We examine such 'market failures' in section 12.2.

- ?**
1. If monopoly power existed in an industry, would production be above or below the socially efficient level (assuming no externalities)? Which would be greater, MSB or P ?
 2. Assuming perfect competition and no externalities, social efficiency will also be achieved in factor markets. Demonstrate that this will be where

$$MSB_f = MRP_f = P_f = MDU_f = MSC_f$$
 (where MRP is the marginal revenue product of a factor, MDU is the marginal disutility of supplying it, and f is any factor – see section 10.1).
 3. Why will marginal social benefit not equal marginal social costs in the labour market if there exists (a) union monopoly power and/or (b) firms with monopsony power?

Interdependence, efficiency and the 'invisible hand': the simple analysis of general equilibrium

If there is perfect competition and an absence of externalities throughout the economy, then the whole economy,

Definition

Total social surplus Total benefits to society from consuming a good minus total costs to society from producing it. In the absence of externalities, total social surplus is the same as total (private) surplus.

when in equilibrium, will be socially efficient. A state of general Pareto optimality will exist.

No economy, however, is static. Conditions of demand and supply are constantly changing. Tastes change, technology changes and so on. Thus old patterns of consumption and production will cease to be Pareto optimal. Nevertheless, provided there is perfect competition and no externalities, forces will come into play to restore Pareto optimality.

In this perfect market economy, Pareto optimality is restored not by government action, but rather by the individual actions of producers, consumers and factor owners all seeking their own self-interest. It is as if an 'invisible hand' were working to guide the economy towards social efficiency (see Box 1.5).

The economic system will respond to any change in demand or supply by a whole series of subsequent changes in various interdependent markets. Social efficiency will thereby be restored. The whole process can be illustrated with a diagram showing the circular flow of income (see Figure 12.2).

Assume, for example, that tastes change such that the marginal utility of a particular good rises. This is illustrated on the right-hand side of the diagram by a shift in the MU curve (i.e. the demand curve) from MU_1 to MU_2 (i.e. D_1 to D_2). This will lead to the following sequence of events, which you can follow round the diagram in an anti-clockwise direction.

Consumer demand

The rise in marginal utility (i.e. the rise in marginal social benefit of the good, MSB_g) leads to increased consumption. The resulting shortage will drive up the market price.

Producer supply

The rise in the market price will mean that price is now above the marginal (social) cost of production. It will thus be profitable for firms to increase their production. This in turn will lead to an increase in marginal cost (a movement up along the marginal cost curve) due to diminishing returns. There is a movement up along the supply curve from point a . Price will continue to rise until equilibrium is reached at P_2Q_2 (point b), where $MSB_g = MSC_g$.

Factor demand

The rise in the price of the good will lead to an increase in the marginal revenue product of factors that are employed in producing the good. The reason for this is that the marginal *revenue* product of a factor is its marginal *physical* product multiplied by the *price* of the good (see section 10.1). The marginal physical product is unchanged, but since the price of the good has now gone up, the output of factors will be worth correspondingly more. The following takes just one factor (f) as an example.

Figure 12.2 The interdependence of goods and factor markets

A rise in the value of the factor's output (due to the higher price of the good) will make its marginal revenue product higher than its marginal cost to the firm. This will increase the demand for the factor. Factor demand shifts to $D_2 (= MRP_{12} = MSB_{f2})$. This in turn will drive up the price of the factor.

Factor supply

The rise in the price of the factor will raise the marginal benefit of supplying it (and hence the marginal social benefit). This will mean that the marginal benefit now exceeds the marginal cost (the marginal disutility, MDU_f) of supplying the factor. There is thus a movement up along the factor supply curve from point c as more units of the factor are supplied. The price of the factor will continue to rise until equilibrium is reached at P_2, Q_{f2} (point d), where $MSB_{f2} = MSC_f$.

The process of adjustment does not end here. If supernormal profits are made, new firms will enter. Similarly, if factor rewards are supernormal, new factors will be attracted from other industries. This in turn will affect prices and hence quantities in *other* industries in both goods and factor markets.

In other words, a single change in tastes will create a ripple effect throughout the economy, through a whole series

of interdependent markets. Eventually, long-run equilibrium will be restored with $MSB = MSC$ in all markets. The economy has returned to a position of Pareto optimality. And all this has taken place with no government intervention. It is the 'invisible hand' of the market that has achieved this state of social efficiency.

These arguments form a central part of the neoclassical case for laissez-faire: the philosophy of non-intervention by the government. Under ideal conditions, it is argued, the free pursuit of individual self-interest will lead to the social good. Since intervention is always associated with costs, the neoclassical case says that the optimal approach is to allow this move to the social good to take place, unimpeded.

1. Trace through the effects in both factor and goods markets of the following: (a) an increase in the productivity of a particular type of labour; (b) an increase in the supply of a particular factor.
2. Show in each case how social efficiency will initially be destroyed and then how market adjustments will restore social efficiency.

The following pages examine social efficiency in more detail. You may omit these and skip straight to section 12.2 (page 356) if you want to.

THRESHOLD CONCEPT 11

ALLOCATIVE EFFICIENCY: PRIVATE AND SOCIAL

THINKING LIKE AN
ECONOMIST

Economics is concerned with the allocation of scarce resources. Whenever choices are made, whether by consumers, firms, the government or any other agency, a choice is being made about the allocation of resources.

When you buy a T-shirt costing £10, you are choosing to allocate £10 of your money to the purchase – £10 that could have been spent on something else. But have you allocated your money in the best way?

Similarly, when a firm chooses to produce one product rather than another, or to use technique A rather than some alternative technique, it is choosing to allocate its resources in particular ways. But are these the best ways?

The question is whether the resources have been allocated *efficiently*. We define an efficient allocation of resources as one which brings the maximum benefit for that level of costs. In other words, no gain would be made by reallocating resources in some alternative way. Thus your decision to spend £10 on a T-shirt is an efficient allocation of your resources, if it brings you more benefit (i.e. utility) for the £10 than could any other purchase. The firm's decision to use technique A is an efficient one if it leads to a higher rate of profit: if the marginal benefit (i.e. marginal revenue) relative to the marginal cost is greater than for any other technique.

What we are talking about here is 'allocative efficiency'. It is a *threshold concept* because to understand it is to understand how to make the most of scarce resources: and scarcity is the

core problem of economics for all of us. It is obvious that poor people on very limited incomes will want to spend their money as efficiently as possible. But even exceedingly rich people, who can buy anything they want, are still likely to have limited time or opportunities.

Allocative efficiency is a threshold concept for another reason. We need to see how it relates to *social* objectives. If people all individually achieve their own *private efficiency*, does this mean that society will have an efficient allocation of resources? The answer is no. The reason is that our decisions often have consequences for *other* people: our actions have external costs and/or benefits. These externalities mean that private efficiency and *social efficiency* diverge. We need to understand how and why, and how social efficiency can be achieved.

Then there is the question of equity. Just because everyone is allocating their resources in the best possible way for them, and even if there were no externalities, it does not follow that the allocation of resources is *fair*. However efficiently rich people spend their money, most people would still argue that it is socially desirable to redistribute part of rich people's income to the poor through the tax and benefit system.

1. Why might consumers not always make efficient consumption decisions?
2. Explain the meaning of social efficiency using the concept of Pareto improvements.

p111KI 4
p14

*The intermediate analysis of social efficiency: marginal benefit and marginal cost ratios

In practice, consumers do not consider just one good in isolation. They make choices between goods. Likewise, firms make choices as to which goods to produce and which factors to employ. A more satisfactory analysis of social efficiency, therefore, considers the choices that firms and households make.

Whether as a producer, consumer or worker, a person will gain by expanding activity X relative to activity Y if

$$\frac{MB_X}{MB_Y} > \frac{MC_X}{MC_Y}$$

The reason is straightforward. Activity X is giving a greater benefit relative to its cost than is activity Y. Only when

$$\frac{MB_X}{MB_Y} = \frac{MC_X}{MC_Y}$$

can no further gain be made by switching from the one activity to the other. At this point, people will be acting efficiently in their own private interest.

By analogy, social efficiency is achieved where the social marginal benefit ratio of two goods is equal to the social marginal cost ratio.

KEY
IDEA
29

Social efficiency (equi-marginal formulation) is achieved where the marginal social benefit ratios are equal to the marginal social cost ratios for any two alternatives. In the case of two alternatives X and Y, this will be where

$$\frac{MSB_X}{MSB_Y} = \frac{MSC_X}{MSC_Y}$$

As with the simple analysis of social efficiency, it can be shown that, provided there is perfect competition and no externalities, the achievement of private efficiency will result in social efficiency also. This will be demonstrated in the following sections.

*Efficiency in the goods market (intermediate analysis)

Private efficiency under perfect competition

Consumption. The optimum combination of two goods X and Y consumed for any consumer is where

$$\frac{MU_X}{MU_Y} \text{ (i.e. MRS)} = \frac{P_X}{P_Y}$$

The *marginal rate of substitution in consumption (MRS)* (see page 115) is the amount of good Y that a consumer would

TC 11
p353KI 14
p111KI 14
p111

be willing to sacrifice for an increase in consumption of good X (i.e. $\Delta Y/\Delta X$). $MRS = MU_X/MU_Y$ since, if X gave twice the marginal utility of Y, the consumer would be prepared to give up two of Y to obtain one of X (i.e. $MRS = 2/1$).

? If MU_X/MU_Y were greater than P_X/P_Y , how would consumers behave? What would bring consumption back to equilibrium where $MU_X/MU_Y = P_X/P_Y$?

Production. The optimum combination of two goods X and Y produced for any producer is where

$$\frac{MC_X}{MC_Y} \text{ (i.e. } MRT) = \frac{P_X}{P_Y}$$

The *marginal rate of transformation in production (MRT)* is the amount of good Y that the producer will have to give up producing for an increase in production of good X (i.e. $\Delta Y/\Delta X$) if total costs of production are to remain unchanged. $MRT = MC_X/MC_Y$ since, if the marginal cost of good X were twice that of Y, the firm's costs would remain constant if it gave up producing two of Y in order to produce an extra X (i.e. $MRT = 2/1$).

? If MC_X/MC_Y were greater than P_X/P_Y , how would firms behave? What would bring production back into equilibrium where $MC_X/MC_Y = P_X/P_Y$?

Social efficiency under perfect competition

In each of the following three cases, it will be assumed that there are no externalities.

Social efficiency between consumers. If MU_X/MU_Y for person a is greater than MU_X/MU_Y for person b, both people would gain if person a gave person b some of good Y in exchange for some of good X. There would be a Pareto improvement. The Pareto optimal distribution of consumption will therefore be where

$$\frac{MU_X}{MU_Y} \text{ person a} = \frac{MU_X}{MU_Y} \text{ person b} = \frac{MU_X}{MU_Y} \text{ (Pareto optimal)}$$

i.e. MRS is the same for all consumers.

But this will be achieved *automatically* under perfect competition, since each consumer will consume that combination of goods where $MU_X/MU_Y = P_X/P_Y$ and all consumers face the *same* (market) prices and hence the *same* P_X/P_Y .

Social efficiency between producers. If MC_X/MC_Y for producer g is greater than MC_X/MC_Y for producer h, then if producer g produced relatively more Y and producer h produced relatively more X, the same output could be produced at a lower total cost (i.e. with less resources). There would be a Pareto improvement. The Pareto optimal distribution of production between firms is therefore where

$$\frac{MC_X}{MC_Y} \text{ producer g} = \frac{MC_X}{MC_Y} \text{ producer h} = \frac{MC_X}{MC_Y} \text{ (producer i) ...}$$

i.e. MRT is the same for all producers.

This too will be achieved *automatically* under perfect competition, since each producer will maximise profits where $MC_X/MC_Y = P_X/P_Y$ and all producers face the *same* (market) prices and hence the *same* P_X/P_Y .

Social efficiency in exchange. If MU_X/MU_Y (i.e. MRS) for all consumers is greater than MC_X/MC_Y (i.e. MRT) for all producers, then there would be a Pareto improvement if resources were reallocated to produce relatively more X and less Y.

Assume the MRS (i.e. $\Delta Y/\Delta X$) = 3/1 and the MRT (i.e. $\Delta Y/\Delta X$) = 2/1. Consumers will be prepared to give up three units of Y to obtain one unit of X, and yet producers only have to sacrifice producing two units of Y to produce one unit of X. Thus consumers can pay producers in full for extra units of X they produce and there will still be a net gain to consumers. There has been a Pareto improvement.

The Pareto optimal allocation of resources is where

$$\text{Social } MRS (\text{SMRS}) = \text{Social } MRT (\text{SMRT})$$

Assuming no externalities, this will be achieved automatically under perfect competition, since (a) with no externalities, social and private marginal rates of substitution will be the same, and similarly social and private marginal rates of transformation will be the same, and (b) P_X/P_Y is the same for all producers and consumers. In other words:

$$\text{SMRS} = \text{MRS}_{\text{all consumers}} = \frac{MU_X}{MU_Y} \text{ all consumers} = \frac{P_X}{P_Y}$$

and

$$\text{SMRT} = \text{MRT}_{\text{all producers}} = \frac{MC_X}{MC_Y} \text{ all producers} = \frac{P_X}{P_Y}$$

i.e.

$$\text{SMRS} = \text{SMRT}$$

Thus the pursuit of private gain, it is argued, has led to the achieving of social efficiency. This is an important conclusion. It is clearly very attractive to people (and to many politicians) to think that, simply by looking after their own interests, social efficiency will thereby be achieved!

This is illustrated graphically in Figure 12.3. A production possibility curve (the red line) shows the various combinations of two goods X and Y that can be produced (see pages 14–17). Its slope is given by $\Delta Y/\Delta X$ and shows how much Y must be given up to produce 1 more of X. Its slope, therefore, is the marginal rate of transformation (MRT).

Social indifference curves can be drawn showing the various combinations of X and Y that give particular levels of satisfaction to consumers as a whole. Their slope is given by $\Delta Y/\Delta X$ and shows how much Y consumers are prepared to give up to obtain one more unit of X. Their slope, therefore, is the marginal rate of substitution in consumption (MRS).

Figure 12.3

Social efficiency under perfect competition

The Pareto optimal combination of goods is at point S, where the production possibility curve is tangential to the highest possible indifference curve. At any other point on the production possibility curve, a lower level of consumer satisfaction is achieved. The slope of the tangent at S is equal to both MRT and MRS, and hence also to P_x/P_y .

? If production were at a point on the production possibility curve below point S, describe the process whereby market forces would return the economy to point S.

***Efficiency in the factor market (intermediate analysis)**

A similar analysis can be applied to factor markets, showing that perfect competition and the absence of externalities will lead to efficiency in the use of factors between firms. Assume that there are two factors: labour (L) and capital (K).

If MPP_L/MPP_K for firm g is greater than MPP_L/MPP_K for firm h, then if firm g were to use relatively more labour and firm h relatively more capital, more could be produced for the same total input. There would be a Pareto improvement.

The Pareto optimum distribution of factors between firms will therefore be where

$$\frac{MPR_L}{MPR_K \text{ firm g}} = \frac{MPR_L}{MPR_K \text{ firm h}} = \frac{MPR_L}{MPR_K \text{ firm i}} \dots$$

But this will be achieved automatically under perfect competition since, as we saw in section 6.3, each producer will be producing where $MPP_L/MPP_K = P_L/P_K$ and each producer will face the same factor prices and hence P_L/P_K .

Provided there are no externalities, the marginal private benefit of labour to a firm (MPP_L) will equal the marginal social benefit of labour (MSB_L). The same applies to capital. Thus $MPP_L/MPP_K = MSB_L/MSB_K = P_L/P_K$. Similarly on the cost side, if there are no externalities, then $MC_L/MC_K = MSC_L/MSC_K = P_L/P_K$. Therefore:

$$\frac{MSB_L}{MSB_K} = \frac{MSC_L}{MSC_K}$$

***The intermediate analysis of general equilibrium**

General equilibrium is where equilibrium exists in all markets. Under perfect competition and in the absence of externalities, general equilibrium will give Pareto optimality.

If any change in the conditions of demand or supply occurs, this disequilibrium will automatically create a whole series of interdependent reactions in various markets.

Assume, for example, that tastes change such that MU_X rises and MU_Y falls. This will lead to the following sequence of events in the goods market.

MU_X/MU_Y will now be greater than P_X/P_Y . Thus consumers buy more X relative to Y. This causes MU_X/MU_Y to fall (due to diminishing marginal utility) and P_X/P_Y to rise (due to a relative shortage of X and a surplus of Y), helping to restore equilibrium where $MU_X/MU_Y = P_X/P_Y$. The rise in P_X/P_Y causes P_X/P_Y to be greater than MC_X/MC_Y . Thus firms produce more X relative to Y. This causes MC_X/MC_Y to rise (due to diminishing returns), helping to restore equilibrium where $P_X/P_Y = MC_X/MC_Y$. This process of price and quantity adjustment thus continues until once more

$$\frac{MU_X}{MU_Y} = \frac{P_X}{P_Y} = \frac{MC_X}{MC_Y}$$

Similar adjustments will take place in the factor market. The price of those factors used in producing good X will be bid up and those used in producing Y will be bid down. This will encourage factors to move from industry Y and into industry X. The whole process of adjustment continues until equilibrium and Pareto optimality are restored in all goods and factor markets.

Section summary

1. Social efficiency (Pareto optimality) will be achieved when it is not possible to make anyone better off without making someone else worse off. This will be achieved if people behave 'rationally' under perfect competition providing there are no externalities.
2. Rational behaviour involves doing more of any activity whose marginal benefit (*MB*) exceeds its marginal cost (*MC*) and less of any activity whose marginal cost exceeds its marginal benefit. The optimum level of consumption or production for the individual consumer or firm will be where $MB = MC$. This is called a situation of 'private efficiency'.
3. In a perfectly competitive goods market, the consumer will achieve private efficiency where $MU = P$, and the producer where $P = MC$. Thus $MU = MC$. In the absence of externalities, private benefits and costs will equal social benefits and costs. Thus $MU = MSB$ and $MC = MSC$. Thus $MSB = MSC$: a situation of social efficiency (Pareto optimality).
4. Given perfect competition and an absence of externalities, if the equality of marginal benefit and marginal cost is destroyed in any market (by shifts in demand or supply), price adjustments will take place until general equilibrium is restored where $MSB = MSC$ in all markets: a situation of general Pareto optimality.
- *5. The rational producer or consumer will choose the combination of any two pairs of goods where their

marginal benefit ratio is equal to their marginal cost ratio. Consumers will achieve private efficiency where

$$\frac{MU_x}{MU_y} \text{ (i.e. } MRS) = \frac{P_x}{P_y}$$

Producers will achieve private efficiency where

$$\frac{P_x}{P_y} = \frac{MC_x}{MC_y} \text{ (i.e. } MRT)$$

Thus:

$$\frac{MU_x}{MU_y} = \frac{MC_x}{MC_y}$$

In the absence of externalities, this will give a situation of social efficiency where

$$\frac{MSB_x}{MSB_y} = \frac{MSC_x}{MSC_y}$$

- *6. Similarly, in factor markets, social efficiency will be achieved if there is perfect competition and an absence of externalities. This will be where the *MSB* ratio for any two factors is equal to their *MSC* ratio.
- *7. Again assuming perfect competition and an absence of externalities, general equilibrium will be achieved where there is a socially efficient level of production, consumption and exchange in all markets: where the *MSB* ratio for any pair of goods or factors is equal to the *MSC* ratio.

12.2 THE CASE FOR GOVERNMENT INTERVENTION

The discussion above considered what happens 'under ideal conditions', but in the real world, markets fail to achieve social efficiency. Part of the problem is the existence of externalities, part is a lack of perfect competition. Even if those were not considerations, we are also faced with markets that may take a long time to adjust to any disequilibrium given short-run immobility of factors. What is more, social efficiency (i.e. Pareto optimality) is not the only economic goal of society. Markets may also fail to the extent that they fail to achieve other objectives such as greater equality and faster growth. In this section we explore the various categories of market failure.

Markets generally fail to achieve social efficiency.

There are various types of market failure. Market failures provide one of the major justifications for government intervention in the economy.

Externalities

The market will not lead to social efficiency if the actions of producers or consumers affect people other than themselves: in other words, when there are *externalities* (side effects).

Externalities are spillover costs or benefits. Where these exist, even an otherwise perfect market will fail to achieve social efficiency.

Whenever other people are affected beneficially, there are said to be *external benefits*. Whenever other people are affected adversely, there are said to be *external costs*.

Thus the full cost to society (the *social cost*) of the production of any good is the private cost faced by firms plus any externalities of production. Likewise the full benefit to society (the *social benefit*) from the consumption of any

Definitions

External benefits Benefits from production (or consumption) experienced by people *other* than the producer (or consumer) directly involved in the transaction.

External costs Costs of production (or consumption) borne by people *other* than the producer (or consumer) directly involved in the transaction.

Social cost Private cost plus externalities in production.

Social benefit Private benefit plus externalities in consumption.

Figure 12.4 Negative externality in production

good is the private benefit enjoyed by consumers plus any externalities of consumption.

In the following section we will consider four different types of externality. (In each case, we will assume that the market is in other respects perfect.)

External costs of production ($MSC > MPC$) with no external cost/benefits of consumption

When a chemical firm dumps waste in a river or pollutes the air, the community bears additional costs to those borne by the firm. There are marginal external costs MEC_p of chemical production. This is illustrated in Figure 12.4. In this example we assume that the external costs begin with the first unit of production and increase at a constant rate.

The marginal social cost (MSC) of chemical production equals the marginal private costs (MPC) plus the MEC_p . This means that the MSC curve is above the MPC curve. The vertical distance between them is equal to the MEC_p . It is also assumed that there are no externalities in consumption, which means that the marginal social benefit (MSB) curve is the same as the marginal private benefit (MPB) curve.

Competitive market forces, with producers and consumers responding only to private costs and benefits, will result in a market equilibrium at point a in Figure 12.4: i.e. where demand equals supply. The market equilibrium price is P_{pc} while the market equilibrium quantity is Q_{pc} .

At P_{pc} , MPB is equal to MSB . The market price reflects both the private and social benefits from the last unit consumed. However, the presence of external costs in production means that $MSC > MPC$.

The *socially optimal output* would be Q^* , where $P = MSB = MSC$. This is illustrated at point c and clearly shows how external costs of production in a perfectly competitive market result in overproduction: i.e. $Q_{pc} > Q^*$. From society's point of view too much waste is being dumped in rivers.

At the market equilibrium (Q_{pc}) there is a *deadweight welfare loss* when compared with the socially optimal output (Q^*). In this context, deadweight welfare loss represents the excess of social costs over social benefits at all outputs above Q^* . At Q_{pc} , this is given by the shaded area, abc . Put another way, moving from Q_{pc} to Q^* would represent a *gain* in *social surplus* of the area abc .

One of the reasons why external costs cause problems in a free-market economy is because no one has legal ownership of factors such as the air or rivers. Therefore, nobody has the ability either to prevent or to charge for their use as a dumping ground for waste. Such a 'market' is *missing*. Control must, therefore, be left to the government, local authorities or regulators.

Other examples of external costs of production include extensive farming that destroys hedgerows and wildlife, and global warming caused by CO_2 emissions from power stations, industry and transport.

External benefits of production ($MSC < MPC$) with no external costs/benefits of consumption

If companies in the forestry industry plant new woodlands, there is a benefit not only to the companies themselves, but also to the world through a reduction of CO_2 in the atmosphere (forests are a carbon sink). In this case there are marginal external benefits of production (MEB_p). These are

Definitions

Socially optimal output The output where $MSC = MSB$: the output where total social surplus is maximised.

Deadweight welfare loss from externalities The loss of social surplus at the competitive market equilibrium compared with the social optimum where $MSC = MSB$.

Social surplus Total social benefits minus total social costs.

Figure 12.5 Positive externality in production

shown in Figure 12.5. We assumed that they begin with the first tree planted but that the marginal benefit declines with each additional tree. In other words, the MEB_p is a downward sloping line.

? Why are marginal external benefits typically likely to decline as output increases? Why in some cases might marginal external benefits be constant at all levels of output or even increase as more is produced?

Given these positive externalities, the marginal social cost (MSC) of providing timber is less than the marginal private cost: $MSC = MPC - MEB_p$. This means that the MSC curve is below the MPC curve. The vertical distance between the curves is equal to the MEB_p . Once again it is assumed that there are no externalities in consumption so that $MSB = MPB$.

Competitive market forces will result in an equilibrium output of Q_{pc} where market demand ($=MPB$) equals market supply ($=MPC$) (point a). The socially efficient level of output, however, is Q^* : i.e. where $MSB = MSC$ (point c). The external benefits of production thus result in a level of output below the socially efficient level. From society's point of view not enough trees are being planted. The deadweight welfare caused by this underproduction is illustrated by the area abc . Output is not being produced between Q_{pc} and Q^* even though $MSB > MSC$.

Another example of external benefits in production is that of research and development. An interesting recent example has been the development of touchscreen technology for tablets and mobile phones. If other firms have access to the results of the research, then clearly the benefits extend beyond the firm which finances it. Since the firm only

receives the private benefits, it may conduct a less than optimal amount of research. In turn, this may reduce the pace of innovation and so negatively affect economic growth over the longer term.

External costs of consumption ($MSB < MPB$) with no external costs/benefits of production ($MSC = MPC$)

Drinking alcohol can sometimes lead to marginal external costs of consumption. For example, there are the extra nightly policing costs to deal with the increased chance of social disorder. Public health costs may also be greater as a direct consequence of peoples' drinking behaviour: e.g. through an increase in hospitalisations. It may also lead to a number of alcohol-related road accidents. These marginal external costs of consumption (MEC_c) result in the marginal social benefit of alcohol consumption being lower than the marginal private benefit: i.e. $MSB = MPB - MEC_c$.

This is illustrated in Figure 12.6 where the MSB curve is below the MPB curve. In this example, it is assumed that there are no externalities in production so that $MSC = MPC$.

Competitive market forces will result in an equilibrium output of Q_{pc} (point a), whereas the socially efficient level of output is Q^* : i.e. where $MSB = MSC$ (point c). The external costs of consumption result in a level of output above the socially efficient level: i.e. $Q_{pc} > Q^*$. From society's point of view too much alcohol is being produced and consumed. The deadweight welfare caused by this overconsumption is illustrated by the area abc .

Other possible examples of negative externalities of consumption include taking a journey by car, noisy music in public places, litter, using a mobile phone while driving and the smoke from cigarettes (passive smoking).

Figure 12.6 Negative externality in consumption

External benefits of consumption ($MSB > MPB$) with no external costs/benefits of production ($MSC = MPC$)

How do people travel to a city centre to go shopping on a Saturday? How do they travel to a football match? If they use the train then other people benefit, as there is less congestion and exhaust fumes and fewer accidents on the roads. These marginal external benefits of consumption (MEB_c) result in the marginal social benefit of rail travel being *greater* than the marginal private benefit (i.e. $MSB = MPB + MEB_c$).

This is illustrated in Figure 12.7 where the MSB curve is above the MPB curve. The vertical distance between the curves is equal to the MEB_c . Once again it is assumed that there are no externalities in production so that $MSC = MPC$.

External benefits of consumption result in a level of output below the socially efficient level: i.e. $Q_{pc} < Q^*$. From society's point of view not enough journeys are being made on the train. The deadweight welfare loss caused by this underconsumption is illustrated by the area abc .

Other examples of external benefits of consumption include the beneficial effects for other people from someone using a deodorant, parents getting their children vaccinated, and people planting flowers in their front garden.

To summarise: whenever there are external benefits, there will be too little produced or consumed. Whenever there are external costs, there will be too much produced or consumed. The market will not equate MSB and MSC .

The above arguments have been developed in the context of perfect competition with prices determined by demand and supply. Externalities can also occur in all other types of market.

1. Give other examples of each of the four types of externality.
2. Redraw Figure 12.4, only this time assume there is only one producer that is a monopoly. How does the existence of market power affect the relationship between the private and the social optimum positions?
3. Redraw Figure 12.4, only this time assume that at low levels of production the good generates no external costs. Only once a certain output is reached (Q^*) does the production of additional units generate rising marginal external costs.

Public goods

There is a category of goods where the positive externalities are so great that the free market, whether perfect or imperfect, may not produce at all. They are called **public goods**. In order to understand exactly what a public good is it is important to discuss two of its key characteristics – **non-rivalry** and **non-excludability**. Before looking specifically at public goods, let us explore the concepts of rivalry and excludability in more detail.

Definitions

Public good A good or service that has the features of non-rivalry and non-excludability and as a result would not be provided by the free market.

Non-rivalry Where the consumption of a good or service by one person will not prevent others from enjoying it.

Non-excludability Where it is not possible to provide a good or service to one person without it thereby being available free for others to enjoy.

Figure 12.7 Positive externality in consumption

The degree of rivalry

Rivalry occurs when one person's consumption of a good reduces the amount of it that is available for other consumers. Goods can vary in their degree of rivalry.

Perfectly rivalrous goods. At one extreme are goods that are perfectly rivalrous. A good has this characteristic if, as one or more people increase their consumption of the product, it prevents all other or 'rival' consumers from enjoying it. This is typical with non-durable goods such as food, alcohol and fuel. For example, imagine that you have purchased a bar of chocolate for your own consumption. Each chunk of the chocolate bar that you eat means that there is less available for other or 'rival' consumers to enjoy. They cannot eat the same piece that you have eaten! The good gets 'used up' when it is consumed.

Many durable goods such as mobile phones also have the property of being rivalrous. For example, if you use your mobile phone it usually prevents other people from using it. Although the mobile phone does not get 'used up', only one person can usually consume the benefits it provides at a time: e.g. sending a text or calling someone.

Perfectly non-rivalrous goods. At the other extreme are goods that have the property of being perfectly non-rivalrous. A good has this characteristic if as one or more people increase their consumption of the product it has no impact on the ability of other, or 'rival', consumers to enjoy the good. For example, imagine that you turn on either your television or tablet to watch a live football match or an episode of your favourite TV programme. Your decision to watch the programme has no impact on the ability of other people to enjoy watching the same programme on a

different device. The television set may be rivalrous but the broadcast is not.

Goods with a degree of rivalry and non-rivalry. In reality, many goods and services will be neither perfectly rival nor non-rival. For example, it may be possible for more than one person to enjoy watching a video clip on a mobile phone. However, a 'crowding effect' will soon occur. As additional people try watching the video it will prevent others from seeing it on the same phone.

There are a number of goods and services that may have the characteristic of being relatively non-rival with low numbers of consumers, before becoming more rivalrous at high levels of consumption. For example, some goods cover a comparatively small geographic area. Here overcrowding, and hence rivalry, will become an issue with relatively few consumers. Viewing a carnival procession, for example, may be non-rivalrous with just a few observers, but quickly any location along the route will become crowded and a good view becomes rivalrous. Another example is enjoying open spaces sitting on a beach: space becomes more rivalrous as the beach fills up with people. In other cases, such as access to the Internet, rivalry might only set in beyond very high levels of usage, when global demand is exceptionally high.

Rather than trying to categorise many goods as either rivalrous or non-rivalrous it makes more sense to think of them as having different degrees of rivalry. They could be placed on a scale of rivalry as illustrated along the horizontal axis in Figure 12.8.

How rivalrous in consumption are each of the following: (a) a can of drink; (b) public transport; (c) a radio broadcast; (d) the sight of flowers in a public park?

Figure 12.8 Classifying goods according to the degree of rivalry and ease of excludability

The ease of excludability

Excludability occurs when the supplier of a good can restrict who consumes it. This is the case for goods sold in the market. Suppliers allow only those consumers who are prepared to pay for the good to have it. Just as with rivalry, goods vary in their ease of excludability

Easily excludable goods. At one extreme, some goods have the property of being very easily excludable. In this case a relatively low-cost and effective system can be implemented which guarantees that only those people who have paid for the good are able to enjoy the benefits it provides. The system must also prevent anyone who does not pay from obtaining any of the benefits that consuming the good provides. For example, although television broadcasts have a high degree of non-rivalry, a relatively straightforward and reasonably effective system of encryption could be implemented to exclude non-payers from watching the programmes. If this were not possible then pay television channels and pay-per-view broadcasting could not exist. YouTube has also introduced a number of subscription channels.

Advances in technology may also change the ease of excludability for any given good or service over time.

Perfectly non-excludable goods. At the other extreme there may be some goods for which excludability is impossible: i.e. they have the property of being non-excludable. A good has this characteristic if it is too costly or simply not feasible to implement a system that would effectively prevent those people who have not paid from enjoying the benefits it provides.

In some circumstances it may be theoretically possible to exclude non-payers, but in reality the transaction costs involved are too great. For example, it may be very difficult

to prevent anyone from fishing in the open ocean or enjoying the benefits of walking in a country park.

Once again, many goods will be neither perfectly excludable nor non-excludable. In these cases it makes more sense to think about the differing levels of ease with which non-payers can be excluded from consuming the good. This is also illustrated in Figure 12.8, this time up the vertical axis.

Pure private goods

Good X in Figure 12.8 is a pure private good. It is very easy to exclude any non-payers from the consuming the product, which is perfectly rivalrous. A pure private good is one where the benefits can be enjoyed only by the consumer who owns (or rents) it.

In reality, many goods will be close to point X and have significant degrees of rivalry and ease of excludability. Products that fall into this category can normally be provided by the market mechanism.

Pure public goods

Good Z in Figure 12.8, by contrast, has the characteristics of being perfectly non-rival and completely non-excludable. This is known as a **pure public good**. Once a given quantity of a pure public good is produced, everyone can

Definition

Pure public good A good or service that has the characteristics of being perfectly non-rival and completely non-excludable and, as a result, would not be provided by the free market.

obtain the same level of benefits it provides. Therefore, the marginal cost of supplying another customer with a given quantity of a public good is zero. However, this should not be confused with the marginal cost of producing another unit of the good. This would involve using additional resources; so the marginal cost of producing another unit would be positive.

Another way to think about the characteristics of pure public goods is that they cannot be sold in separate units to different customers. For example, it is impossible for you to consume five units of a pure public good while somebody else consumes an additional two units of the good. Once five units are produced for one person's consumption, those same five units are freely available for everyone else to consume.

There is some debate as to whether pure public goods actually exist or whether they are merely a theoretical idea. Perhaps one of the closest real-world examples is that of national defence. Once a given investment in national defence has been made, additional people can often benefit from the protection it provides at no additional cost. It would also be very difficult to exclude anyone within a country from obtaining the benefits from the increase in security.

 *To what extent is national defence a pure public good? Can it ever be rivalrous or excludable in consumption.*

Impure pure goods

Good W in Figure 12.8 is an example of an **impure public good**. It has a low level of rivalry, without being perfectly rivalrous, and it is difficult, but not impossible, to exclude non-payers. In reality, many public goods will fall into this category, with some being more impure than others. We will see later that as the degree of rivalry and ease of excludability fall it becomes increasingly difficult for the good to be provided by the market mechanism.

Club goods. Good Y has a low degree of rivalry but exclusion is relatively easy. This is called a **club good**. Wireless Internet connection on a train or in a café are examples of a club good if a password is required; other examples include subscription TV services, such as Netflix or Amazon Prime.

Common good or resource. Good V has a high degree of rivalry but the exclusion of non-payers is very difficult. This is called a **common good or resource**. The high degree of rivalry means that the quantity or quality of the common resource available to one person is negatively affected by the number of other people who consume or make use of the same resource. Because it is difficult to exclude non-payers, a common resource is also potentially available to everyone, free of charge.

Fishing in the open ocean is an example. In the absence of intervention, fishing boats can catch as many fish as is possible. There is no 'owner' of either the fish or the sea to stop them. As one fishing boat catches more fish, it means there is less available for other fishing boats: fish are *rivalrous*. Other

examples include the felling of trees in the rainforests and the use of the atmosphere as a common 'dump' for emissions.

If producers/consumers only consider the costs and benefits to themselves, then it is inevitable that common resources will be overused. As the good is free, a rational self-interested individual will keep consuming or using it until the marginal private benefit is zero, even though they are reducing the quantity or quality available for others; they are consuming past the point where $MSC = MSB$. This is the extreme case of a negative externality where the cost of the resource to the user is zero.

The inevitability of the outcome is known as the **tragedy of the commons**. Depleted fish stocks, disappearing rainforests and a heavily polluted atmosphere all provide evidence to support the tragedy of the commons.

However, is it inevitable that all common resources will be overused? The Nobel Prize winning economist Elinor Ostrom discovered many real-world common resources that were consumed in a sustainable manner. Her work is discussed in more detail in Box 12.2.

1. To what extent can the following be regarded as common resources? (a) Rainforests; (b) children's playgrounds in public parks; (c) silence in a library; (d) the Internet.
2. Where would you place each of the following in Figure 12.8: (a) an inner city road at 3:00am; (b) an inner city road at 8:00am; (c) a toll motorway at 3:00am; (d) a toll motorway at 8:00am?

The efficient level of output for a pure public good

The socially efficient level of output is the quantity at which the marginal social benefit is equal to the marginal social cost. In a competitive market without externalities the marginal social benefit curve is the same as the market demand curve.

The market demand curve for a private good illustrates the sum of all the quantities demanded by all consumers at each possible price. Different consumers will each want to purchase varying amounts at each price. These different individual demands at each price are simply added together in order to derive the market demand curve for a private good. This is known as horizontal aggregation or summation of individual demand curves.

Definitions

Impure public good A good that is partially non-rivalrous and non-excludable.

Club good A good which has a low degree of rivalry but is easily excludable.

Common good or resource A good or resource that has a high degree of rivalry but the exclusion of non-payers is difficult

Tragedy of the commons When resources are commonly available at no charge, people are likely to overexploit them.

The market demand curve for a pure public good cannot be derived in the same way, because consumers are unable to purchase and consume different quantities of the good. Once a given amount of a pure public good is produced for one customer, every other customer can consume that same amount at no additional cost.

Therefore, instead of thinking about how much people are willing to buy at each different price, we have to work out how much people are willing to pay *in total* for each possible level of output. In other words, we have to add together the maximum amount each consumer is willing to pay for each possible level of output. This is illustrated in Figure 12.9.

To keep the example simple it is assumed that there are just two consumers of the public good – Dean and Jon. In most real-world examples there would be many more. The maximum amount Dean would be willing to pay to consume the 10th unit of the good is illustrated at point *a* on his demand curve (D_D) and is £30. The maximum amount Jon would be willing to pay for the 10th unit of the good is illustrated at point *b* on his demand curve (D_J) and is £50.

Therefore, if we simply add these willingness-to-pay figures together we obtain the marginal benefit to society from producing the tenth unit of the public good. This is illustrated at point *c* and is £80. This provides us with one point on the marginal social benefit curve. If we continue this exercise for each different level of output, the marginal social benefit (MSB) can be derived as illustrated in Figure 12.9. The curve has been derived in this example by vertically aggregating Dean's and Jon's individual demand curves: $MSB = D_D + D_J$.

Producing a public good would normally have the same characteristics as producing a private good. Costs would vary with output in a very similar manner. Therefore the marginal cost (MC) for the market as a whole would be derived in the same way as it would be for a private good: i.e. by adding together the quantities that each firm would want to supply at each price – the horizontal summation of all the individual

firms' marginal cost curves. Hence it is drawn as an upward-sloping line.

Assuming there are no externalities in production, the private marginal cost curve is the same as the social marginal cost curve ($MC = MSC$). The socially efficient quantity can be found where $MSC = MSB$, which is at point *f* at an output level of 16.

Provision of pure public goods and the free-rider problem

Assume a private firm produced 16 units of the good and charged Jon a price of £20 per unit (point *e*) and Dean £12 per unit (point *d*). These prices would equal their maximum willingness to pay for 16 units. If Jon acts in a perfectly rational and selfish manner we can predict that he will not pay for the good. Why? Because once the 16 units are produced he can consume them whether he has paid for them or not. He can act as a **free-rider** by enjoying the benefits of a good which have been paid for by Dean.

Unfortunately for Jon, if Dean thinks the same way, then he will not pay for the good either. If neither of them pays for the good then the firm will not generate any revenue and

KEY
IDEA
32

The free-rider problem. People are often unwilling to pay for things if they can make use of things other people have bought. This problem can lead to people not purchasing things that would be to the benefit of them and other members of society to have.

Definition

Free-rider problem When it is not possible to exclude other people from consuming a good that someone has bought.

Figure 12.9 The efficient output of a pure public good

BOX 12.1 THE POLICE AS A PUBLIC SERVICE

CASE STUDIES AND APPLICATIONS

Could some aspects of policing be provided privately?

A good example of a good or service that has public-good properties is policing. Take the case of police officers on the beat. They are providing a general service to the community by deterring and detecting crime.

The cost to individuals of privately employing their own police officers would be considerable. For most people this cost would far outweigh the benefits. However, the impact of having police officers on the beat would benefit many individuals in a community.

Voluntary contributions from local residents for local policing

Perhaps local residents could all privately contribute a relatively small amount towards the costs of employing the police officers and collectively enjoy the benefits.

This idea might seem rather strange, but this is exactly what the residents of Frinton-on-Sea in Essex have done. Following cuts in police services, 400 of the 4000 residents have been making a voluntary contribution of £2 per week to fund a private security firm, AGS, to patrol the streets from 7:00pm to 7:00am. The money was collected door to door following a leaflet campaign. The security staff who patrol the streets have exactly the same powers as any other private citizen.

Why is it unlikely that everyone would contribute?

Employing security staff to deter crime in a whole town has public-good properties. If one member of the community benefits from the lower chance of a crime being committed, it does not prevent other members of the community from enjoying the same benefits. The deterrence effect is not 'used up' in consumption and so has a very low degree of rivalry.

It would also be very difficult to prevent someone in the local community from benefiting, even if they had not paid towards the costs of the scheme. In the Frinton-on-Sea example, the owner of AGS has stated that 'we don't avoid the streets where people are not paying'.

Because it is difficult to exclude non-payers and there is a strong incentive for people to free-ride, this provides an economic rationale for the police to be funded by the government and paid for from taxation. The case of

Frinton-on-Sea is very unusual and it will be interesting to see if enough people continue to make the voluntary contributions in order for the business to remain viable.

Policing where there is no free-rider problem

But do all aspects of policing have a free-rider problem? The answer is no. When there is a *specific* task of guarding specific property, policing could be provided by the market. This is in fact done by security firms. Security guards are employed by banks, shops, etc., to prevent theft or criminal damage to their property. In these cases, the private benefits are perceived to exceed the private costs.

Should such security services be provided privately or are they better provided by the police? Since the *private* benefits in such cases are large, there is a strong argument for charging the recipient. But why should the service be provided by private security firms? Could the police not charge firms for specific guard duties? The problem here is that, if private security firms were not allowed to operate, the police would have a monopoly and could charge very high prices unless the prices were regulated by the government. Also, the quality of the service might be poorer than that provided by private security companies which were competing against each other for business.

On the other hand, the police are likely to bring greater expertise to the job. There are also economies of scale to be gained: for example, the police may have knowledge of criminal activities in other parts of the area which may pose a threat to the particular property in question. Finally, there is the problem that private security guards may not show the same level of courtesy as the police in dealing with the public (or criminals for that matter).

1. The police charge football clubs for policing inside football grounds, but make no charge for policing outside the ground. Explain this approach.
2. Could other aspects of policing make use of market forces? Examine the case for charging to investigate the theft of a bicycle. Would your conclusion differ if the crime involved an attack on an individual rather than property?

quickly go out of business. As a result, both Dean and Jon will be worse off. Because of the free-riding problem, firms cannot produce the good and make a profit in a private market; so the output will be zero. The social inefficiency this creates can be illustrated by the area of deadweight welfare loss in Figure 12.9: i.e. the shaded area *fgh*.

With just two people it may be possible for the consumers to agree on contribution levels. However, as the number of people who benefit from the public good gets larger, free-riding becomes more likely. This will make it increasingly difficult for private firms to produce public goods in an unregulated market without any government support. If they charge a price they are, in effect, asking for a voluntary

contribution from each customer who can consume the good, whether they have paid or not. If no voluntary contributions are forthcoming, then the good will not be provided. Some newspapers, such as *The Guardian*, provide a website that is freely accessible without a password. They do, however, ask for contributions from readers to help fund the site. (This is not a pure public good, however, as newspaper sites sell advertising space, which is both rivalrous and excludable.)

The more closely an impure public good resembles a pure public good, the more likely the free-riding problem becomes. It is then increasingly unlikely that the market mechanism will produce the socially efficient level of the good. In these

BOX 12.2

A COMMONS SOLUTION

EXPLORING
ECONOMICS

Making the best use of common resources

To avoid the tragedy of the commons, one solution is to change the status of such resources. There are two obvious ways of doing this.

The first is for the government or an intergovernmental agency either to take over the resources or to regulate their use. Thus a national or local government could pass laws preventing people from tipping waste onto common land or into rivers. Alternatively, groups of governments could act collectively to regulate activities. An example here is the EU's common fisheries policy or international agreements to ban whaling.

The second is to privatise such resources. Common land could be sold or given to private landowners. Such land would then have the property of excludability. This solution clearly raises questions of fairness. How should the land be divided up? If it is sold, how should the previous users of the resource be compensated – if at all? In the 'enclosure movement' in Britain in the eighteenth and nineteenth centuries, common lands were often acquired by wealthy aristocracy and hedges put around them. Poor peasants, who had previously used the land, either had to rent it from the landlords or left the land and were forced to take low-paid work in the cities.

But is there any way for resources to stay as common resources without them being overexploited? After all, economic theory would seem to suggest that the overexploitation of such resources is inevitable: that common ownership will end in tragedy.

Social attitudes towards common resources

In practice, many common resources are used sustainably without government regulation.

When economists began to look at how systems of commonly managed resources actually worked, they found to their surprise that they often worked quite well. Swiss Alpine pastures; Japanese forests; irrigation systems in Spain and the Philippines. All these were examples of commons that lasted for decades. Some irrigation networks held in common were more efficiently run than the public and private systems that worked alongside them. Though there were failures, too, it seemed as if good management could stave off the tragedy.¹

The crucial factor here is whether a sense of individual responsibility can be fostered and whether mechanisms can be found for the users to act collectively to manage the resources – a form of quasi-government. Also, there has to be some agreement about what is a fair use of such resources and, in many cases, rules will have to be developed.

In *Governing the Commons*, which was published in 1990, Elinor Ostrom of Indiana University described the rules needed to keep a commons going. She showed that there are almost always elaborate conventions over who can use

resources and when. What you take out of a commons has to be proportional to what you put in. Usage has to be compatible with the commons' underlying health (i.e., you cannot just keep grazing your animals regardless). Everyone has to have some say in the rules. And people usually pay more attention to monitoring abuses and to conflict resolution than to sanctions and punishment.²

Sometimes the rules of behaviour can be deeply embedded in culture. Thus indigenous peoples operating on marginal lands, such as the Aborigines in Australia or the San in the Kalahari, have a culture that respects common resources and puts sustainability at the heart of its philosophy.

Land is fundamental to the wellbeing of Aboriginal people. The land is not just soil or rocks or minerals, but a whole environment that sustains and is sustained by people and culture. For Indigenous Australians, the land is the core of all spirituality and this relationship and the spirit of 'country' is central to the issues that are important to Indigenous people today.³

But if rules are not embedded in culture, how can they be made to stick? One way is through the development of pressure groups, such as Friends of the Earth or local community action groups.

Mrs Ostrom suggests the so-called 'miracle of the Rhine' – the clean-up of Europe's busiest waterway – should be seen as an example of successful commons management because it was not until local pressure groups, city and regional governments and non-governmental organisations got involved that polluters were willing to recognise the costs they were imposing on others, and cut emissions. An intergovernmental body (the International Commission for the Protection of the Rhine) did not have the same effect.⁴

The importance of Elinor Ostrom's work was recognised when she was awarded the Nobel Prize in Economic Sciences in 2009.

1. *Is there any way in which people's behaviour towards the global commons can be changed so as to reduce the problem of climate change?*
2. *List some factors which would make successful management of common resources achievable. You might want to think about the number of people, the stability of the population and the role of traditions. What others can you identify?*

1 'Commons sense', *The Economist*, 31 July 2008.

circumstances the good may have to be provided by the government or by the government subsidising private firms.

Note that not all goods and services produced by the public sector come into the category of public goods and services. Thus education and health are publicly provided, but they *can* be, and indeed are, privately provided as well.

- ?**
1. Give some other examples of public goods. Does the provider of these goods (the government or local authority) charge for their use? If so, is the method of charging based on the amount of the good that people use? Is it a good method of charging? Could you suggest a better method?
 2. Name some goods or services provided by the government or local authorities that are not public goods.
 3. Are there ways in which we could overcome the free-rider problem? Start by thinking about the provision of a public good amongst a group of friends or neighbours.

Market power

Lack of Pareto optimality

Whenever markets are imperfect, whether as pure monopoly or monopsony or as some form of imperfect competition, the market will fail to equate MSB and MSC . Pareto optimality will not be achieved.

This is illustrated in Figure 12.10, which shows revenue and cost curves for a monopolist. It assumes no externalities. The socially efficient (Pareto optimal) output is Q_2 , where $MSB = MSC$. The monopolist, however, produces the lower output Q_1 , where $MR = MC$.

? Referring back to Figure 10.8 on page 287, and assuming that the MRP_1 curve represents the marginal social benefit from the employment of a factor, and that the price of the factor represents its marginal social cost (i.e. assuming no externalities), show that a monopsony will employ less than the Pareto optimal amount of factors.

Deadweight loss under monopoly

Once again the welfare loss can be illustrated by using the concepts of *consumer* and *producer surplus*. The two concepts are illustrated in Figure 12.11, which is similar to Figure 12.10. The diagram shows an industry that is initially under perfect competition and then becomes a monopoly (but faces the same revenue and cost curves).

Under *perfect competition* the industry will produce an output of Q_{pc} at a price of P_{pc} , where $MC (= S) = P (= AR)$: i.e. at point a . Consumer surplus is shown by areas 1 + 2 + 3, and producer surplus by areas 4 + 5. Total surplus (i.e. consumer plus producer surplus) is maximised at this output (see Figure 12.1 on page 349).

What happens when the industry is under *monopoly*? The firm will produce where $MC = MR$, at an output of Q_m and a price of P_m (at point b on the demand curve). Total revenue is $P_m \times Q_m$ (areas 2 + 4 + 6). Total cost is the area under the MC curve (area 6). Thus the producer surplus is areas 2 + 4. This is clearly a *larger* surplus than under perfect competition

(since area 2 is larger than area 5). The consumer surplus, however, will fall dramatically. With consumption at Q_m , total utility is given by areas 1 + 2 + 4 + 6, whereas consumer expenditure is given by areas 2 + 4 + 6. Consumer surplus, then, is simply area 1. (Note that area 2 has been transformed from consumer surplus to producer surplus.)

Total surplus under monopoly is therefore areas 1 + 2 + 4: a smaller surplus than under perfect competition. 'Monopolisation' of the industry has resulted in a loss of total surplus of areas 3 + 5. The producers' gain has been more than offset by the consumers' loss. This loss of surplus is known as the *deadweight welfare loss of monopoly*.

Definition

Deadweight welfare loss of monopoly The loss of consumer plus producer surplus in monopoly or other imperfect markets (when compared with perfect competition).

Figure 12.10 The monopolist producing less than the Pareto optimum

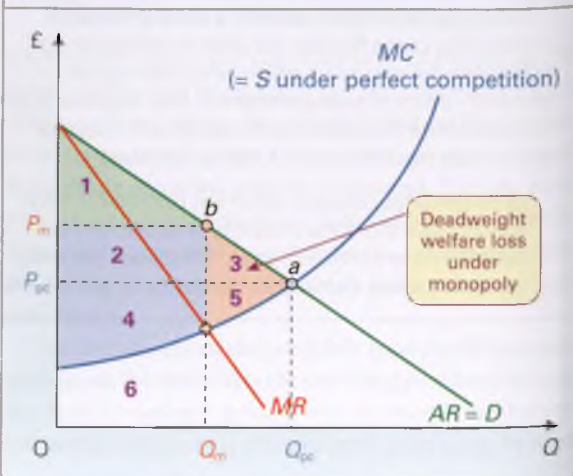

Figure 12.11 Deadweight loss under monopoly

* LOOKING AT THE MATHS

Total consumer surplus (*TCS*) equals total utility minus total expenditure (i.e. total revenue). Total producer surplus (*TPS*) equals total revenue minus total variable cost. Thus total surplus (*TS*) is given by:

$$TS = TCS + TPS = (TU - TR) + (TR - TVC) = TU - TVC$$

Assuming that the demand curve traces out the marginal utility curve (see pages 109–10), this allows us to derive the total utility function. To do this, you would need to use the technique of integration. Assuming that the total utility function is

$$TU = bQ - cQ^2$$

and that the total variable cost function is

$$TVC = jQ - kQ^2 + lQ^3$$

this will give a total surplus function of

$$TS = (bQ - cQ^2) - (jQ - kQ^2 + lQ^3) \quad (1)$$

To find the level of deadweight welfare loss, we would then subtract total surplus under perfect competition from that under monopoly. To do this, we would solve equation (1) first for Q_{pc} and then for Q_m and then subtract the second from the first. A worked example of this is given in Maths Case 12.1 on the student website.

Conclusions

The firm with market power uses fewer factors and produces less output than the Pareto optimum. It also causes deadweight welfare loss. To the extent, however, that the firm seeks aims *other* than profit maximisation and thus may produce more than the profit-maximising output, so these criticisms must be relaxed.

As was shown in Chapter 7, there are possible social *advantages* from powerful firms: advantages such as economies of scale and more research and development. These advantages may outweigh the lack of Pareto optimality. It can be argued that an ideal situation would be where firms are large enough to gain economies of scale and yet are somehow persuaded or compelled to produce where $P = MC$ (assuming no externalities).

With oligopoly and monopolistic competition, further wastes may occur because of possibly substantial resources involved in non-price competition. Advertising is the major example. It is difficult to predict just how much oligopolists will diverge from the Pareto optimum, since their pricing and output depends on their interpretation of the activities of their rivals.

? Why will Pareto optimality not be achieved in markets where there are substantial economies of scale in production?

Other market failures

Imperfect information

Perfect competition assumes that consumers, firms and factor suppliers have perfect knowledge of costs and benefits. In the real world, there is often a great deal of ignorance and uncertainty. Thus people are unable to equate marginal benefit with marginal cost.

Consumers purchase many goods infrequently. Cars, washing machines and other consumer durables fall into this category, as do houses. Consumers may not be aware of the quality of such goods until they have purchased them, by which time it is too late. Advertising may contribute to people's ignorance by misleading them as to the benefits of a good.

Firms are often ignorant of market opportunities, prices, costs, the productivity of factors (especially white-collar workers), the activity of rivals, etc.

Many economic decisions are based on expected future conditions. Since the future can never be known for certain, many decisions may turn out to be wrong.

In some cases, it may be possible to obtain the information through the market. There may be an agency that will sell you the information or a newspaper or magazine that contains the information. In this case, you will have to decide whether the cost to you of buying the information is worth the benefit it will provide you. A problem here is that you may not have sufficient information to judge how reliable the information is that you are buying!

1. Assume that you wanted the following information. In which cases might you (i) buy perfect information, (ii) buy imperfect information, (iii) be able to obtain information without paying for it, (iv) not be able to obtain information?
 - (a) Which washing machine is the most reliable?
 - (b) Which of two vacant jobs is more satisfying?
 - (c) Which builder will repair my roof most cheaply?
 - (d) Which builder is the best value for money?
 - (e) How big a mortgage would it be wise for me to take out?
 - (f) Should I take a degree or get a full-time job?
 - (g) What brand of washing powder washes whiter?
 - (h) Will a house need any work done on it over the next few years?
2. Make a list of pieces of information that a firm might want to know, and consider whether it could buy the information and how reliable that information might be.
3. What has been the impact of the Internet on the provision of information?

Asymmetric information. One form of imperfect information occurs when different sides in an economic relationship have different amounts of information. This, as we saw on page 266, is known as 'asymmetric information' and is at the heart of the principal-agent problem.

Take the case of a firm (the principal) using the services of a bank (the agent) to finance its investments. The bank is likely to have a much better knowledge of its range of products and of the current state of financial markets and may mis-sell products to the firm in order to earn a larger profit for the bank. For example, it could provide loans at fixed rates of interest, knowing that rates were likely to fall. The firm would end up being locked into paying a higher rate of interest than if it had taken out a variable rate loan and the bank would consequently make more profit. This practice came to light in 2012, with banks accused of mis-selling such products to some 28 000 small and medium-sized enterprises (SMEs).

Immobility of factors and time lags in response

Even under conditions of perfect competition, factors may be very slow to respond to changes in demand or supply. Labour, for example, may be highly immobile both occupationally and geographically. This can lead to large price changes and hence to large supernormal profits and high wages for those in the sectors of rising demand or falling costs. The long run may be a very long time coming!

The problem of time lags. Many economic actions can take a long time to take effect. This can cause problems of instability and an inability of the economy to achieve social efficiency.

In the meantime, there will be further changes in the conditions of demand and supply. Thus the economy is in a constant state of disequilibrium and the long run never comes. As firms and consumers respond to market signals and move towards equilibrium, so the equilibrium position moves and the social optimum is never achieved.

Whenever monopoly/monopsony power exists, the problem is made worse if firms or unions put up barriers to the entry of new firms or factors of production.

Protecting people's interests

Dependants. People do not always make their own economic decisions. They are often dependent on decisions made by others. Parents make decisions on behalf of their children; partners on each other's behalf; younger adults on behalf of old people; managers on behalf of shareholders; etc. This, again, is an example of the principal-agent issue.

A free market will respond to these decisions, however good or bad they may be, and whether or not they are in the interests of the dependant. Thus the government may feel it necessary to protect dependants.

Give examples of how the government intervenes to protect the interests of dependants from bad economic decisions taken on their behalf.

Poor economic decision making by individuals on their own behalf. The government may feel that people need protecting from poor economic decisions that they make on their own behalf. As we discussed in Chapter 5, this may be a particular problem when the benefits from consuming a good are immediate while the cost happens at some point in the future. People may place too much weight on the immediate benefits and too little weight on the long-run costs of their decisions. Products where this might be an issue include tobacco, alcohol and fast/unhealthy food.

On the other hand, the government may feel that people consume too little of things that are good for them: things such as education, preventative health care and sports facilities. Such goods are known as *merit goods*. The government could either provide them free or subsidise their production; it could also make their consumption compulsory (e.g. as with fluoride added to water in many areas).

How do merit goods differ from public goods?

Other objectives

As we saw in Chapter 11, one of the major criticisms of the free market is the problem of *inequality*. The Pareto criterion gives no guidance, however, as to the most desirable distribution of income. A redistribution of income will benefit some and make others worse off. Thus Pareto optimality can be achieved for *any* distribution of income. Pareto optimality merely represents the efficient allocation of resources for any *given* distribution of income.

In addition to social efficiency and greater equality, we can identify other social goals: goals such as moral behaviour (however defined), enlightenment, social consciousness, cooperation, the development of culture, fulfilment, freedom from exploitation, and freedom to own, purchase and inherit property. The unfettered free market may not be very successful in achieving social efficiency. It may be even less successful in achieving many other social goals.

Finally, the free market is unlikely to achieve simultaneously the *macroeconomic objectives* of rapid economic growth, full employment, stable prices and a balance of international payments. These problems, and methods of government intervention that may be used to deal with them, are examined in later chapters.

Conclusions

It is not the role of economists to make judgements as to the relative importance of social goals. Economics can only consider the means to achieving stated goals. First, therefore,

Definition

Merit goods Goods that the government feels people will underconsume and which therefore ought to be subsidised or provided free.

the goals have to be clearly stated by the policy makers. Second, they have to be quantifiable so that the effectiveness of different policies can be compared. Certain goals, such as growth in national income, changes in the distribution of income and greater efficiency, are relatively easy to quantify. Others, such as enlightenment, are virtually impossible to quantify. For this reason, economics tends to concentrate on the means to achieving a relatively narrow range of goals. The danger is that, by concentrating on a limited number of goals, economists may well influence policy makers into doing the same, and thus into neglecting other social goals.

Different objectives are likely to conflict. For example, economic growth may conflict with greater equality. In the case of such 'trade-offs', all the economist can do is to demonstrate the effects of a given policy, and leave the policy makers to decide whether the benefits in terms of one goal outweigh the costs in terms of another goal.

 *How do the economic policies of the major political parties differ? How far can an economist go in assessing these policies?*

Section summary

1. Real-world markets will fail to achieve Pareto optimality. What is more, there are objectives other than social efficiency, and real-world markets may fail to achieve these too.
2. Externalities are costs and benefits of consumption experienced by people other than those directly involved in the transaction. Whenever there are external costs, the market will (other things being equal) lead to a level of production and consumption *above* the socially efficient level. Whenever there are external benefits, the market will (other things being equal) lead to a level of production and consumption *below* the socially efficient level.
3. Public goods have the characteristics of being non-rival and non-excludable. Once a given quantity of a pure public good is produced, everyone can obtain the same level of benefit it provides. They will tend to be underprovided by the market. Without government intervention it would not be possible to prevent people having a 'free ride' and thereby escaping any contributions to their cost of production.
4. Common resources are likely to be overused – a problem known as the 'tragedy of the commons'. This is because people are unlikely to take into account the effect of their use of such resources on other people.
5. Monopoly power will (other things being equal) lead to a level of output below the socially efficient level. It will lead to a deadweight welfare loss: a loss of consumer plus producer surplus.
6. Imperfect information may prevent people from consuming or producing at the levels they would otherwise choose. There may be an asymmetry of information between buyers and sellers, which can result in a principal-agent problem. Information, however, may sometimes be provided (at a price) by the market.
7. Markets may respond sluggishly to changes in demand and supply. The time lags in adjustment can lead to a permanent state of disequilibrium and to problems of instability.
8. In a free market there may be inadequate provision for dependants and an inadequate output of merit goods; there are likely to be macroeconomic problems and problems of inequality and poverty; finally, there may be a whole series of social, moral, attitudinal and aesthetic problems arising from a market system.
9. These being normative questions, the economist cannot make ultimate pronouncements on the rights and wrongs of the market. The economist can, however, point out the consequences of the market and of various government policies, and also the trade-offs that exist between different objectives.

12.3 FORMS OF GOVERNMENT INTERVENTION

Faced with all the problems of the free market, what is a government to do?

There are several policy instruments that a government can use. At one extreme, it can totally replace the market by providing goods and services itself. At the other extreme, it can merely seek to persuade producers, consumers or workers to act differently. Between the two extremes, the government has a number of instruments that it can use to change the way markets operate. These include taxes, subsidies, laws and regulatory bodies.

Before looking at different forms of government intervention and their relative merits, it is first necessary to look at a general problem concerned with all forms of intervention. This is known as the *problem of the second best*.

Definition

Problem of the second best The difficulty of working out the best way of correcting a specific market distortion if distortions in other parts of the market continue to exist.

BOX 12.3

SHOULD HEALTH-CARE PROVISION BE LEFT TO THE MARKET?

A case of multiple market failures

In the UK, the National Health Service provides free hospital treatment, a free general practitioner service, and free prescriptions for certain categories of people. Their marginal cost to the patient is thus zero. Of course, these services use resources and they thus have to be paid for out of taxes.

But why are these services not sold directly to the patient, thereby saving the taxpayer money? There are, in fact, a number of reasons why the market would fail to provide the optimum amount of health care.

The issue of equity

This is a problem connected with the distribution of income. Because income is unequally distributed, some people will be able to afford better treatment than others, and the poorest people may not be able to afford treatment at all. On grounds of equity, therefore, it is argued that health care should be provided free – at least for those on low incomes.

The concept of equity that is usually applied to health care is that individuals should be able to access treatment according to their medical need rather than according to their ability to pay.

1. Does this argument also apply to food and housing?

Difficulty of predicting future medical needs

If you were suddenly taken ill and required a major operation, it could be very expensive if you had to pay. On the other hand, you may go through life requiring very little if any medical treatment. In other words, there is great uncertainty about your future medical needs. As a result it would be very difficult to plan your finances and budget for possible future medical expenses if you had to pay for treatment.

Medical insurance could provide a solution to this problem if the probability of requiring different treatments (a) can be

estimated and (b) is independent across different individuals. There would also have to be no serious problems of adverse selection or moral hazard. Even if an effective market for medical insurance could be established there would still remain a problem of equity. Would the chronically sick or very old be able to obtain cover and, if so, would they be able to afford the premiums? This issue of 'gaps' in an insurance-based system means that some form of intervention on grounds of equity may be needed, even if most provision is private.

2. Give some examples of adverse selection and moral hazard that might occur with medical insurance (see section 5.1, pages 133–6).

Externalities

Health care generates a number of benefits *external* to the patient. If you are cured of an infectious disease, for example, it is not just you who benefits but also others, since you will not infect them. In addition, if you have a job you will be able to get back to work, thus reducing the disruption there. These external benefits of health care could be quite large.

If sick people have to pay the cost of their treatment, they may decide not to be treated – especially if they are poor. They will consider the costs and benefits they might experience, but will probably not take into account the effect that their illness has on other people. The market, by equating *private* benefits and costs, would produce too little health care.

Information problems and patient ignorance

Markets only function well to allocate resources efficiently if the consumer has the knowledge to make informed decisions. For many products we purchase, there is reasonably good information and so we can judge which products/services we will like the most.

In an ideal free market, where there are no market failures of any sort (the 'first-best' world), there would be no need for government intervention at all. If in this world there did then arise just one failure, in theory its correction would be simple. Say a monopoly arose, or some externality (e.g. pollution) was produced by a particular firm, with the result that the marginal social cost was no longer equal to the marginal social benefit. In theory, the government should simply intervene to restore production to the point where $MSC = MSB$. This is known as the *first-best solution*.

Of course, the real world is not like this. It is full of imperfections. What this means is that, if one imperfection is 'corrected' (i.e. by making $MSB = MSC$), it might aggravate problems elsewhere. For example, if a local authority introduces residents-only parking in an inner city area to prevent

commuters parking there, they may simply park just outside the area, thus imposing additional costs on people living there.

- Give some examples of how correcting problems in one part of the economy will create problems elsewhere.

Definition

First-best solution The solution of correcting a specific market distortion by ensuring that the whole economy operates under conditions of social efficiency (Pareto optimality).

In the case of health care the situation is different. Much of the information is complex and a patient might require specialist knowledge to understand it. The one-off nature of many treatments also means that patients are unable to learn from repeat purchases.

In some circumstances the demand for health care might be urgent. In these cases people do not have the time to shop around and may be unable to make rational decisions because of heightened emotional distress. For these reasons a patient has to rely on the professional advice of others. They have to enter an agency relationship with a doctor or health-care provider.

For example, if you have a pain in your chest, it may be simple muscular strain, or it may be a symptom of heart disease. You rely on the doctor (the *supplier* of the treatment) to give you the information: to diagnose your condition. The key issue is whether the incentives of the doctor and the patient are aligned.

If health care was provided through the market, unscrupulous doctors might advise more expensive treatment than is necessary; they might even have an agreement with certain drugs companies that they will try to persuade you to buy an expensive branded product rather than an identical cheaper version. This problem will also exist in an insurance-based system, where the doctor may be even more inclined to oversupply if the patient has sufficient cover.

If people had to pay, those suffering from the early stages of a serious disease might not consult their doctor until the symptoms become very acute, by which time it might be too late to treat the disease, or very expensive to do so. With a health service that is free at the point of use, however, a person is more likely to receive an earlier diagnosis of serious conditions.

Oligopoly

If doctors and hospitals operated in the free market as profit maximisers, it is unlikely that competition would drive down

their prices. Instead they might collude to fix standard prices for treatment, so as to protect their incomes. Even if doctors did compete openly, it is unlikely that consumers would have enough information to enable them to 'shop around' for the best value.

We have to be careful: to argue that the market system will fail to provide an optimal allocation of health-care resources does not in itself prove that *free provision* will result in optimal provision. For example, with no charge for GP appointments it is likely that some patients will consult their doctors over trivial complaints. The result will be consumption beyond the socially efficient point.

In the USA there is much more reliance on *private medical insurance*. Alternatively, the government may simply *subsidise* health care, so as to make it cheaper rather than free. This is the case with prescriptions and dental treatment in the UK, where many people only have to pay part of the cost of treatment. Also, the government can *regulate* the behaviour of the providers of health care, to prevent exploitation of the patient. Thus only people with certain qualifications are allowed to operate as doctors, nurses, pharmacists, etc.

3. If health care is provided free at the point of consumption, the demand is likely to be high. How is this high demand likely to be dealt with? Is this a good way of dealing with the issue?
4. Go through each of the market failings identified in this box. In each case, consider what alternative policies are open to a government to tackle them. What are the advantages and disadvantages of these alternatives?
5. Does the provision of free health care mean that it needs to be publicly produced? What would be the advantages, and disadvantages, of private provision?

As the first-best solution of a perfectly efficient, distortion-free world is obviously not possible, the **second-best solution** needs to be adopted. Essentially this involves seeking the best compromises. This means attempting to minimise the *overall* distortionary effects of the policy measure. Some second-best *rules* can be applied in certain cases.

Definition

Second-best solution The solution to a specific market distortion that recognises distortions elsewhere and seeks to minimise the overall distortionary effects to the economy of tackling this specific distortion.

We will examine these in the following sections as we look at specific policy measures.

Taxes and subsidies

A policy instrument particularly favoured by many economists is that of taxes and subsidies. They can be used for two main microeconomic purposes: (a) to promote greater social efficiency by altering the composition of production and consumption: and (b) to redistribute incomes. We examined their use for the second purpose in Chapter 11. Here we examine their use to achieve greater social efficiency.

When there are imperfections in the market (such as externalities or monopoly power), Pareto optimality will not be achieved. Taxes and subsidies can be used to correct these

imperfections. Essentially the approach is to tax those goods or activities where the market produces too much, and subsidise those where the market produces too little.

Taxes and subsidies to correct externalities

The first-best solution. The *first-best solution* when there is only one market imperfection is simple: the government should impose a tax equal to the marginal external cost (or grant a subsidy equal to the marginal external benefit). This is known as a *Pigouvian tax* (or *Pigouvian subsidy*).

Previously, we examined the impact of external costs of pollution created by the chemical industry as a whole. We will now focus on one firm in that industry, which otherwise is perfectly competitive. Assume that this particular chemical company emits smoke from a chimney and thus pollutes the atmosphere. This creates external costs for the people who breathe in the smoke. The marginal social cost of producing the chemicals thus exceeds the marginal private cost to the firm: $MSC > MPC$. This is illustrated in Figure 12.12.

In this example, it is assumed the external pollution cost begins with the first unit of production but remains constant. Hence the MEC_p is drawn as a horizontal line. The vertical distance between the MPC and MSC curves is equal to the MEC_p . The firm produces Q_1 where $P = MPC$ (its

profit-maximising output), but in doing so takes no account of the external pollution costs it imposes on society.

If the government now imposes a tax on production equal to the marginal pollution cost, it will effectively 'internalise' the externality. The firm will have to pay an amount equal to the external cost it creates. It will therefore now maximise profits at Q_2 , which is the socially optimal output where $MSB = MSC$.

By analogy, if a firm produced an external benefit, then in the first-best world it ought to be given a subsidy equal to that marginal external benefit.

Note that a tax or subsidy ought to be directed as closely as possible to the source of the externality. For example, if a firm trains labour, and that creates a benefit to society, then ideally it ought to be given a subsidy for each person trained, rather than a general output subsidy. After all, an output subsidy not only encourages the firm to train more people (the desired effect), but also encourages it to use more capital and raw materials (an undesired side effect). This is a general maxim of welfare economics: *a distortion should be corrected at source if side-effect problems are to be avoided.*

Second-best tax and subsidy policies. In reality, the government must tackle imperfections in a world that has many other imperfections. Figure 12.13 shows a firm that both produces an external cost ($MSC > MPC$) and also has monopoly power. It will maximise profits at Q_1 where $MPC = MR$ (point x).

The socially efficient level of output in this case is Q_2 , where MSB equals MSC . Note that in this case, the welfare loss from a monopoly is actually less than if the market were perfectly competitive: i.e. the extent of overproduction is lower. The perfectly competitive equilibrium would be at point c , with price P_{pc} and output Q_{pc} .

Definition

Pigouvian tax (or subsidy) A tax (or subsidy) designed to 'internalise' an externality. The marginal rate of a Pigouvian tax (or subsidy) should be equal to the marginal external cost (or benefit).

Figure 12.12 Using taxes to correct a market distortion: an individual firm

BOX 12.4

DEADWEIGHT LOSS FROM TAXES ON GOODS AND SERVICES

EXPLORING
ECONOMICS

The excess burden of taxes

Taxation can be used to correct market failures, but taxes can have adverse effects themselves. One such effect is the deadweight loss that results when taxes are imposed on goods and services (see page 336).

The diagram shows the demand and supply of a particular good. Equilibrium is initially at a price of P_1 and a level of sales of Q_1 (i.e. where $D = S$). Now an excise tax is imposed on the good. The supply curve shifts upwards by the amount of the tax, to $S + \text{tax}$. Equilibrium price rises to P_2 and equilibrium quantity falls to Q_2 . Producers receive an after-tax price of $P_2 - \text{tax}$.

Consumer surplus falls from areas 1 + 2 + 3, to area 1 (the green area). Producer surplus falls from areas 4 + 5 + 6 to area 6 (the blue area). Does this mean, therefore, that total surplus falls by areas 2 + 3 + 4 + 5? The answer is no, because there is a gain to the government from the tax revenue (and hence a gain to the population from the resulting government expenditure). The revenue from the tax is known as the **government surplus**. It is given by areas 2 + 4 (the pink area).

Deadweight loss from an indirect tax

But even after including government surplus, there is still a fall in total surplus of areas 3 + 5. This is the deadweight loss of the tax. It is sometimes known as the **excess burden**.

Does this loss of total surplus from taxation imply that taxes on goods are always a 'bad thing'? The answer is no. This conclusion would follow only in a 'first-best' world where there were no market failures: where competition was perfect, where there were no externalities and where income distribution was optimum. In such a world, the loss of surplus from imposing a tax on a good would represent a reduction in welfare.

In the real world of imperfect markets and inequality, taxes can do more good than harm. As we have shown in this section, they can help to correct for externalities; and as we showed in the previous chapter, they can be used as a means of redistributing incomes. Nevertheless, the excess burden of taxes is something that ideally ought to be considered when weighing up the desirability of imposing taxes on goods and services, or of increasing their rate.

1. How far can an economist contribute to this normative debate over the desirability of an excise tax?
2. What is the excess burden of a lump-sum tax? (For a clue, see Figure 12.14.)

Definitions

Government surplus (from a tax on a good) The total tax revenue earned by the government from sales of a good.

Excess burden (of a tax on a good) The amount by which the loss in consumer plus producer surplus exceeds the government surplus.

To provide an incentive for the monopolist to produce Q_2 , a tax of $a - b$ must be imposed (since at point a , $MR = MPC + \text{tax}$). This tax is less than the full amount of the externality because of the monopoly power. Were the monopolist to be charged a tax equal to the externality (so that its $MPC + \text{tax}$ curve was equal to the MSC curve), it would maximise profits at point y , at a price of P_3 and an output of Q_3 . This would not be socially efficient, since MSB would now be above MSC .

Taxes to correct for monopoly

So far we have considered the use of taxes to correct for externalities. Taxes can also be used to regulate the behaviour of monopolies and oligopolies.

If the government wishes to tackle the problem of excessive monopoly profits, it can impose a lump-sum tax on the

monopolist. An example of such a tax was the 'windfall tax', imposed by the UK government in 1997. This was on the profits of various privatised utilities. In 2005, another tax was imposed on the 'excess' profits of oil companies operating in the North Sea. There were also numerous calls in 2008 to impose a windfall tax on energy companies, but this was never implemented. The use of a lump-sum tax is illustrated in Figure 12.14.

Being of a fixed amount, a lump-sum tax is a fixed cost to the firm. It does not affect the firm's marginal cost. It shifts the AC curve upwards.

Profits continue to be maximised where $MC = MR$, at an output of Q_1 and a price of P_1 . But profits are reduced from areas 1 + 2 to area 1 alone. Area 2 now represents the amount of tax paid to the government. If the lump-sum tax were large enough to make the $AC + \text{lump-sum tax}$ curve

Figure 12.13 Using taxes to correct for externalities: firms with monopoly power

Figure 12.14 Using a lump-sum tax to reduce monopoly profits

cross the demand curve at point *a*, all the supernormal profits would be taken as tax.

If the government also wants to increase the monopolist's output to the socially efficient level of Q_2 , and wants it to charge a price of P_2 , it could do this with a careful combination of a per-unit subsidy (which will shift both the AC and the MC curves downwards) and a lump-sum tax. The required level of subsidy will be that which shifts the MC curve downwards to the point where it intersects MR at output Q_2 . Then a lump-sum tax would be imposed that would be big enough to shift the AC curve back up again so that it crosses the demand curve at point *b*.

What could we say about the necessary subsidy if the MR curve crossed the horizontal axis to the left of point *b*?

Advantages of taxes and subsidies

Many economists favour the tax/subsidy solution to market imperfections (especially the problem of externalities) because it still allows the market to operate. It forces firms to take on board the full social costs and benefits of their actions; as we have seen, this is often described as *internalising the externality*. Furthermore, once the policy is in place, taxes and subsidies can be adjusted according to the magnitude of the problem.

Moreover, if firms are taxed for polluting, they are encouraged to find cleaner ways of producing. The tax acts as an incentive over the longer run to reduce pollution. Likewise, by subsidising *good* practices, firms are given the incentive to adopt more good practices.

The most suitable situation for imposing a pollution tax is when there is a clearly measurable emission, like a particular chemical waste. The government can then impose a tax per litre or per tonne of that waste.

Disadvantages of taxes and subsidies

Infeasibility of using different tax and subsidy rates. Each firm produces different levels and types of externality and operates under different degrees of imperfect competition. It would be administratively very difficult and expensive to charge every offending firm its own particular tax rate (or grant every relevant firm its own particular rate of subsidy). Even in the case of pollution where it is possible to measure

a firm's emissions, there would still have to be a different tax rate for each pollutant and even for each environment, depending on its ability to absorb the pollutant.

Lack of knowledge. Even if a government did decide to charge a tax equal to each offending firm's marginal external costs, it would still have the problem of measuring those costs and apportioning blame. The damage to lakes and forests from acid rain has been a major concern since the beginning of the 1980s. But just how serious is that damage? What is its current monetary cost? How long lasting is the damage? Just what and who are to blame? These questions cannot be answered precisely. It is thus impossible to fix the 'correct' pollution tax on, say, a particular coal-fired power station.

-  1. Why is it easier to use taxes and subsidies to tackle the problem of car exhaust pollution than to tackle the problem of peak-time traffic congestion in cities?
2. CFCs in fridges were known to cause environmental damage and their use has been banned in most countries. Why has this approach been adopted rather than the tax solution?

Changes in property rights

One cause of market failure is the limited nature of property rights. If someone dumps a load of rubble in your garden, you can insist that it is removed. If, however, someone dumps a load of rubble in their *own* garden, which is next door to yours, what can you do? You can still see it from your window. It is still an eyesore. But you have no property rights over the next-door garden.

Property rights define who owns property, to what uses it can be put, the rights other people have over it and how it may be transferred. By *extending* these rights, individuals may be able to prevent other people from imposing costs on them or charge them for doing so.

The socially efficient level of charge would be one that was equal to the marginal external cost (and would have the same effect as the government charging a tax on the firm of that amount: see Figure 12.12). The *Coase theorem*¹ states that when there are well-defined property rights and there are no bargaining or negotiation costs, then the socially efficient charge *will* be levied. But why?

Definition

Coase theorem When there are well-defined property rights and zero bargaining costs, then negotiations between the party creating the externality and the party affected by the externality can bring about the socially efficient market quantity.

Let us take the case of river pollution by a chemical works that imposes a cost on people fishing in the river. If property rights to the river were now given to the fishing community, they could impose a charge on the chemical works per unit of output. If they charged *less* than the marginal external cost, they would suffer more from the last unit (in terms of lost fish) than they were being compensated. If they charged *more*, and thereby caused the firm to cut back its output below the socially efficient level, they would be sacrificing receiving charges that would be greater than the marginal suffering. It will be in the sufferers' best interests, therefore, to charge an amount *equal* to the marginal externality.

Alternatively, the property rights to the river could be awarded to the chemical works. In this situation the fishing community could offer payments to the firm on condition that it did not pollute the river.

One interesting result is that the efficient solution to the problem caused by the externality does not depend on which party is assigned the property rights: i.e. the fishing community or the chemical works. All that matters is that the property rights are fully assigned to either one or the other and that there are no bargaining costs.

 If the sufferers had no property rights, show how it would still be in their interests to 'bribe' the firm to produce the socially efficient level of output.

In most instances, however, this type of solution is totally impractical. It is impractical when *many* people are *slightly* inconvenienced, especially if there are many culprits imposing the costs. For example, if I were disturbed by noisy lorries passing by my house, it would not be practical to negotiate with every haulage company involved. What if I wanted to ban the lorries from the street but my next-door neighbour wanted to charge them 10p per journey? Who gets their way?

The extension of private property rights becomes more practical where the parties involved are few in number, are easily identifiable and where the costs are clearly defined. Thus a noise abatement Act could be passed which allowed me to prevent my neighbours from playing noisy radios, having noisy parties or otherwise disturbing the peace in my home. The onus would be on me to report them. Or I could agree not to report them if they paid me adequate compensation.

But even in cases where only a few people are involved, there may still be the problem of litigation. I may have to incur the time and expense of taking people to court. Justice may not be free, and thus there may be concerns about equity. The rich can afford 'better' justice. They can employ top lawyers. Even if I have a right to sue a large company for dumping toxic waste near me, I may not have the legal muscle to win.

Finally, there is the broader question of equity. Although the socially efficient outcome does not depend on who has the property rights, the equity of the outcome will. Extending the rights of property owners may favour the rich, who

¹ Named after Ronald Coase, who developed the theory. See his 'The problem of social cost', *Journal of Law and Economics*, vol. 3 (1960).

tend to have more property, at the expense of the poor. Ramblers may get great pleasure from strolling across a great country estate, along public rights of way. If the owner's property rights were now extended to exclude the ramblers, would this be a social gain?

Of course, equity considerations can also be dealt with by altering property rights, but in a different way. *Public* property, like parks, open spaces, libraries and historic buildings, could be extended. Also, the property of the rich could be redistributed to the poor. Here it is less a question of the rights that ownership confers, and more a question of altering the ownership itself.

1. To what extent could property rights (either public or private) be successfully extended and invoked to curb the problem of industrial pollution (a) of the atmosphere; (b) of rivers; (c) by the dumping of toxic waste; (d) by the erection of ugly buildings; (e) by the creation of high levels of noise?
2. What protection do private property rights in the real world give to sufferers of noise (a) from neighbours; (b) from traffic; (c) from mobile phones on public transport?

Laws prohibiting or regulating undesirable structures or behaviour

Laws are frequently used to correct market imperfections. This section examines three of the most common cases.

Laws prohibiting or regulating behaviour that imposes external costs

Laws can be applied both to individuals and to firms. In the case of individuals, it is illegal to drive when drunk. Drunk driving imposes costs on others in the form of accidents and death. Other examples include the banning of (a) smoking in public places (b) using mobile phones while driving.

In the case of firms, various polluting activities could be banned or restricted; safety standards could be imposed in the place of work; building houses or factories could be prohibited in green-belt areas.

In the case of common resources, restrictions could be placed on their use. For example, in the case of fishing grounds, governments could limit the size of fleets, impose quotas on catches or specify the types of net to be used. In extreme cases, they could ban fishing altogether for a period of time to allow fish stocks to recover. In order to be able to enforce restrictions, many governments have extended their 'territorial waters' to 200 miles from their coast.

Advantages of legal restrictions

- They are simple and clear to understand and are often relatively easy to administer. Inspectors or the police can conduct spot checks to see that the law is being obeyed.
- When the danger is very great, it might be much safer to ban various practices altogether rather than to rely on

taxes or on individuals attempting to assert their property rights through the civil courts.

- When a decision needs to be taken quickly, it might be possible to invoke emergency action. For example, in a city it would be simpler to ban or restrict the use of private cars during a chemical smog emergency than to tax their use (see Case Study 13.5 on the student website).

Disadvantages of legal restrictions. The main problem is that legal restrictions tend to be a rather blunt weapon. If, for example, a firm were required to reduce the effluent of a toxic chemical to 20 tonnes per week, it would have no incentive to reduce it further. With a tax on the effluent, however, the more the firm reduced the effluent, the less tax it would pay. Thus with a system of taxes there is a *continuing* incentive to cut pollution.

Laws to prevent or regulate monopolies and oligopolies

Governments often introduce laws that prohibit various types of collusive activities, the misuse of market power by a dominant firm and mergers or takeovers that would result in a substantial lessening of competition. These will be examined in detail in Chapter 14.

How suitable are legal restrictions in the following cases? (a) Ensuring adequate vehicle safety; (b) reducing traffic congestion; (c) preventing the abuse of monopoly power; (d) ensuring that mergers are in the public interest; (e) ensuring that firms charge a price equal to marginal cost.

Laws to prevent firms from exploiting people's ignorance

Given that consumers have imperfect information, consumer protection laws can make it illegal for firms to sell shoddy or dangerous goods, or to make false or misleading claims about their products.

The problem is that the firms most likely to exploit the consumer are often the ones that are most elusive when it comes to prosecuting them.

Regulatory bodies

A more subtle approach than banning or restricting various activities involves the use of regulatory bodies.

Having identified possible cases where action might be required (e.g. potential cases of pollution or the abuse of monopoly power), the regulatory body would probably conduct an investigation and then prepare a report containing its findings and recommendations. It might also have the power to enforce its decisions, or this might be up to some higher authority.

An example of such a body is the UK's Competition and Markets Authority, the work of which is examined in section 14.1. Other examples are the bodies set up to regulate the privatised utilities: e.g. Ofwat (the Office of Water Services). These are examined in section 14.2.

The advantage of this approach is that a case-by-case method can be used and, as a result, the most appropriate solution adopted. However, investigations may be expensive and time-consuming, only a few cases may be examined and offending firms may make various promises of good behaviour which, if not followed up by the regulatory body, may not in fact be carried out.

What other forms of intervention are likely to be necessary to back up the work of regulatory bodies?

Price controls

Price controls could be used to prevent a monopoly or oligopoly from charging excessive prices. Currently, sections of various privatised industries, such as water and rail industries, are restricted in their ability to raise their prices (see section 14.2).

Price controls could also be used with the objective of redistributing incomes. Prices could be fixed either above or below equilibrium. Thus (high) minimum farm prices can be used to protect the incomes of farmers, and minimum wage legislation can help those on low incomes. On the consumption side, (low) maximum rents might be put in place with the intention of helping those on low incomes afford housing, and price ceilings on food or other essentials during a war or other emergency can ensure everyone can afford such items. However, as was argued in section 3.1, the problem with price controls is that they cause shortages (in the case of low prices) or surpluses (high prices).

Provision of information

When imperfect information is a reason for market failure, the direct provision of information by the government or one of its agencies may help to correct that failure. An example is the information on jobs provided by job centres to those looking for work. This will speed up the 'matching process' between the unemployed and employers. It helps the labour market to work better and increases the elasticity of supply of labour.

Another example is the provision of consumer information – for example, on the effects of smoking, or of the benefits of eating vegetables. Another is the provision of government statistics on prices, costs, employment, sales trends, etc. This enables firms to plan with greater certainty.

In what way is the provision of information a public good? Do all the examples above come into the category of public goods? Give some other examples of information that is a public good. (Clue: refer back to the characteristics of public goods in section 12.2 and do not confuse a public good with something merely provided by the government which could also be provided by the private sector.)

The direct provision of goods and services

In the case of public goods and services, such as streets, pavements, seaside illumination and national defence, the

market may completely fail to provide the socially efficient amount because of free-riding. Government may have to finance the optimal provision of the public good by requiring compulsory payments from members of society. One way of obtaining the compulsory payments is through the central/local tax system.

Before collecting the money the government needs to try to work out the socially efficient amount of the public good to finance. How could the real-world equivalent of point *f* in Figure 12.9 be identified in practice? The solution is to identify all the costs and benefits to society and to weight them appropriately. This is where cost-benefit analysis comes in – the subject of section 12.4.

Once the compulsory payments have been collected, the central government, local government or some other government agency could then manage the production of the goods or services directly. Alternatively, they could pay private firms to do so.

The government could also provide goods and services directly which are *not* public goods. Examples include health and education. There are four reasons why such things are provided free or well below cost.

Social justice. Society may feel that these things should not be provided according to ability to pay. Rather, as *merit goods*, they should be provided according to need.

Large positive externalities. People other than the consumer may benefit substantially. If a person decides to get treatment for an infectious disease, other people benefit by not being infected. A free health service thus helps to combat the spread of disease.

Dependants. If education were not free, and if the quality of education depended on the amount spent, and if parents could choose how much or how little to buy, then the quality of children's education would depend not just on their parents' income, but also on how much they cared. A government may choose to provide such things free in order to protect children from 'bad' or 'foolish' parents. A similar argument is used for providing free prescriptions and dental treatment for all children.

Imperfect information. Consumers may not realise how much they will benefit. If they had to pay, they might choose (unwisely) to go without. Providing health care free may persuade people to consult their doctors before a complaint becomes serious.

Public ownership

This is different from direct provision, in that the goods and services produced by publicly owned (nationalised) industries are sold in the market. The costs and benefits of public ownership are examined in detail in section 14.2.

Section summary

1. If there were a distortion in just one part of the economy, the 'first-best' solution would be possible. This would be to correct that one distortion. In the real world, where there are many distortions, the first-best solution will not be possible. The second-best solution will be to seek the best compromise that minimises the *relative* distortions between the industry in question and other parts of the economy.
2. Taxes and subsidies are one means of correcting market distortions. In the first-best world, externalities can be corrected by imposing tax rates equal to the size of marginal external costs, and granting rates of subsidy equal to marginal external benefits. In the second-best world, taxes and subsidies can be used to correct externalities that create *relative* distortions between this industry and others, or externalities that exist along with other distortions within this industry.
3. Taxes and subsidies can also be used to affect monopoly price, output and profit. Subsidies can be used to persuade a monopolist to increase output to the competitive level. Lump-sum taxes can be used to reduce monopoly profits without affecting price or output.
4. Taxes and subsidies have the advantages of 'internalising' externalities and of providing incentives to reduce external costs. On the other hand, they may be impractical to use when different rates are required for each case, or when it is impossible to know the full effects of the activities that the taxes or subsidies are being used to correct.
5. An extension of property rights may allow individuals to prevent others from imposing costs on them. This is not practical, however, when many people are affected to a small degree, or where several people are affected but differ in their attitudes towards what they want doing about the 'problem'.
6. Laws can be used to tackle various market failures. Legal controls are often simpler and easier to operate than taxes, and are safer when the danger is potentially great. However, they tend to be rather a blunt weapon.
7. Regulatory bodies can be set up to monitor and control activities that are against the public interest (e.g. anti-competitive behaviour of oligopolists).
8. The government may provide information in cases where the private sector fails to provide an adequate level. It may also provide goods and services directly. These could be either public goods or other goods where the government feels that provision by the market is inadequate.

* 12.4 COST-BENEFIT ANALYSIS

Cost-benefit analysis (CBA) is a technique used to help governments decide whether to go ahead with various projects such as a new motorway, a bypass, an underground line, a hospital, a health-care programme, a dam, and so on. The analysis seeks to establish whether the benefits to society from the project outweigh the costs, in which case the project should go ahead; or whether the costs outweigh the benefits, in which case it should not.

CBA's are usually commissioned either by a government department or by a local authority. Unlike the techniques of project evaluation used by private firms, which take into account only *private monetary* costs and benefits, CBA takes into account *externalities* and *private non-monetary* costs and benefits as well. Thus a cost-benefit study of a proposed new road might attempt to assess the external costs of noise to local residents and destruction of wildlife as well as the direct costs and benefits to motorists.

The procedure

The procedure at first sight seems fairly straightforward.

- All costs and benefits are identified. These include all private monetary and non-monetary costs and benefits and all externalities.

- A monetary value is assigned to each cost and benefit. This is essential if costs and benefits are to be added up: a common unit of measurement must be used. As might be expected, assigning monetary values to externalities like noise, pollution and the quality of life is fraught with difficulties and may involve subjective decisions.
- Account is taken of the likelihood of a cost or benefit occurring. The simplest way of doing this is to multiply the monetary value of a cost or benefit by the probability of its occurrence. This is called the *expected value*. So if there were a 60 per cent chance of a cost of £100 occurring, it would be valued at £60.
- Account is taken of the timing of the costs and benefits. Thus £100 of benefits received today would be regarded as more desirable than having to wait, say, 10 years to

Definitions

Expected value The value of a possible outcome multiplied by the probability of its occurrence.

receive the £100. Likewise it is a greater sacrifice to pay £100 today than to have to pay it within 10 years. Thus future costs and benefits must be reduced in value to take this into account. Discounting techniques (similar to those we examined in section 10.3: see pages 304–6) are used for this purpose.

- Some account may also be taken of the distribution of the costs and benefits. Is it considered fair that, although some people will gain from the project, others will lose? Will the losers be compensated in any way?
- A recommendation is then made by weighing up the costs and benefits. In the simplest terms, if the benefits exceed the costs, it will be recommended that the project goes ahead.

Each of these stages involves a number of difficulties. These are examined in the following sections.

Identifying the costs and benefits

Identifying costs and benefits is relatively easy, although there are some problems in predicting what types of external effect are likely to occur.

Costs

Direct (private) monetary costs. These include all the construction costs and the operating and maintenance costs.

External costs. These fall into two categories:

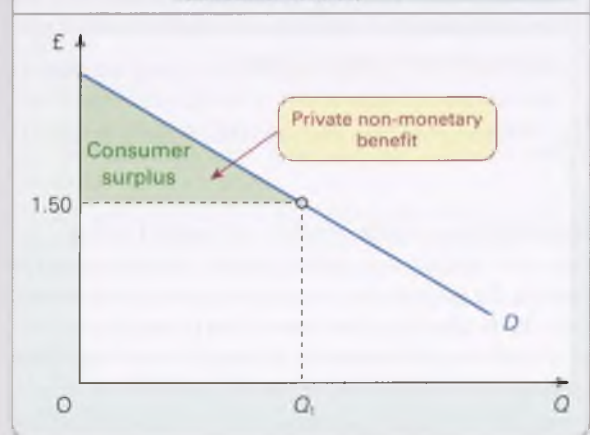

- **Monetary costs**, such as the loss of profits to competitors. Thus in the case of a CBA of a tunnel under a river, external monetary costs would include the loss of profits to ferry operators.
- **Non-monetary costs**, such as pollution, spoiling the landscape, noise and various other forms of inconvenience to local residents. In some projects, such as a tunnel, these costs will be confined largely to the construction phase. With other projects, however, such as a new airport, there may be considerable externalities resulting from its operation (e.g. noise). These non-monetary externalities are usually the most difficult costs to identify.

Benefits

Direct (private) monetary benefits. These are also easy to identify. They consist of the revenues received from the users of the project. The direct monetary benefits of a toll bridge, for example, are the tolls paid.

Private non-monetary benefits. These are the benefits to consumers over and above what they actually pay: in other words, the consumer surplus. For example, if a bridge had a toll of £1.50, and yet a person was prepared to pay £3 if necessary to avoid the long trip round the estuary, then the person's consumer surplus is £1.50. Total consumer surplus is thus the area between the demand curve (which shows

Figure 12.15 Private non-monetary benefits (consumer surplus)

what people are willing to pay) and the price charged. This is illustrated in Figure 12.15.

External benefits. These are the benefits to the non-users of the project. For example, the Victoria Underground line CBA identified external benefits to road users in central London. The roads would become less congested as people used the new Underground line. Usually these benefits are non-monetary benefits, but sometimes they may result in direct financial gain (e.g. higher profits to companies from reduced transport costs on less crowded roads).

Measuring the costs and benefits

Identifying costs and benefits may be relatively easy: measuring them is another matter. Difficulties in measurement depend on the type of cost and benefit. There are four types.

Direct private monetary costs and benefits

These would seem to be the simplest to measure. Normally the simple financial costs and revenues are used. In the case of a new Underground line, for example, such costs would include excavation, construction and capital costs (such as new rolling stock) and the operating costs (such as labour, electricity and maintenance). Revenues would be the fares paid by travellers. There are two problems, nevertheless:

- What *will* these financial costs and revenues be? It is all very well using current prices, but prices rise over time, and at different and unpredictable rates. Also, it is difficult to forecast demand and hence revenues. There is thus a large element of *uncertainty*.
- The prices will often be distorted by the existence of monopoly power. Should this be taken into account? In an otherwise perfect world (the first-best situation), the answer would be yes. But in the real world, where price distortions exist throughout the economy, actual prices should normally be used. In the case of a proposed Underground line, for example, it makes sense to use market

prices, given that market prices are paid by car drivers and by users of taxis and buses (the alternatives to using the Underground). Thus the second-best solution is to use actual market prices *unless* there is a price distortion that applies *only* to the specific project.

What price should be used when there is such a distortion?

Non-monetary private benefits: consumer surplus

Consumer surplus is a private benefit – it accrues to the users of the project – but is not part of the money earned from the project. There are two ways of estimating it.

The first way is to estimate the demand curve and then estimate the shaded area in Figure 12.15. Estimating demand is very difficult, since it depends on the price and availability of substitutes. The demand for the Channel Tunnel depends on the price, frequency and convenience of ferry crossings. It also depends on the overall level of activity in the economy and perhaps the world generally. Thus estimates of air traffic (essential information when deciding whether to build a new airport) have often been proved wrong as the world economy has grown more rapidly or less rapidly than previously forecast.

Another problem is that the consumer surplus gained from the project (e.g. the Channel Tunnel) may replace some of the albeit smaller consumer surplus from a competing service (e.g. cross-Channel ferries). In this case, the non-monetary private benefit is merely the *additional* consumer surplus of those who switch, but still the *full* consumer surplus of those who would not otherwise have crossed the Channel. This makes calculation less straightforward.

An alternative approach is to focus on specific non-monetary benefits to consumers. This approach is more useful when the service is to be provided free and thus no estimate of a demand curve can be made. Assume that a new motorway saves 20 000 hours of travelling time per week. (This, of course, will first have to be estimated, and again a prediction will have to be made of the number of people using the motorway.) How is this 20 000 hours to be evaluated? In the case of businesspeople and lorry drivers, the average hourly wage rate will be used to estimate the value of each labour hour saved. In the case of leisure time, there is less agreement on how to value an hour saved. Usually it is simply assumed to be some fraction of the average hourly wage. This method is somewhat arbitrary, however, and a better approach, though probably impractical, would be to attempt to measure how the travellers themselves evaluate their time.

Another way of measuring time saved would be to see how much money people would be prepared to spend to save travelling time. For example, how much extra would people be prepared to pay for a taxi that saved, say, 10 minutes over the bus journey? This method, however, has to take account of the fact that taxis may be more desirable for other reasons too, such as comfort.

How would you attempt to value time that you yourself save (a) getting to work; (b) going on holiday; (c) going out in the evening?

Monetary externalities

These would normally be counted at face value. Thus the external monetary costs of a new Underground line would include the loss of profits to taxi and bus companies. The external monetary benefits of a new motorway would include the profits to be made by the owners of the motorway service stations.

Non-monetary externalities

These are likely to be the hardest to measure. The general principle employed is to try to find out how much people would be prepared to pay to obtain the benefits or avoid the costs, if they were able to do so. There are two approaches here.

Ask people (questionnaires). Take the case of noise from an airport or motorway. People could be asked how much they would need to be compensated. There are two problems with this:

- *Ignorance.* People will not know just how much they will suffer *until* the airport or motorway is built.
- *Dishonesty.* People will tend to exaggerate the compensation they would need. After all, if compensation is actually going to be paid, people will want to get as much as possible. But even if it is not, the more people exaggerate the costs to themselves, the more likely it is that they can get the project stopped.

These problems can be lessened if people are questioned who have already experienced a similar project elsewhere. They have less to gain from being dishonest.

Make inferences from people's behaviour. Take the case of noise again. In similar projects elsewhere, how have people actually reacted? How much have they spent on double glazing or other noise insulation? How much financial loss have they been prepared to suffer to move somewhere quieter? What needs to be measured, however, is not just the financial cost, but also the loss of consumer surplus. The Roskill Commission in 1968 examined the siting of a third London airport. It attempted to evaluate noise costs, and looked at the difference in value of house prices round Gatwick compared with elsewhere. A problem with this approach is in finding cases elsewhere that are directly comparable. Were the four potential sites for the third London airport directly comparable with Gatwick?

Another example of externalities would be a reduction in accidents from a safer road. How is this to be measured? Obviously there are the monetary benefits from reduced medical expenditures. But how would you value a life saved? This question is examined in Box 12.5.

BOX 12 5 WHAT PRICE A HUMAN LIFE?

EXPLORING
ECONOMICS

A difficult question for cost-benefit analysis

Many projects involve saving lives, whether they be new hospitals or new transport systems. This is obviously a major benefit, but how is a life to be evaluated?

Some people argue: 'You can't put a price on a human life: life is priceless.' But just what are they saying here? Are they saying that life has an *infinite* value? If so, this project must be carried out *whatever* the costs, and even if other benefits from it were zero! Clearly, when evaluating lives saved from the project, a value less than infinity must be given.

Other people might argue that human life cannot be treated like other costs and benefits and put into mathematical calculations. But what are these people saying? That the question of lives saved should be excluded from the cost-benefit study? If so, the implication is that life has a *zero* value! Again this is clearly not the case.

So if a value somewhere between zero and infinity should be used, what should it be?

Some economists have suggested that a life be valued in terms of a person's future earning potential. But this implies that the only value of a person is as a factor of production. Would the life of a disabled person, for example, who is unable to work and draws state benefit, be given a *negative* value? Again this is clearly not the solution. It would also value the life of a banker considerably higher than that of most other workers; an approach that would be hard to justify politically!

Can any inferences be drawn from people's behaviour?

How much are people prepared to spend on safety: on making their car roadworthy, on buying crash helmets, etc.? This approach too has serious drawbacks. People are wishful thinkers. They obviously do not want to be killed, but simply believe that accidents happen to other people, not to them.

Then again, there are the problems of estimating the effects on other people: on family and friends. Can the

amount that people are willing to spend on life insurance be a guide here? Again, people are optimists and in any case may be cash-constrained. Also, it is not the family and friends who buy the insurance; it is the victim, who may not take the effect on others fully into account.

The Department for Transport¹ puts a value of £1 873 498 on a life saved from a road safety project (in 2015 prices). This is based partly on the (discounted) average value of individuals' lost output for the rest of their lives (£620 466), partly on emergency services and hospital costs (£23 548), partly on the costs of insurance and damage to property (£11 561) and partly on the human cost based on people's willingness to pay (if they had to) for the enjoyment of life over and above the consumption of goods and services plus costs to family and friends (£1 217 923). The US Department of Transportation, by contrast, uses the much higher average valuation of \$9.4 million (in 2015 prices).

1. Can you think of any other ways of getting a more 'rational' evaluation of human life? Would the person's age make any difference?
2. If you had to decide whether more money from a hospital's budget were to be spent on hip replacements (which do not save lives, but do dramatically improve the quality of the patient's life), or on heart transplants (which do save lives, but are expensive), how would you set about making a rational decision?
3. If different values are used in different countries, does this have implications for policy makers? Does your answer change if different departments within a government use varying valuations?

¹ Reported Road Casualties Great Britain, Annual Report: 2015, Table RAS60003 (Department of Transport, 2016).

How would you evaluate (a) the external effects of building a reservoir in an area of outstanding natural beauty; (b) the external effects of acid rain pollution from a power station?

Risk and uncertainty

Taking account of *risk* is relatively straightforward. The value of a cost or benefit is simply multiplied by the probability of its occurrence.

The problem is that *risk* is less frequent than *uncertainty*. As was explained in section 4.3, in the case of uncertainty all that is known is that an outcome *might* occur. The likelihood of its occurring, however, is uncertain.

How then can uncertainty be taken into account? The best approach is to use *sensitivity analysis*. Let us consider two cases.

Individual uncertain outcomes

A range of possible values can be given to an uncertain item in the CBA: for example, damage from pollution. Table 12.1 illustrates two possible cases.

The lowest estimate for pollution damage is £10 million; the highest is £50 million. In case A, given a very high margin of benefits over *other* costs, the project's desirability is *not* sensitive to different values for pollution damage. Even with the highest value (£50 million), the project still yields a net benefit.

Definition

Sensitivity analysis Where a range of possible values of uncertain costs and benefits are given to see whether the project's desirability is sensitive to these different values.

BOX 12.6 HS2: IS IT REALLY WORTH IT?**The case for (and against) High Speed Rail in the UK**

In January 2009, the Department for Transport published a report¹ into various options for a new high speed rail network in the UK. It concluded that an initial route between London and the West Midlands would be the best way forward. The then Labour government acted swiftly. It set up a company, High Speed Two Limited (HS2 Ltd), tasked with further investigating the proposals and providing advice on factors such as connectivity with the existing network and further extensions of the line to cities in the north of England and in Scotland.

In 2011, the first section of the route was confirmed as running from London Euston to Birmingham Curzon Street. After three years of parliamentary scrutiny, legislation was finally passed in February 2017 which meant work on construction of the line could finally begin. A completion date for phase 1 was set for December 2026.

HS2 Ltd has also made an economic case for the 'V'-shaped second phase of the project. The two routes will take services from Birmingham Curzon Street to Manchester Piccadilly and to Leeds. The finalised route from Birmingham to Manchester was announced in November 2016, while Birmingham to Leeds remains under discussion.

HS2 Ltd also examined the possibility of further extending the service to Scotland. In May 2015, it announced that there was 'no business case' for this extension.

The rationale for HS2

HS2 Ltd published a detailed analysis of the potential benefits of this infrastructure project in February 2011. The report focused on both phases of the project and stated that:

The economic appraisal of a transport scheme seeks to cover the full economic costs and full economic benefits of a scheme and to quantify these in monetary terms. . . . we look at some of the wider economic impacts on the UK economy, using Department for Transport guidance to quantify and value these impacts. The appraisal of quantified benefits provides a numerical result, a 'benefit-cost ratio' or BCR. This ratio represents the level of benefit per pound (£) spent by Government (e.g. if a scheme generates £2 of benefit for every £1 spent this is presented as a BCR of 2.0).²

The report identified the following as the most important benefits of the scheme:

- Reduced journey times.
- Additional capacity resulting in reduced crowding and waiting times.
- Improved connectivity that would help to rebalance the economy: i.e. the greatest benefits would be for the regions outside of London.
- Environmental benefits from people substituting road and air travel for HS2.
- Improving links with key international gateways.

There was considerable public debate about the estimated costs and benefits published in the initial report. Following

criticism of the estimates, HS2 Ltd extended and updated its initial analysis and a new set of estimated costs and benefits were published in October 2013.³ The net benefits were slightly lower than in the 2011 report – mainly due to a £10bn rise in the projected costs of the scheme. The main findings are summarised in the table.

Quantified benefits and costs (£ billions) of the Y network (2011 PV/prices) and the resulting benefit-cost ratio (BCR)

(1) Transport user benefits	Business £40.5bn Other £19.3bn
(2) Other quantifiable benefits (excl. carbon)	£0.8bn
(3) Loss to government of indirect taxes	–£2.9 bn
(4) Net transport benefits = (1) + (2) + (3)	£57.7bn
(5) Wider economic impacts (WEIs)	£13.3bn
(6) Net benefits including WEIs (4) + (5)	£71.0bn
(7) Capital costs	£40.5bn
(8) Operating costs	£22.1bn
(9) Total costs = (7) + (8)	£62.6bn
(10) Revenues	£31.1bn
(11) Net costs to government = (9) – (10)	£31.5bn
(12) BCR without WEIs (ratio) = (4)/(11)	1.8
(13) BCR with WEIs (ratio) = (6)/(11)	2.3

Source: *Economic Case for HS2*, Table 15 (Department for Transport, October 2013).

The estimated values of the two largest benefits of the project help to illustrate the complexity of the economic assessment, and the sensitivity of results to any assumptions used in the analysis.

HS2 Ltd estimated that reductions in crowding would generate just over £7.5bn of benefits – 11 per cent of the total net benefits of the full network. The key assumption here is that the capacity of the rail network is beginning to reach its limit and the growth in the demand for rail travel will continue at a similar rate in the future. For example, the number of passenger journeys and total distance travelled by rail doubled between 1993/94 and 2013/14.

To estimate demand, the report uses the elasticity of rail demand to changes in GDP. This requires forecasting GDP over very long periods of time, which involves high levels uncertainty.

To deal with this uncertainty, a demand cap is used in the analysis. This is a rather arbitrary assumption that growth in demand for rail travel will cease at some predetermined point in the future. The benefits in the table above are estimated by introducing a demand cap in 2036. This assumes that there is

no growth in the demand for rail travel for 57 years: i.e. from 2036 to 2093. If the cap is introduced at a later point the estimated benefits increase significantly. For example, if it is introduced in 2049 the BCR increases from 2.3 to 4.5.

Will the demand for rail travel increase in the future if the economy continues to grow? One factor that might influence this relationship is technological developments. In particular, improvements in Internet availability/speed and broadband width might lead to more people working from home and thus reducing the demand for travel at any given level of GDP. The effect could also be in the opposite direction, with more people travelling by train if they are able to make productive use of the travel time. Thus the impact of technology is very uncertain.

The benefits of time saved

The most significant projected advantage of HS2 is the value of the time saved by business, commuter and leisure travellers. For example, the following reductions in travel time have been forecast:

- Birmingham to London: 1hr 21mins to 49mins.
- Birmingham to Leeds: 2hrs to 57mins.
- Manchester to London: 2hr 8mins to 1hr 8mins.

HS2 Ltd estimated that the total time saved was worth £37bn or 44 per cent of the total benefits of the project. How did HS2 Ltd calculate this figure?

It tried to find out how much people are willing to pay for shorter journey times. The values of non-work travel time were estimated by using the results from surveys of motorists carried out in 1994. In these surveys people were asked to choose between journey options (i.e. different prices and times) for a hypothetical trip. From the responses, a value of £6.04 was placed on each hour for a leisure traveller.

No surveys such as these have been carried out with business travellers; so the value of their time was estimated using a cost-savings approach. This assumes that any travel time saved can be put to productive use in the workplace. The value of this work was estimated by using the gross wage of workers who use the train for business purposes. Taking this approach, a figure of £31.96 was estimated for each hour of time saved per person.

There is considerable uncertainty and debate about the use of each of these figures. For example, the survey used to value non-work time is very dated. It is also very difficult to adjust the figures to account for business travellers being able to use some of their travel time productively: i.e. checking/responding to emails, writing reports and doing other work. The HS2 Ltd results assume that people cannot use *any* of their time on a train productively. If further research finds that travellers do use a large proportion of their time productively, then the benefits of HS2 will be considerably lower than have been estimated.

Overall, the report found that the HS2 scheme would produce economic benefits of £71.6bn. Comparing this with estimated net costs (after revenues) of £31.5bn, the result would be a BCR of 2.3 – enough to recommend that the scheme go ahead. It should be noted, however, that this *excludes* environmental impacts, which were assessed for Phase 1 in a separate report⁴.

Opposition to HS2

HS2 has been subject to a great deal of opposition, particularly from those directly affected by the proposed route. Two major groups, *Stop HS2* and *HS2 Action Alliance*, have been established to campaign against the building of infrastructure. Eighteen local authorities have also created a group called *51m* which is also opposed to the project.

Both the Institute of Economic Affairs⁵ and Adam Smith Institute⁶ have published reports that question the reliability of the estimated project costs. Given the expensive tunnelling and technically complex work in urban areas both reports argued that the final costs could be in excess of £80bn. The forecasts have already increased from £33bn to £50bn.

A major study by the House of Lords Economic Affairs Committee published in March 2015⁷ also argued that the government had not made a convincing case for continuing with the project. In particular, the report questioned the assumption that the rail network had a capacity issue. The authors argued that rail usage data indicated that there was no existing overcrowding problem on long-distance trains and there was unlikely to be one in the near future.

It also questioned the premise that the greatest benefits would go to the regions outside of London because evidence from other countries suggests that firms in London may actually benefit the most. For example, shorter travel times mean that their employees can live further away and benefit from lower house prices. In order to boost the economies in the north of England, the report argues that investment should be focused on improving regional transport link between cities other than London.

Despite the criticisms, the government has remained committed to the general approach. Chris Grayling, the Transport Secretary, stated in February 2017 that:

HS2 will be the world's most advanced passenger railway and the backbone of our rail network. Royal Assent is a major step towards significantly increasing capacity on our congested railways for both passengers and freight; improving connections between the biggest cities and regions; generating jobs, skills and economic growth and helping build an economy that works for all.⁸

With time-frames that stretch over decades, it will be a long wait until we find out whose views were correct: those thinking the scheme will prove to be a driver for economic growth, or those who are convinced it will be an expensive white elephant.

HS2: IS IT REALLY WORTH IT? (continued)

1. Why is this type of cost–benefit analysis so complex?
2. ‘The “losers” will be compensated, so there is no reason for them to protest.’ Assess this statement with reference to HS2.
3. Explain why companies in London might benefit as much from HS2 as those in Manchester.

Table 12.1 Effect of different estimates of the costs of production on the viability of a project

	Total costs other than pollution (£m)	Total pollution cost (£m)	Total benefits (£m)	Net benefits (total benefits – total costs) (£m)
Case A	100	10	200	90
	100	20	200	80
	100	50	200	50
Case B	140	10	160	10
	140	20	160	0
	140	50	160	–30

In case B, however, the project’s desirability is sensitive to pollution damage. If the damage exceeds £20 million, the project becomes undesirable. In this case, the government will have to decide whether it is prepared to take the gamble.

A number of uncertain outcomes

When there are several uncertain outcomes the typical approach is to do three cost–benefit calculations: the most optimistic (where all the best possible outcomes are estimated), the most pessimistic (where all the worst possible outcomes are estimated) and the most likely (where all the middle-of-the-range outcomes are estimated). This approach can give a good guide to just how ‘borderline’ the project is.

Discounting future costs and benefits

As we saw in section 10.3, discounting is a procedure for giving a present value to costs and benefits that will not occur until some time in the future.

Discounting in CBA

The procedure is as follows:

- Work out the costs and benefits for each year of the life of the project.

- Subtract the costs from the benefits for each year, to give a net benefit for each year.
- Discount each year’s net benefit to give it a present value.
- Add up all of these present values. This gives a *net present value (NPV)*.
- If the NPV is greater than zero, the benefits exceed the costs: the project is worthwhile.

Maths Case 12.2 on the student website gives a worked example.

Choosing the discount rate

Apart from the problems of measuring the costs and benefits, there is the problem of choosing the rate of interest/discount.

If it were a private-sector project, the firm would probably choose the market rate of interest as its rate of discount. This is the rate that it would have to pay to borrow money to finance the project.

In the case of CBA, however, it is argued that the government ought to use a *social rate of discount*. This rate should reflect society’s preference for present benefits over future benefits. But just what is this rate? If a high rate is chosen, then future net benefits will be discounted more, and projects with a long life will appear less attractive than projects yielding a quick return. Since the government has a responsibility to future generations and not just to the present one, it is argued that a relatively low discount rate should be chosen.

Imagine that a specific public project yields a return of 13 per cent (after taking into account all social costs and benefits), whereas a 15 per cent private return could typically be earned by projects in the private sector. How would you justify diverting resources from the private sector to this project?

Definition

Social rate of discount A rate of discount that reflects society’s preferences for present benefits over future ones.

Inevitably, the choice of discount rate is arbitrary. As a result, the analysis will normally be conducted using two or three alternative discount rates to see whether the outcome is sensitive to the choice of discount rate. If it is, then again the project will be seen as borderline.

CBA and the distribution of costs and benefits

Virtually all projects involve gainers and losers. For example, the majority may gain from the construction of a new motorway, but not those whose homes lie alongside it. So how is the distribution of costs and benefits to be taken into account?

The strict Pareto criterion

According to the strict Pareto criterion, a project is unequivocally desirable only if there are some gains and *no one* is made worse off. But are there likely to be any projects that fulfil this criterion? If there are always losers then let us think about a situation where the losers are compensated. Thus we can now state that a project would be accepted only if the gainers *fully* compensated the losers, with the gainers still being better off after doing so.

In practice, this never happens. Often compensation is simply not paid. Even when it is, the recipients rarely feel as well off as before, and there will still be many who do not get compensation. Also, the compensation is usually paid not by the project users, but by the general taxpayer (who will thus be *worse off*).

The Hicks–Kaldor criterion

To get round this problem, J. R. Hicks and N. Kaldor suggested an alternative criterion. This states that a project is desirable if it leads to a *potential* Pareto improvement: in other words, if the gainers could *in principle* fully compensate the losers and still have a net gain, even though in practice they do not pay any compensation at all.

This criterion is what lies behind conventional CBA. If the benefits of a project are greater than the costs, then in

principle the losers could be fully compensated with some net benefits left over.

But what is the justification for using this test? The losers, after all, will still lose. Its advocates argue that questions of *efficiency* should be kept separate from questions of *equity*. Projects, they argue, should be judged on efficiency grounds. They are efficient if their benefits exceed their costs. Questions of fairness in distribution, on the other hand, should be dealt with through the general system of taxation and welfare.

This is a ‘useful’ argument because it lets the proponents of the project off the hook. Nevertheless, the problem still remains that some people will lose. People do not like living near a new motorway, airport or power station. These people cannot expect to receive special welfare benefits from general taxation.

Thus other economists have argued that more specific account should be taken of distributional effects when *measuring* costs and benefits.

Taking specific account of distributional consequences

One way this could be done would be to give a higher weighting to the costs of individual, as opposed to corporate, losers. The justification is simple. The pain for one person of losing £10 000 is greater than the collective pain of 10 000 people losing just £1 each. Just how much higher this weighting should be, however, is a matter of judgement, not of precise calculation.

Another way distribution can be taken into account is to give a higher weighting to the costs incurred by poor people than to those incurred by rich people. For example, assume that a new airport is built. As a result, house prices nearby fall by 10 per cent. A rich person’s house price falls from £2 000 000 to £1 800 000 – a loss of £200 000. A poor person’s house price falls from £200 000 to £180 000 – a loss of £20 000. Is the loss to the rich person eight times as painful as that to the poor person? Probably not. It is argued, therefore, that the poorer people are, the higher the weighting that should be given to each £1 lost. Just what this weighting should be, however, is controversial.

Section summary

1. Cost–benefit analysis (CBA) can help a government decide whether or not to go ahead with a particular public project, or which of alternative projects to choose. CBA involves a number of stages.
2. All costs and benefits must be identified. These include the direct costs of constructing and operating the project, the direct monetary benefits to the operators and the consumer surplus of the users. They also include external costs and benefits to non-users.
3. Direct monetary costs and benefits are relatively easy to measure. Nevertheless there is still uncertainty about their *future* values. Also, there is a problem if prices are distorted.
4. Non-monetary private benefit (consumer surplus) is difficult to estimate because of the difficulty of estimating the shape and position of the demand curve. The alternative approach is to focus on specific non-monetary benefits, such as journey time saved, and then to evaluate how much people would be prepared to pay for them if they could.
5. Monetary externalities would normally be counted at face value. Non-monetary externalities are much more difficult to estimate. The approach is to try to estimate the value that consumers would put on them in a market environment. Questionnaire techniques could be used, or inferences could be drawn from people's actual behaviour elsewhere.
6. Figures would then have to be adjusted for risk and uncertainty.
7. Discounting techniques would then have to be used to reduce future benefits and costs to a present value.
8. The study may also take distributional questions into account. The Hicks–Kaldor criterion suggests a compensation test for deciding whether a project is desirable. But given that in practice full compensation would be unlikely, the distributional questions may need to be taken into account more specifically.
9. Having adjusted the costs and benefits for risk and uncertainty, timing and distributional effects, a recommendation to go ahead with the project will probably be given if its net present value (NPV) is positive: in other words, if the discounted social benefits exceed the discounted social costs.

12.5 GOVERNMENT FAILURE AND THE CASE FOR THE MARKET

Government intervention in the market can itself lead to problems. The case for non-intervention (*laissez-faire*) or very limited intervention is not that the market is the *perfect* means of achieving given social goals, but rather that the problems created by intervention are greater than the problems overcome by that intervention.

Drawbacks of government intervention

Shortages and surpluses. If the government intervenes by fixing prices at levels other than the equilibrium, this will create either shortages or surpluses (see section 3.1).

If the price is fixed *below* the equilibrium, there will be a shortage. For example, if the rent of social housing is fixed below the equilibrium in order to provide affordable housing for low-income households, demand will exceed supply. In the case of such shortages the government will have to adopt a system of waiting lists, or rationing, or giving certain people preferential treatment. Alternatively it will have to allow allocation to be on a first-come, first-served basis or allow queues to develop. Underground markets are also likely to develop (see page 82 and Case Study 3.2 on the book's website).

If the price is fixed *above* the equilibrium price, there will be a surplus. Such surpluses are wasteful, and high prices may protect inefficient producers. (The problem of food surpluses in the EU was examined in section 3.4.)

What are the possible arguments in favour of fixing prices (a) below and (b) above the equilibrium? Are there any means of achieving the same social goals without fixing prices?

Poor information. The government may not know the full costs and benefits of its policies. It may genuinely wish to pursue the interests of consumers or any other group, and yet may be unaware of people's wishes or misinterpret their behaviour.

Bureaucracy and inefficiency. Government intervention involves administrative costs. The more wide-reaching and detailed the intervention, the greater the number of people and material resources that will be involved. These resources may be used wastefully and the effect on welfare may not be an improvement on the free-market situation. Think back to the problem of scarcity we discussed in Chapter 1; if we 'use up' resources on managing intervention, we need to be sure that the outcome is markedly better than without intervention.

Lack of market incentives. If government intervention removes market forces or reduces their effect (by the use of subsidies, welfare provisions, minimum wages, etc.), it may remove certain useful incentives. Subsidies may allow inefficient firms to survive. Welfare payments may discourage

people from working. The market may be imperfect, but it does tend to encourage efficiency by allowing the efficient to receive greater rewards.

Shifts in government policy. Industrial performance may suffer if government intervention changes too frequently. It makes it difficult for firms to plan if they cannot predict tax rates, subsidies, wage controls, etc. Shifts in policy are also likely to involve costs for both business and public-sector providers. This may result in wasted resources.

Lack of freedom for the individual. Government intervention may involve a loss of freedom for individuals to make economic choices. The argument is not just that the pursuit of individual gain is seen to lead to the social good, but that it is desirable in itself that individuals should be as free as possible to pursue their own interests with the minimum of government interference, and with that minimum being largely confined to the maintenance of laws consistent with the protection of life, liberty and property.

Go through the above arguments and give a reply to the criticisms made of government intervention.

Advantages of the free market

Although markets in the real world are not perfect, even imperfect markets can be argued to have positive advantages over government provision or even government regulation.

Automatic adjustments. Government intervention requires administration. A free-market economy, on the other hand, leads to the automatic, albeit imperfect, adjustment to demand and supply changes.

Even under oligopoly, it is claimed, the competition between firms will be enough to encourage firms to produce goods that are desirable to consumers and at not excessively high prices, and will encourage more efficient production methods. Cases of pure monopoly with total barriers to entry are extremely rare.

Dynamic advantages of the free market. The chances of making high monopoly/oligopoly profits will encourage capitalists to invest in new products and new techniques. Prices may be high initially, but new firms will sooner or later break into the market and competition will ensue. If the government tries to correct the misallocation of resources under monopoly/oligopoly, either by regulating monopoly power or by nationalisation, any resulting benefits could be outweighed by a loss in innovation and growth. This is one of the major arguments put forward by the neo-Austrian libertarian school – a school that passionately advocates the free market (see Box 12.7).

Are there any features of free-market capitalism that would discourage innovation?

A high degree of competition even under monopoly/oligopoly. Even though an industry at first sight may seem to be highly monopolistic, competitive forces may still work for the following reasons.

- A fear that excessively high profits might encourage firms to attempt to break into the industry (assuming that the market is contestable).
- Competition from closely related industries (e.g. coach services for rail services, or electricity for gas).
- The threat of foreign competition. Additional competition was one of the main purposes behind the Single European Act which led to the abolition of trade barriers within the EU in 1993 (see section 25.4).
- Countervailing powers. Large, powerful producers often sell to large, powerful buyers. For example, the power of detergent manufacturers to drive up the price of washing powder is countered by the power of supermarket chains to drive down the price at which they purchase it. Thus power is to some extent neutralised.
- The competition for corporate control (see pages 210–11).

Should there be more or less intervention in the market?

No firm conclusions can be drawn in the debate between those who favour more and those who favour less government intervention, for the following reasons:

- The debate involves normative issues that cannot be settled by economic analysis. For example, it could be argued that freedom to set up in business and freedom from government regulation are desirable *for their own sake*. As a fundamental ethical point of view, this can be disputed, but not disproved.
- In principle, the issue of whether a government ought to intervene in any situation could be settled by weighing up the costs and benefits of that intervention. Such costs and benefits, however, even if they could be identified, are extremely difficult, if not impossible, to measure, especially when the costs are borne by different people from those who receive the benefits and when externalities are involved.
- Often the effect of more or less intervention simply cannot be predicted: there are too many uncertainties.

Nevertheless, economists can make a considerable contribution to analysing problems of the market and the effects of government intervention. Chapters 13 and 14 illustrate this by examining specific problem areas.

BOX 12.7 MISES, HAYEK AND THE MONT PELERIN SOCIETY**The birth of post-war libertarianism**

After the Second World War, governments in the Western world were anxious to avoid a return to the high levels of unemployment and poverty experienced in the 1930s. The free market was seen to have failed. Governments, it was therefore argued, should take on the responsibility for correcting or counteracting these failings. This would involve various measures such as planning, nationalisation, the restriction of monopoly power, controls on prices, the macroeconomic management of the economy and the provision of a welfare state.

But this new spirit of intervention deeply troubled a group of economists and other social scientists who saw it leading to an erosion of freedom. In 1947, this group met in a hotel in the Swiss Alps. There they formed the Mont Pelerin Society: a society pledged to warn against the dangers of socialism and to advocate the freedom for individuals to make their own economic choices.

Two of the most influential figures in the society were the Austrians Ludwig von Mises (1881–1973) and Friedrich von Hayek (1889–1992). They were the intellectual descendants of the nineteenth-century 'Austrian school'. Carl Menger, the originator of the school, had (along with Jevons and Walras (see Box 4.2)) emphasised the importance of individuals' marginal utility as the basis of demand. The Austrian school of economists was famous for its stress on individual choice as the basis for rational economic calculation and also for its advocacy of the free market.

Mises and Hayek (the 'neo-Austrians' as they became known) provided both a critique of socialism and an advocacy of the free market. There were two main strands to their arguments.

The impossibility of rational calculation under socialism

In his famous book *Socialism* (1922), Mises argued that centrally planned socialism was logically incapable of achieving a rational allocation of resources. Given that

scarcity is the fundamental economic problem, all societies, whether capitalist or socialist, will have to make choices. But rational choices must involve weighing up the costs and benefits of alternatives. Mises argued that this cannot be done in a centrally planned economy. The reason is that costs and benefits can be measured only in terms of money prices, prices which reflect demand and supply. But such prices can be established only in a market economy.

In a centrally planned economy, prices will be set by the state and no state will have sufficient information on demand and supply to set rational prices. Prices under centrally planned socialism will thus inevitably be arbitrary. Also, with no market for land or capital these factors may not be given a price at all. The use of land and capital, therefore, may be highly wasteful.

Many democratic socialists criticised Mises' arguments that rational prices *logically* cannot be established under socialism. In a centrally planned economy, the state can in theory, if it chooses, set prices so as to balance supply and demand. It can, if it chooses, set an interest rate for capital and a rent for land, even if capital and land are owned by the state. And certainly in a mixed-market socialist economy, prices will merely reflect the forces of demand and supply that have been modified by the state in accordance with its various social goals.

Hayek modified Mises' arguments somewhat. He conceded that some imperfect form of pricing system could be established under socialism, even under centrally planned socialism. Hayek's point was that such a system would inevitably be inferior to capitalism. The problem was one of imperfect information under socialism.

Calculation of costs and benefits requires knowledge. But that knowledge is dispersed amongst the millions of consumers and producers throughout the economy. Each consumer possesses unique information about his or her own tastes; each manager or worker possesses unique information

Section summary

1. Government intervention in the market may lead to shortages or surpluses; it may be based on poor information; it may be costly in terms of administration; it may stifle incentives; it may be disruptive if government policies change too frequently; it may remove certain liberties.
2. By contrast, a free market leads to automatic adjustments to changes in economic conditions; the prospect of monopoly/oligopoly profits may stimulate risk taking and hence research and development and innovation; there may still be a high degree of actual or potential competition under monopoly and oligopoly.
3. It is impossible to draw firm conclusions about the 'optimum' level of government intervention. This is partly due to the normative nature of the question, partly due to the difficulties of measuring costs and benefits of intervention/non-intervention, and partly due to the difficulties of predicting the effects of government policies, especially over the longer term.

about his or her own job. No government could hope to have this knowledge. Planning will inevitably, therefore, be based on highly imperfect information.

The market, by contrast, is a way of co-ordinating this dispersed information: it co-ordinates all the individual decisions of suppliers and demanders, decisions based on individuals' own information. And it does it all without the need for an army of bureaucrats.

The economic problem of society is thus not merely a problem of how to allocate 'given' resources – if 'given' is taken to mean given to a single mind which deliberately solves the problem set by these 'data'. It is rather a problem of how to secure the best use of resources known to any of the members of society, for ends whose relative importance only these individuals know. Or, to put it briefly, it is a problem of the utilization of knowledge not given to anyone in its totality.¹

Lack of dynamic incentives under socialism

A planned socialist economy will, according to Mises and Hayek, lack the incentives for people to take risks. Even a 'market socialist' society, where prices are set so as to equate demand and supply, will still lack the crucial motivating force of the possibility of large personal economic gains. Under capitalism, by contrast, a firm that becomes more efficient or launches a new or improved product can gain huge profits. The prospect of such profits is a powerful motivator.

Without the striving of entrepreneurs (including the shareholders) for profit, of the landlords for rent, of the capitalists for interest and the labourers for wages, the successful functioning of the whole mechanism is not to be thought of. It is only the prospect of profit which directs production into those channels in which the demands of the consumer are best satisfied at least cost. If the prospect of profit disappears the mechanism of the market loses its mainspring, for it is only this prospect

which sets it in motion and maintains it in operation. The market is thus the focal point of the capitalist order of society; it is the essence of capitalism. Only under capitalism, therefore, is it possible; it cannot be 'artificially' imitated under socialism.²

In addition to these economic criticisms of socialism, Mises and Hayek saw government intervention as leading down the road towards totalitarianism. The more governments intervened to correct the 'failings' of the market, the more this tended to erode people's liberties. But the more people saw the government intervening to help one group of people, the more help they would demand from the government for themselves. Thus inexorably the role of the state would grow and grow, and with it the size of the state bureaucracy.

In the early years after the war, the Mont Pelerin Society had little influence on government policy. Government intervention and the welfare state were politically popular.

In the late 1970s, however, the society, along with other similar libertarian groups, gained increasing influence as a new breed of politicians emerged who were wedded to the free market and were looking for an intellectual backing for their beliefs.

Libertarian thinkers such as Hayek and Milton Friedman (see Case Study 16.2 on the student website) had a profound effect on many right-wing politicians, and considerably influenced the economic programmes of the Thatcher, Reagan and both Bush (Snr and Jnr) administrations.

Do the arguments of Mises and Hayek necessarily infer that a free market is the most desirable alternative to centrally planned socialism?

END OF CHAPTER QUESTIONS

1. Assume that a firm discharges waste into a river. As a result, the marginal social costs (*MSC*) are greater than the firm's marginal private costs (*MPC*). The following table shows how *MPC*, *MSC*, *AR* and *MR* vary with output.

Output	1	2	3	4	5	6	7	8
<i>MPC</i> (£)	23	21	23	25	27	30	35	42
<i>MSC</i> (£)	35	34	38	42	46	52	60	72
<i>TR</i> (£)	60	102	138	168	195	219	238	252
<i>AR</i> (£)	60	51	46	42	39	36.5	34	31.5
<i>MR</i> (£)	60	42	36	30	27	24	19	14

- (a) How much will the firm produce if it seeks to maximise profits?
- (b) What is the socially efficient level of output (assuming no externalities on the demand side)?
- (c) How much is the marginal external cost at this level of output?
- (d) What size tax would be necessary for the firm to reduce its output to the socially efficient level?
- (e) Why is the tax less than the marginal externality?
- (f) Why might it be equitable to impose a lump-sum tax on this firm?
- (g) Why will a lump-sum tax not affect the firm's output (assuming that in the long run the firm can still make at least normal profit)?
2. Why might it be argued that a redistribution of consumption, while not involving a Pareto improvement, could still be desirable?
3. Assume that a country had no state education at all. For what reasons might the private education system not provide the optimal allocation of resources to and within education?
4. Why might it be better to ban certain activities that cause environmental damage rather than to tax them?
5. Distinguish between publicly provided goods, public goods and merit goods.
6. Consider the advantages and disadvantages of extending property rights so that everyone would have the right to prevent people imposing any costs on them whatsoever (or charging them to do so).
7. The food industry provides a great deal of information about its products. Why, despite this, does the government run various campaigns about healthy eating?
8. Should all investment be subject to a social cost–benefit appraisal?
9. Make out a case for (a) increasing and (b) decreasing the role of the government in the allocation of resources.

Conclusions	417

Just how far should things be left to the market in practice? Just how much should a government intervene? These are clearly normative questions, and the answers to them may depend on a person's politics. Politicians on the right tend to favour a lesser degree of intervention while those on the left generally prefer more intervention.

In the final two chapters of Part D we examine some topics that illustrate well the possible strengths and weaknesses of both the market and government intervention. In Chapter 13 we look closely at the environment, an area where the existence of externalities results in substantial market failure. We start by considering the broader environmental issues and then turn to alternative policies for dealing with pollution and urban traffic congestion.

As we shall see, the economist's approach is to focus on both the costs and the benefits of various policies and how these costs and benefits can be weighed up. Scientists are the ones who need to assess whether global warming is a real phenomenon and to determine the physical consequences of our actions, such as the degree of warming that might result from a particular level of CO₂ emissions. But it is economists who must assess the implications for various policies to deal with the problems.

13.1 ECONOMICS OF THE ENVIRONMENT

Scarcely a day goes by without some environmental issue featuring in the news: another warning about global warming, a company fined for illegally dumping waste, a drought or flood blamed on pollution, poor air quality in our major cities. Attempts by policy makers to improve the environment also cause controversy and hit the headlines: for example, the impact of government climate change policies on the size of customers' energy bills.

Nearly everyone would like a cleaner, more attractive environment but there are deep disagreements about how much people should pay for it. Environmental improvement normally comes at a cost: whether in cleaning up waste or pollution, or in terms of the higher price we might need to pay for 'green' products, such as organic foods, low-emission cars and electricity from renewable sources.

Economists are concerned with choices, and rational choices involve weighing up costs and benefits. Increasingly, people are recognising that such costs and benefits ought to include the effects on the environment: the effects on the planet we share with each other and with future generations.

The environmental problem

Why is the environment used in such a suboptimal way? Why are policies that try to address these environmental issues always so controversial? To answer these questions

we have to understand the nature of the economic relationship between humans and the natural world.

We all benefit from the environment in three ways:

- as an amenity to be enjoyed;
- as a source of primary products (food, raw materials and other resources);
- as a place where we can dump waste.

The relationship between these uses and the rest of the economy are illustrated in Figure 13.1. Unfortunately, having more of one of these benefits usually means having less of another.

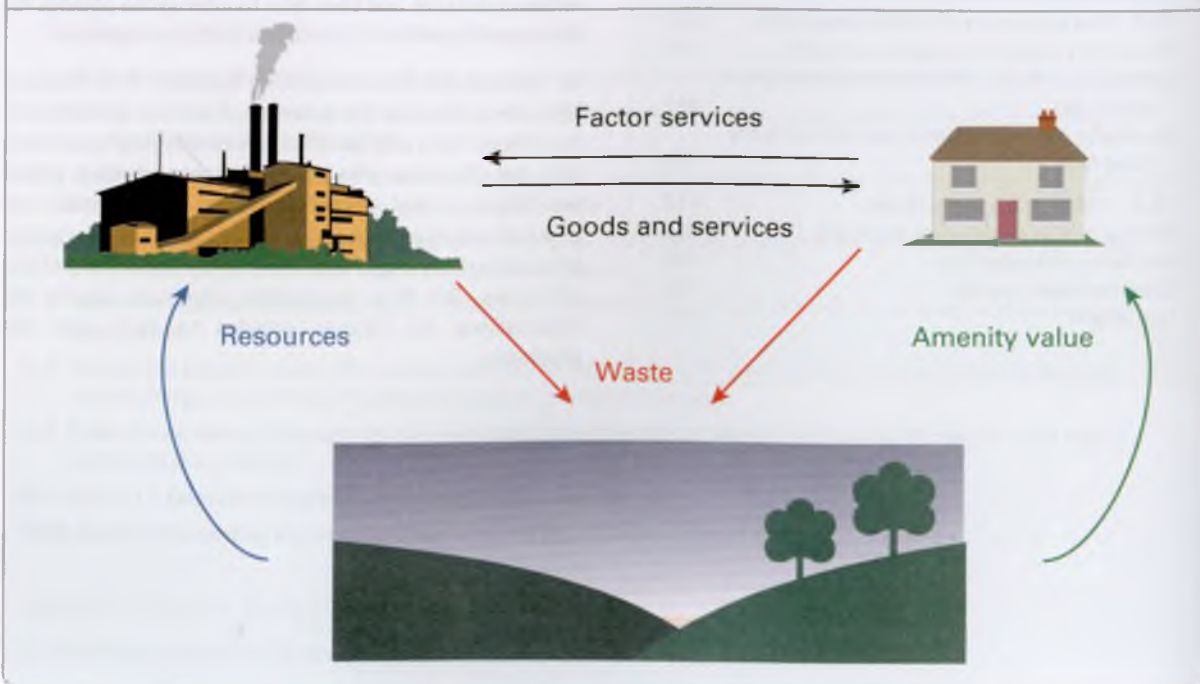

The use of the environment as a productive resource reduces its amenity value. Intensive agriculture, with hedges and woods removed, spoils the beauty of the countryside and can lead to a decline in animal and plant species. Mines and quarries are ugly. Commercial forestry is often at the expense of traditional broad-leaved forests.

Similarly, the use of the environment as a dump for waste reduces its amenity value. The environment becomes dirtier and uglier. The burning of fossil fuels dumps CO₂ into the atmosphere and contributes towards global warming.

? *Using examples, discuss the conflicts between using the environment as a productive resource and as a dump?*

These conflicts have always existed, but are they getting worse? Let us examine the arguments.

Figure 13.1 The economy and the environment

Population pressures and limited resources

As we saw in Box 6.1, as more people crowd on to the fixed supply of world land, so diminishing returns to labour will occur. If food output per head is to remain constant, let alone increase, land must be made to yield more and more. One answer has been to use increasing amounts of fertiliser and pesticides. Likewise, if the increasing world population is to have higher levels of material consumption, this will generate increased demands for natural resources, many of which are non-renewable and generate pollution. With the rapid growth of countries such as China and India, the pressures on the environment are already growing sharply.

The environment is able to absorb most types of waste up to certain levels of emission. Beyond such levels, however, environmental damage is likely to accelerate. Other things being equal, as population and waste grow, so environmental degradation is likely to grow at a faster rate.

Cause for optimism?

Despite population pressures, there are various factors that are helping to reduce environmental degradation.

Technological developments. Many newer industrial processes are cleaner and make a more efficient use of resources, leading to less waste and a slowdown in the rate of extraction of various minerals and fossil fuels. For example, the amount of CO₂ emitted per \$ of GDP has fallen from 0.475kg in 1990 to 0.354kg in 2013 (at 2011 prices). What is more, the production of less waste, or the recycling of waste, is often in the commercial interests of firms: it allows them to cut costs. In 2013, the Department of Energy and Climate Change estimated that large firms in the UK could contribute £1.9 billion in net social benefits if they spent money on energy saving investments. Much of this would be in the form of lower costs for the firms themselves. Firms thus have an incentive both to use such technology and also to research into cleaner and more resource-efficient techniques.

Increased price of non-renewable resources. As we saw in Box 10.11 (see page 312), as resources become scarcer, so their prices rise. This encourages people to use less of them, either by using more efficient technology or by switching to renewable alternatives as they become available.

Public opinion. As knowledge about environmental damage has grown, so too has pressure from public opinion to do something about it. Many firms see the opportunity to gain commercially from having a 'green image' and to publicise their positive attitude towards corporate social responsibility. In addition, governments see electoral advantage in policies to create a cleaner, greener environment.

Despite these developments, however, many aspects of environmental degradation continue to worsen.

Global emissions have continued to increase. For example, CO₂ tonnes per capita have risen from 4.059 in 2002 to

4.996 in 2014. A UN Environment Report¹ published in November 2016 concluded that by 2030 emissions would be 12 to 14 gigatonnes above the levels required to limit the growth in global warming to 2°C.

An OECD report² published in 2012 identified and classified environmental issues according to a traffic-light system as serious (red light), moderate (amber light) or satisfactory (green light). The following four challenges were identified as most urgent (and badged as red light); climate change, biodiversity, water and the health impacts of pollution.

An optimum use of the environment

If the current levels of pollution and environmental degradation are too high, then can we identify an optimum use of the environment? To do this, we have to go back to first principles of efficiency and also look at our attitudes towards *sustainability*.

Different approaches to sustainability

We can identify four different approaches to the environment and sustainability.

The free-market approach. At the one extreme, we could regard the world as there purely for ourselves: a resource that belongs to individual property owners to do with as they choose, or a 'common asset', such as the air and seas, for individuals to use for their own benefit. In this view of the world, we are entitled simply to weigh up the marginal costs and benefits to ourselves of any activity. Sustainability is achieved in this free-market world only to the extent that resource prices rise as they become scarce and to the extent that environmentally friendly technologies are in firms' (or consumers') private interests.

The social efficiency approach. A somewhat less extreme version of this view is one that takes the social costs and benefits of using the environment into account: i.e. the costs and benefits not only to the direct producer or consumer, but to people in general. Here we would apply the standard rules for social efficiency: use resources to provide goods/services until the marginal social benefit equals the marginal social cost. Even though this approach does take into account environmental externalities (such as pollution), it is only to the extent that they adversely affect *human beings*.

Within this general approach, however, more explicit account can be taken of sustainability, by including the

Definition

Sustainability The ability of the environment to survive its use for economic activity.

BOX 13.1 A STERN WARNING

Economists can offer solutions, but they can't solve the problem

The analysis of global warming is not just for climate scientists. Economists have a major part to play in examining its causes and consequences and the possible solutions. And these solutions are likely to have a major impact on business.

Perhaps the most influential study of climate change in recent times was the Stern Review of 2006. This was an independent review lead by Sir Nicholas Stern, the then head of the Government Economic Service and former chief economist of the World Bank. Here was an economist using the methods of economics to analyse perhaps the most serious problem facing the world.

Climate change presents a unique challenge for economics: it is the greatest and widest-ranging market failure ever seen. The economic analysis must therefore be global, deal with long time horizons, have the economics of risk and uncertainty at centre stage, and examine the possibility of major, non-marginal change.¹

Dealing with long time horizons presents some interesting problems. The benefits to society from acting on climate change today will occur in the future. The problem is that the cost of these policies will be felt today: e.g. higher prices and less consumption.

In order to carry out an assessment of environmental policies, therefore, the future social benefits need to be *discounted* (see pages 304–6 and 384–5) so that they can be compared with the current social costs. But what social discount rate should be chosen? This is a major issue as the results obtained from any economic assessment that involve costs and benefits over such a long period of time are very sensitive to the discount rate used. Stern used a relatively low social discount rate, which meant that the future benefits and costs were more highly valued. Some economists criticised the report, claiming that a much higher discount rate should have been chosen.

First the bad news . . .

According to the Stern Report, if no action were taken, global temperatures would rise by some 2–3°C within the next 50 years. As a result the world economy would shrink by an average of up to 20 per cent. The economies of the countries most seriously affected by floods, drought and crop failure could shrink by considerably more. Rising sea levels could displace some 200 million people; droughts could create tens or even hundreds of millions of 'climate refugees'.

. . . Then the good

However, Stern concluded that these consequences could be averted – and at relatively low cost – if action were taken early enough. According to the report, a sacrifice of just 1 per cent of global GDP (global income) could be enough to stabilise greenhouse gases to a sustainable level. To achieve this, action would need to be taken to cut emissions from their various sources (see the chart). This would involve a mixture of four things:

- Reducing consumer demand for emissions-intensive goods and services.
- Increased efficiency, which can save both money and emissions.
- Action on non-energy emissions, such as avoiding deforestation.
- Switching to lower-carbon technologies for power, heat and transport.

As one might expect from a report produced by an economist, the policy proposals focused on altering incentives. This could involve taxing polluting activities; subsidising green alternatives, including the development of green technology;

Greenhouse gas emissions in 2000, by source

Total emissions in 2000: 42 GtCO₂e.

Energy emissions are mostly CO₂ (some non-CO₂ in industry and other energy related).

Non-energy emissions are CO₂ (land use) and non-CO₂ (agriculture and waste).

Source: Stern Review on the Economics of Climate Change, Office of Climate Change (OCC) (Stern Review, 2006), Executive Summary, Figure 1 based on data drawn from World Resources Institute Climate Analysis Indicators Tool (CAIT) on-line database version 3.0.

costs of our use of the environment today to *future* generations. For example, we could take into account the effects of climate change not just on ourselves, but on our children and their descendants. Depending on people's views on 'intergenerational' equity, a higher or lower weighting could be given to future (as opposed to present) costs and benefits (see page 384 on the choice of a social discount rate).

The conservationist approach. Many environmentalists argue that our responsibilities should not be limited to each other, or even to future generations, but should include the environment for its own sake. Such a view would involve downplaying the relative importance of material consumption and economic growth, and putting greater emphasis on the maintenance of ecosystems. Growth in consumption would be ethically acceptable only if it led to no (or only very minor)

establishing a price for carbon through trading carbon (see section on tradable permits on pages 401–403 below) and regulating its production; and encouraging behavioural change through education, better labelling of products and encouraging public debate.

Heeding the warnings?

So just over 10 years after the Stern Report, how much progress has been made? We have already seen on page 393 that the OECD is very concerned about the environmental impact on growth and is pressing for a global response. So are national governments therefore acting with urgency?

In 2014, the Intergovernmental Panel on Climate Change (IPCC) issued its *Fifth Assessment Report (AR5)*² – the first one had been published in 1990. This major document consists of three working group reports and an overarching synthesis. The first working group looked at the physical science. The second considered impacts, adaptation and vulnerability, while the third focused on mitigation of climate change. Economists contributed substantially to both the second and third groups.

The report on impact³ confirmed that the effects of climate change are already occurring on all continents and across the oceans. It concluded that the world is ill-prepared for the risks that climate change brings.

As with Stern, it stated that there are currently opportunities to respond to such risks, though this will be difficult to manage with high levels of warming.

The report details the impacts of climate change to date, the future risks from a changing climate, and the opportunities for effective action to reduce risks. It identifies vulnerable people, industries and ecosystems around the world. It finds that risk from a changing climate comes from vulnerability (lack of preparedness) and exposure (people or assets in harm's way) overlapping with hazards (triggering climate events or trends). Each of these three components can be a target for smart actions to decrease risk.

Adaptation to reduce the risks from a changing climate is now starting to occur, but with a stronger focus on reacting to past events than on preparing for a changing future. According to Chris Field, the Co-Chair of Working Group II:

Climate-change adaptation is not an exotic agenda that has never been tried. Governments, firms, and communities around the world are building experience

with adaptation. This experience forms a starting point for bolder, more ambitious adaptations that will be important, as climate and society continue to change.⁴

Less than a month after this report, the working group on mitigation published its own findings.⁵ It summarised the diverse options open to policy makers and reaffirmed the conclusion that the worst effects of climate can be prevented, if action is taken.

Part of the Mitigation report takes the form of a summary for policy makers. It acknowledges that substantial reductions in emissions will require major changes in investment patterns. The report finds that some progress in policy development has been achieved, particularly at a national level. These policies are often at sectoral level and involve the regulatory, financial and information measures that economists have recommended for some time.

There is, however, a substantial time lag between the implementation of policies and the impact on the environment. AR5 found that since 2008 emission growth has not yet deviated from the previous trend. Of course, a major characteristic of climate change is that it is not restricted by national boundaries. This highlights the potential for international co-operation and we look at this further in Box 13.4 on page 406.

The IPCC is currently working on its sixth Assessment Report, which will be published in 2022.

1. *Would it be in the interests of a business to reduce its carbon emissions if this involved it in increased costs?*
2. *How is the concept of 'opportunity cost' relevant in analysing the impact of business decisions on the environment?*
3. *The Stern Report was produced in 2006. Why has progress to date been slow? Does this reflect a lack of political will or scepticism about the extent of climate change?*

environmental degradation. Maintenance of the environment is thus seen as an ethical *constraint* on human activity.

The Gaia approach. The strongest approach to sustainability involves a fundamentally different ethical standpoint. Here the Earth itself, and its various natural species of animals and plants, have moral rights. According to this *Gaia philosophy*, people are seen as mere custodians of the

Definition

Gaia philosophy The respect for the rights of the environment to remain unharmed by human activity. Humans should live in harmony with the planet and other species. We have a duty to be stewards of the natural environment, so that it can continue to be a self-maintaining and self-regulating system.

planet: the planet does not belong to them, any more than a dog belongs to the fleas on its back! This view of the environment is similar to that held by some indigenous peoples living in marginal areas, such as the Aborigines in Australia and the San (Bushmen) of the Kalahari, and to various other 'hunter-gatherer' peoples in developing countries. Their ethic is that the land they leave their descendants should be as good as, if not better than, the land they inherited from their ancestors. Conservation is a 'prime directive'. This approach to the environment has been dubbed the 'deep green' approach.

Making optimum decisions concerning the environment

Choice between these four approaches is essentially normative, and therefore we cannot as economists stand in judgement between them.

Nevertheless, economists can help in identifying optimum decisions *within* a given set of values. Most environmental economists adopt an approach that is consistent with the social efficiency view, which can be easily modified to fit the conservationist view. The main area for disagreement is over the *value* to be placed on specific environmental costs and benefits.

Let us take the case of the production of a good by a firm in a perfectly competitive market that yields benefits to consumers, but which involves pollution to the environment. What is the optimum level of output of the good? The choices are illustrated in Figure 13.2.

The line $MEC_{\text{pollution}}$ shows the external costs of pollution from each additional unit of the good produced by the firm. This diagram is very similar to Figure 12.12 on page 372. However, we now assume that up to Q_1 there are no external costs: the environment can cope with the waste generated. We also assume that the curve gets steeper as output increases because the environment is increasingly unable to cope with

the waste. The marginal external costs of pollution therefore accelerate.

A profit-maximising firm will produce Q_4 units of output, with external pollution costs of C_4 . The *socially* efficient level of output (where $MSB = MSC$), however, is Q_3 , with the lower external costs of pollution, C (We are assuming that there are no other externalities.) Identifying this socially efficient level of output is not easy in practice, since it requires us to *measure* pollution costs, and that is fraught with problems. These problems were considered in section 12.4.

A more conservationist approach could be to set a maximum pollution cost of, say, C_2 . This would reduce the optimum output to Q_2 . A Gaian approach would be to restrict output to Q_1 in order to prevent any pollution. Of course, as we move towards 'greener' approaches, so it becomes more important to look for less polluting methods for producing this good (causing the $MEC_{\text{pollution}}$ curve to shift downwards), and for alternative goods that involve less pollution (thus reducing the need to consume this good).

Market failures

What is clear from all the attitudes towards sustainability, other than the free-market one, is that the market system will fail to provide adequate protection for the environment. In fact, the market fails for various reasons.

Externalities. We saw above (Figure 13.2) how pollution could be classified as a 'negative externality' of production or consumption. In the case of production, there are marginal external costs (MEC), which means that the marginal social costs (MSC) are greater than the marginal private costs (MC) to the polluter. The failure of the market system to equate MSC and marginal social benefit (MSB) is due to either consumers or firms lacking the appropriate property rights.

Figure 13.2 Optimum level of an activity that involves pollution

The environment as a common resource. The air, the seas and many other parts of the environment are not privately owned. It is argued that they are a global 'commons'. As such it is extremely difficult to exclude non-payers from consuming the benefits they provide. Because of this property of 'non-excludability', the environment can often be consumed at a zero price. If the price of any good or service to the user is zero, there is no incentive to economise on its use.

Many parts of the environment, however, are *scarce*: there is *rivalry* in their use. As people increase their use of the environment, it may prevent other or rival consumers from enjoying it. This could lead to the *tragedy of the commons* (see page 362).

Ignorance. There have been many cases of people causing environmental damage without realising it, especially when the effects build up over a long time. Take the case of aerosols. It was not until the 1980s that scientists connected their use to ozone depletion. Even when the

problems are known to scientists, consumers may not appreciate the full environmental costs of their actions. So even if people would like to be more 'environmentally friendly' in their activities, they might not have the knowledge to be so.

Intergenerational problems. The environmentally harmful effects of many activities are long term, whereas the benefits are immediate. Thus consumers and firms are frequently prepared to continue with various practices and leave future generations to worry about their environmental consequences. The problem, then, is a reflection of the importance that people attach to the present relative to the future.

 Look through the categories of possible market failings in section 12.2. Are there any others, in addition to the four we have just identified, that will result in a socially inefficient use of the environment?

Section summary

1. The environment benefits humans in three ways: as an amenity, as a source of primary products and as a dump for waste.
2. Given the increasing population pressures and the demands for economic growth, the pressures on the environment are likely to grow. These pressures can be lessened, however, with the use of cleaner technology, a more efficient use of natural resources and 'greener' behaviour of consumers, firms and governments.
3. The concept of an 'optimum' use of the environment depends on people's attitudes towards sustainability. These attitudes vary from regarding the environment simply as a resource for human use at the one extreme to seeing the environment as having moral rights at the other.
4. Under the social efficiency approach to sustainability, the optimum output of a good is where the marginal external environmental cost is equal to the marginal net benefit to users (assuming no other externalities).
5. The market fails to achieve a socially efficient use of the environment because large parts of the environment are a common resource, because production or consumption often generates environmental externalities, because of ignorance of the environmental effects of our actions, and because of a lack of concern for future generations.

13.2 POLICIES TO TACKLE POLLUTION AND ITS EFFECTS

Environmental policy can take many forms. However, it is useful to put the different types of policy into three broad categories: (a) those that attempt to work through the market by changing property rights or by changing market signals (e.g. through the use of charges, taxes or subsidies); (b) those that involve the use of laws, regulations and controls (e.g. legal limits on the volume of sulphur dioxide emissions); (c) those that attempt to combine the approaches (e.g. 'cap and trade'). The following sections will examine each of these three categories in more detail.

Market-based policies

The policies that a government adopts to reduce pollution will depend on its attitudes towards sustainability: on how 'green' it is.

If governments adopt a social efficiency approach to sustainability, environmental problems are seen to be the result of prices not reflecting marginal social costs and benefits. In this section, we look at ways in which markets can be adjusted so that they do achieve social efficiency.

Extending private property rights

If those suffering from pollution, or causing it, are granted property rights, then charges can be introduced for the right to pollute. According to the Coase theorem (see page 375), this would result in the socially efficient level of output being achieved.

We can use Figure 13.2 to illustrate the Coase theorem. If output is initially less than Q_3 , the marginal profit to the polluter will exceed the external costs the pollution imposes on the sufferers. In this case, if the sufferers impose a charge on

the polluter that is greater than the sufferers' marginal pollution cost but less than the polluter's marginal profit, both sides will benefit from more of the good being produced. Such a situation can continue up to Q_3 . Beyond Q_3 , the marginal pollution cost exceeds the marginal profit. There is no charge that would compensate for the victim's suffering and leave enough over for the polluter to make a profit. Equilibrium output is therefore at Q_3 , the socially efficient output.

Similarly, if the polluting *firm* is given the right to pollute, victims could offer a payment to persuade it not to pollute. The victims would be prepared to pay only up to the cost to them of the pollution. The firm would cut back production only provided the payment was at least as great as the loss in profit. This would be the case at levels of output above Q_3 . Once output falls below Q_3 , the maximum payment that the victim would be prepared to pay would be less than the minimum that the firm would be prepared to accept. Again, equilibrium would be at Q_3 .

Extending private property rights in this way is normally impractical whenever there are many polluters and many victims. But the principle of the victims paying polluters to reduce pollution is sometimes followed by governments. Thus, one element of the 2015 Paris Agreement on tackling climate change is for the developed countries to provide £66 billion of financial assistance to the developing countries to help them reduce greenhouse gas emissions (see Box 13.3 for more details).

In addition, there are sometimes direct environmental gains to be made from extending private property rights to individuals. In many developing countries, tenant farmers or squatters in urban slums have no incentive to invest in the land where they work or live. Give such people secure property rights, however, and they are more likely to take care of the property. For example, farmers are much more likely to plant trees if they know they have the right to the wood or fruit several years later.

Introducing charges for use of the environment

We previously discussed how the environment can be thought of as a common or natural resource where the user pays no price. For example, the emissions created by a coal burning power station can be spewed into the atmosphere at no cost to the firm even though it imposes costs on society. A firm could also use resources from the environment in its production process at a zero price. For example, it could extract water, cut down trees for timber or extract minerals out of the ground (assuming it owned or rented the land). With a zero price these resources will tend to be depleted at rate that is not optimal for society: i.e. too quickly.

To overcome these problems the government could introduce *environmental charges* for use of resources that would otherwise be free to the user. Thus *emissions charges* could be levied on firms discharging waste. Another example is the use of *user charges* to households for rubbish collection. If a social efficiency approach to sustainability is taken, the optimum level of environmental use would be where the

Figure 13.3 An emissions charge

marginal social benefits and costs of that use were equal. This is illustrated in Figure 13.3, which shows the emission of toxic waste into a river by a chemical plant.

It is assumed that all the benefits from emitting the waste into the river accrue to the firm (i.e. there are no external benefits). Marginal private and marginal social benefits are thus the same ($MB = MSB$). The curve slopes downwards because, with a downward-sloping demand for the good, higher output results in lower marginal benefit, and so too will the waste associated with it.

But what about the marginal costs? Without charges, the marginal private cost of using the river for emitting the waste is zero. The pollution of the river, however, imposes an external cost on those using it for fishing or water supply. The marginal external cost rises as the river becomes less and less able to cope with increased levels of emission. As there is no private cost, the marginal social cost is the same as the marginal external cost.

Without a charge, the firm will emit L_1 , since this is where its private marginal cost ($= 0$) equals its private marginal benefit. The socially efficient level of emission is L_2 and the socially efficient level of emission charge, therefore, is P_2 .

If these charges are to achieve a reduction in pollution, they must be a charge *per unit* of emissions or resource use (as in Figure 13.3). *Fixed total* charges, by contrast, such as water rates or council tax, will *not* encourage households to cut back on water use or reduce domestic refuse, since this will not save them any money: such charges have a *marginal*

Definitions

Environmental charges Charges for using natural resources (e.g. water or national parks), or for using the environment as a dump for waste (e.g. factory emissions or sewage).

rate of zero. If the firm in Figure 13.3 were charged a fixed total pollution fee, it would still choose to emit L_1 waste.

Environmental ('green') taxes and subsidies

Rather than charging for environmental use, a tax could be imposed on the output (or consumption) of a *good*, wherever external environmental costs are generated. Such taxes are known as *green taxes*. In this case, the good already has a market price but this price is below the marginal cost to society: the tax has the effect of increasing the price, thus pushing it closer to the MSC.

To achieve a socially efficient output, the rate of tax should be equal to the marginal external cost (i.e. distance $b-d$ in Figure 13.2 on page 396) and so make the price equal to MSC. As such, it should fully internalise the costs of the externality.

An alternative is to subsidise activities that reduce pollution (such as the installation of loft insulation). Here the rate of subsidy should be equal to the marginal external benefit.

Although green taxes and subsidies are theoretically a means of achieving social efficiency, they do have serious limitations (see Box 13.2).

Draw a diagram like Figure 13.2, only this time assume that the activity has the effect of reducing pollution, with the result that there are marginal external benefits. Identify the socially optimal level of the activity. What would be the level of subsidy required to achieve this level of activity?

Non-market-based policies

Command-and-control systems (laws and regulations)

One way of tackling pollution has been to set maximum permitted levels of emission or resource use, or minimum acceptable levels of environmental quality, and then to fine firms contravening these limits. Measures of this type are known as *command-and-control (CAC) systems*. Clearly, there have to be inspectors to monitor the amount of pollution, and the fines have to be large enough to deter firms from exceeding the limit.

Virtually all countries have environmental regulations of one sort or another. For example, the EU has over 230 items of legislation covering areas such as air and water pollution, noise, the marketing and use of dangerous chemicals, waste management, the environmental impacts of new projects (such as power stations, roads and quarries), recycling, depletion of the ozone layer and global warming.

Typically, there are three approaches to devising CAC systems.³

- **Technology-based standards.** The focus could be on the amount of pollution generated, irrespective of its environmental impact. As technology for reducing pollutants improves, so tougher standards could be imposed, based on the 'best available technology' (as long as the cost were not excessive). For example, the European Union

introduced a directive in 1992, called Euro 1, which set permitted levels of harmful emissions from new petrol and diesel cars in the European Economic Area for the following – Nitrogen Oxide (NO_x), Carbon Monoxide (CO), Hydrocarbons (HC) and Particulate Matter (PM). In September 2015, the sixth version of the directive, Euro 6, came into effect. For new diesel cars, it imposed the following restrictions – CO: 0.5g/km; NO_x: 0.08g/km; PM: 0.005g/km. Companies, such as Volkswagen, breaking these rules led to the so-called *dieselgate scandal*.

- **Ambient-based standards.** Here the focus is on the environmental impact. For example, standards could be set for air or water purity. Depending on the location and the number of polluters in that area, a given standard would be achieved with different levels of discharge. If the object is a cleaner environment, this approach is more efficient than technology-based standards.
- **Social-impact standards.** Here the focus is on the effect on people. Thus tougher standards would be imposed in densely populated areas. Whether this approach is more efficient than that of ambient-based standards depends on the approach to sustainability. If the objective is to achieve social efficiency, human-impact standards are preferable. If the objective is to protect the environment for its own sake (a deeper green approach), ambient standards would be preferable.

Assessing CAC systems. Given the uncertainty over the environmental impacts of pollutants, especially over the longer term, it is often better to play safe and set tough emissions or ambient standards. These could always be relaxed at a later stage if the effects turn out not to be so damaging, but it might be too late to reverse damage if the effects turn out

Definitions

Green tax A tax on output designed to charge for the adverse effects of production on the environment. The socially efficient level of a green tax is equal to the marginal environmental cost of production.

Command-and-control (CAC) systems The use of laws or regulations backed up by inspections and penalties (such as fines) for non-compliance.

Technology-based standards Pollution control that requires firms' emissions to reflect the levels that could be achieved from using the best available pollution control technology.

Ambient-based standards Pollution control that requires firms to meet minimum standards for the environment (e.g. air or water quality).

Social-impact standards Pollution control that focuses on the effects on people (e.g. on health or happiness).

³ See R. K. Turner, D. Pearce and I. Bateman, *Environmental Economics* (Harvester Wheatsheaf, 1994), p. 198.

BOX 13.2 GREEN TAXES

Are they the perfect answer to the problem of pollution?

Countries are increasingly making use of 'green' taxes to discourage pollution. The Office for National Statistics estimated that environmental taxes raised £45.974 billion of revenue for the UK government in 2015 (7.4 per cent of total taxes and national insurance) and that households paid an average of £761 in green taxes in 2013. The table shows some of the more important environmental taxes that have been used in the UK. Taxes on hydrocarbon oils (i.e. duty on petrol and diesel) are by far the most significant and account for nearly 60 per cent of total revenue from all environmental taxes.

Environmental tax revenue in the UK as a percentage of GDP has remained broadly stable over the past 20 years at between 2 to 3 per cent. The chart shows how the UK compares with other countries.

As can be seen, they are higher than average in Scandinavian countries, reflecting the strength of their environmental concerns. They are lowest in the USA.

There are various problems, however, with using taxes to tackle pollution.

Identifying the socially efficient tax rate. It will be difficult to identify the $MEC_{\text{pollution}}$ curve for each firm (see Figure 13.2), given that each one is likely to produce different amounts of pollutants for any given level of output. Even if two firms produce identical amounts of pollutants, the environmental damage might be quite different, because the ability of the environment to cope with it will differ between the two locations. Also, the human impact will vary. We can

Green tax revenues as a percentage of GDP

Source: Based on data in *Environmentally Related Taxes Database* (OECD, 2016).

to be more serious. Taxes may be a more sophisticated means of reaching a socially efficient output, but CAC methods are usually more straightforward to devise, easier to understand by firms and easier to implement.

Voluntary agreements

Rather than imposing laws and regulations, the government can seek to enter into voluntary agreements (VAs) with firms for them to cut pollution. For example, the UK government operates a system of climate change agreements (CCAs). These are voluntary agreements by firms to

reduce energy use and carbon dioxide (CO₂) emissions in return for a reduction in the Climate Change Levy (a tax on fuel bills).

VAs may involve a formal contract, and hence be legally binding, or they may be looser commitments by firms. VAs will be helped if (a) companies believe that this will improve their image with customers and hence improve sales; (b) there is an underlying threat by the government of introducing laws and regulations should voluntary agreements fail; (c) there are financial incentives (as with CCAs).

Environmental taxes and charges in the UK

Tax	Revenue £ millions (2015)
Tax on hydrocarbon oils (i.e. petrol and diesel)	27 415
Climate Change Levy	1 743
Renewables Obligations (energy)	3 691
Emissions Trading Scheme	552
CRC Energy Efficiency Scheme	535
Air Passenger Duty	3 119
Rail franchise premia	1 546
Vehicle Excise Duty	
Households	4 787
Businesses	1 112
Landfill Tax	1 083
Aggregates Levy	354
Other	37
Total	45 974

Source: *Environmental Taxes*, Table 1 (ONS, 5 July 2016).

add to these issues the fact that harmful effects are likely to build up over time, and predicting this is fraught with difficulty.

Problems of demand inelasticity The less elastic the demand for the product, the less effective will a tax be in cutting production and hence in cutting pollution. Thus taxes on petrol (where we know demand is inelastic) would have to be very high to make significant reductions in the exhaust gases that contribute towards global warming and acid rain.

Problems with international trade If a country imposes pollution taxes on its industries, its products will become less competitive in world trade. To compensate for this, it may be necessary to give the industries tax rebates for exports. Also, taxes would have to be imposed on imports of competitors'

products from countries where there is no equivalent green tax.

Effects on employment Reduced output in the industries affected by green taxes will lead to a reduction in employment. If, however, the effect was to encourage investment in new cleaner technology, employment might not fall. Furthermore, employment opportunities could be generated elsewhere, if the extra revenues from the green taxes were spent on alternative products (e.g. buses and trains rather than cars).

Redistributive effects Many green taxes are regressive. The poor spend a higher proportion of their income on domestic fuel than the rich. A 'carbon tax' on such fuel therefore has the effect of redistributing incomes away from the poor. The poor also spend a larger proportion of their income on food than the rich do. Taxes on agriculture, designed to reduce the intensive use of fertilisers and pesticides, also tend to hit the poor proportionately more than the rich.

Not all green taxes, however, are regressive. The rich spend a higher proportion of their income on motoring than the poor (see Figure 13.4 on page 409). Thus petrol and other motoring taxes could have a progressive effect.

Despite these problems, such taxes can still move output closer to the socially efficient level. What is more, they do have the major advantage of providing a continuing incentive to firms to find cleaner methods of production and thereby save more on their tax bills.

1. *Is it a good idea to use the revenues from green taxes to subsidise green alternatives (e.g. using petrol taxes for subsidising rail transport)? Consider the implications for wider tax policy in your answer.*
2. *If a green tax is highly regressive, does this mean that a government concerned with inequality should avoid implementing it? Consider the long-term impact of climate change on welfare, in your answer.*

Firms often prefer VAs to regulations, because they can negotiate such agreements to suit their own particular circumstances and build them into their planning. The result is that the firms may be able to meet environmental objectives at lower cost. This clearly helps their competitive position.

Education

People's attitudes are very important in determining the environmental consequences of their actions. Fortunately for the environment, people are not always out simply to

maximise their own narrow self-interest. They are sometimes willing to pay higher prices for 'green products' and keen to recycle products wherever possible. There is evidence that peoples' attitudes have changed markedly over the past few decades. Partly this is due to education and better environmental information.

Tradable permits

A policy measure that has grown in popularity in recent years is that of *tradable permits*, also known as a

'cap-and-trade' system. This is a combination of command-and-control and market-based systems.

Capping pollution

Initially, some criteria have to be set in order to determine which factories, power plants and installations will be covered by the scheme. Policy makers then have to set a limit or 'cap' on the total volume of pollution these organisations will be collectively allowed to produce before any financial penalties are incurred.

Once an aggregate cap has been set, pollution permits, known as allowances, are either issued or sold to the firms. Each allowance held by a firm gives it the right to produce a given volume of pollution. The total volume of all the allowances should be equal to the size of the aggregate cap set by the authorities. The quantity of allowances awarded in subsequent years to each firm is then reduced by a certain percentage – the cap is tightened – to give firms an incentive to invest in more environmentally friendly technology.

The number of permits allocated to an individual plant, factory or installation at the beginning of the scheme are often based on its current level of pollution. This approach is known as *grandfathering*. A major criticism of this method is that it seems unfair on those firms that have already invested in cleaner technology. Why should they be required to make the same reductions in the future as firms currently using older polluting technology? An increasing number of allowances are now auctioned – see Box 13.4.

All firms covered by the scheme must monitor and report the levels of pollution from their production. At the end of the year they must then submit enough allowances to the authorities to match the level of pollution they have caused. Each allowance can only be used once. If a firm fails to submit enough allowances then it is subject to heavy fines.

The EU ETS scheme. The biggest cap-and-trade system in the world is the European Union's Emissions Trading Scheme (EU ETS) – for more details see Box 13.4. It covers energy-intensive installations in four broad sectors that have emissions above certain threshold levels. The four sectors are energy (electricity, oil, coal), ferrous metals (iron, steel), minerals (cement, glass, ceramics) and wood pulp

(paper and card). The EU set a total cap on the aggregate CO₂ emissions produced by organisations in these sectors of 2039 152 882 tonnes for 2013. The cap has been set to decline by 1.74 per cent each year to 2020, so the figure for 2017 was 1 889 411 334 tonnes.

Trading under a cap-and-trade system

The 'trade' part of the scheme refers to the ability of firms to buy and sell allowances in a secondary market once they have been allocated by the authorities. However, in what circumstances would a firm wish either to buy or to sell an allowance?

Take the example of an organisation that estimates it will not have enough permits at the end of the year to match its forecast level of pollution. If it cannot reduce its pollution, say by installing new equipment, or if it is too costly to do so, then it can purchase extra permits.

In order to buy permits (allowances) in the secondary market there must be other firms that have excess permits and hence are willing to sell. These may be firms which have recently made large investments in a more energy-efficient production process.

The price that firms pay to buy, or receive from selling, the allowances in the secondary market will depend on the levels of demand and supply. These will be heavily influenced by the initial number of permits allocated by the authorities, the state of the economy and developments in technology.

The principle of tradable permits can be used as the basis of international agreements on pollution reduction – see Box 13.3 for more details.

Assessing the system of tradable permits

It is argued that one major advantage of the cap-and-trade system over most command-and-control methods is that it can reduce pollution at a much lower cost to society. This can be illustrated by using the following simple example.

Assume there are just two firms that each own one plant that pollutes the environment. Firm A and B's production processes currently result in 2000 tonnes of CO₂ being emitted into the atmosphere each year – 1000 tonnes by each firm. Decreasing emissions of CO₂ would cost firm A £100 per tonne, whereas it would cost firm B £200 per tonne.

Assume that the government wishes to reduce emissions from 2000 to 1600 tonnes. It could do this by setting an emissions cap on both firms of 800 tonnes of CO₂. Each would be given permits for that amount. Without the possibility of trading the permits, firm A would have to spend £20 000 to comply with the cap (200 tonnes × £100), while firm B would have to spend £40 000 (200 tonnes × £200). Thus the cost to society of reducing total emissions from 2000 to 1600 tonnes is £60 000.

With trading, however, the cost can be reduced below £60 000. If the two firms traded permits at a price somewhere between £100 and £200 per tonne, say £150, both could gain. Firm A would have an incentive to reduce its emissions

Definitions

Tradable permits Firms are issued or sold permits by the authorities that give them the right to produce a given level of pollution. Firms that do not have sufficient permits to match their pollution levels can purchase additional permits to cover the difference, while those that reduce their pollution levels can sell any surplus permits for a profit.

Grandfathering Where the number of emission permits allocated to a firm is based on its current levels of emission (e.g. permitted levels for all firms could be 80 per cent of their current levels).

to 600 tonnes, costing £40 000 ($400 \times £100$). It could then sell the unused permits (200 tonnes) to firm B for £30 000 ($200 \times £150$), which could then maintain emissions at 1000 tonnes. The net cost to firm A is now only £10 000 ($£40 000 - £30 000$), rather than the £20 000 from reducing its production to 800 without trade. The cost to Firm B is £30 000, rather than the £40 000 from reducing its production to 800.

Society will have achieved the same total reduction in pollution (i.e. from 2000 tonnes to 1600 tonnes) but at a much lower cost: i.e. £40 000 instead of £60 000. The smaller increase in costs means that price increases in the sector for consumers will be lower than they would otherwise have been.

One potential drawback of using tradable permits is that it could result in pollution being concentrated in certain geographic areas. Some other problems are discussed Box 13.3.

Comparison with CAC systems. In theory, the same outcome could be obtained in a CAC system if the policy makers knew the compliance costs of the different firms. In this case, an emission standard of 600 tonnes could be placed on firm A and a 1000 tonnes on firm B. However, this would require the authorities collecting enormous amounts of detailed information on plant-specific costs in order to calculate the appropriate emissions standard for each business. The cap-and-trade system allows policy makers to achieve the same outcome without the need to collect such large amounts of detailed information.

Comparison with green taxes/charges. An interesting comparison can also be made between tradable permits and green taxes or charges. With the cap-and-trade scheme, the authorities determine the quantity of pollution, while the market determines the price. With a green tax, the authorities determine the price of pollution, while the market determines the quantity. In certain circumstances, green taxes and tradable permits will produce the same outcome.

What determines the size of the administrative costs of a system of tradable permits? For what reasons might green taxes be cheaper to administer than a system of tradable permits?

How much can we rely on governments?

If governments are to be relied upon to set the optimum green taxes or regulations, several conditions must be met.

First, they must have the will to protect the environment. But governments are accountable to their electorates and must often appease various pressure groups, such as representatives of big business. In the USA, for example, there has been great resistance to cuts in greenhouse gases from the automobile, power and various other industries, many of which have powerful representation in Congress. So there must be the political will in a country if significant environmental improvements are to be made. One of the problems

here is that many of the environmental effects of our actions today will be on future generations; but governments are elected by today's generation, and today's generation may not be prepared to make the necessary sacrifices. This brings us back to the importance of education.

Second, it must be possible to identify just what the optimum is. This requires a clear set of objectives concerning sustainability and any conflicts between human and ecological objectives. It also requires a knowledge of just what are the environmental effects of various activities, such as the emission of CO₂ into the atmosphere, and that is something on which scientists disagree.

Finally, there is the problem that many environmental issues are global and not just local or national. Many require concerted action by governments around the world. The history of international agreements on environmental issues, however, is one plagued with difficulties between countries, which seem more concerned with their own national interests. To understand the difficulties of reaching international agreements, we can draw on game theory (see section 8.3).

Game theory and international agreements

Assume that the world would benefit from a reduction in greenhouse gases and that these benefits would exceed the costs of having to cut back on activities (such as motoring or the generation of electricity) that release such gases into the atmosphere. What would be in the interests of an *individual* country, such as the USA? Its optimum solution would be for *other* countries to cut their emissions, while maintaining its own levels. This approach would yield most of the benefits to the USA and none of the costs. However, when *all* countries refuse to cut emissions, no one gains! This is an example of the *prisoners' dilemma* (see Box 8.5, page 237), and is illustrated in Table 13.1.

Table 13.1 Outcomes for countries from strategies of pollution reduction

		Other countries' strategy		
		All cut pollution	Some cut pollution	None cut pollution
USA's strategy	Cut pollution	A Moderate net gain for all	B Small loss for USA; gain for countries not cutting pollution	C Large loss for USA; slight gain for other countries
	Don't cut pollution	D High gain for USA; small gain for other countries	E Fairly high gain for USA; loss for other countries	F No gain for any country

BOX 13.3 INTERNATIONAL CO-ORDINATION ON CLIMATE CHANGE

From the Kyoto Protocol to the Paris Agreement

In 1992, governments from around the world met at Rio de Janeiro and established the United Nations Framework Convention on Climate Change (UNFCCC). The aim of the UNFCCC is to limit the concentration of greenhouse gas in the atmosphere to avoid climate change. Representatives from the countries involved in the UNFCCC have met annually since 2005. These meetings are known as 'Conferences of the Parties of UNFCCC' or more simply 'COP'.

The third meeting, COP3, took place in Kyoto in Japan in 1997, where a draft accord was agreed to reduce greenhouse gas emissions by 5.2 per cent (based on 1990 levels) by the year 2012.

To become a legally binding treaty, the Kyoto Protocol had to be signed and ratified by nations accounting for at least 55 per cent of greenhouse gas emissions. In March 2001, the US government announced that it would not ratify the accord so the 55 per cent target was not met until the Russian parliament voted to sign the agreement in October 2004.

The treaty finally came into force on 16 February 2005 and was ratified by 192 parties in total. Of these, 39 Annex 1 countries (those that are developed or 'in transition') agreed to specific emissions reductions. For example, the UK had a 12.5 per cent reduction target for 2012.

Market-based systems

Although not originally envisaged in this way, the agreement turned climate change into a market, where the right to pollute can be bought and sold through a system of emissions credits. These credits can be earned by reducing emission levels below those agreed or by creating conditions that help to minimise the impact of greenhouse gases on global warming: for example, by planting forests (which absorb carbon).

Within the Kyoto Protocol there are three distinct market-based mechanisms:

- Emissions trading;
- Joint implementation (JI);
- Clean Development Mechanism (CDM).

Emissions trading. The countries that ratified the Kyoto Protocol are allowed to trade amongst themselves rights to emit six greenhouse gases. If a country reduces emissions below its agreed limit, it can sell the additional reduction as a credit. If a country is finding it difficult to cut emissions, it

can buy these credits within a type of marketplace. (Box 13.4 explains how CO₂ emissions trading began within the EU in January 2005.)

Joint implementation. Under Article 6 of the protocol, an industrialised country can earn credits by investing in projects that reduce emissions in other industrialised countries (primarily former Soviet countries). These credits, in this case called 'emission reduction units' (ERUs), then reduce the country's own requirement to cut emissions.

Clean Development Mechanism. This is similar to the joint implementation process above, but involves a country or company from the industrialised world earning credits, in this case called 'certified emissions reductions' (CERs), by investing in emissions reduction schemes in *developing* countries. For example, a typical CDM or JI project might involve installing solar panels, planting forests, or investing in a factory producing energy-efficient light bulbs.

Assessing the Kyoto Protocol

The Kyoto Protocol was criticised on a number of grounds. For example:

- Many commentators argued that the 5.2 per cent target was too low. The Intergovernmental Panel on Climate Change estimated that a 60 to 80 per cent cut in greenhouse gas emissions from 1990 levels is required to avert serious climate disruption.
- Some of the reduction in emissions that did take place would have happened anyway. For example, Russia had CO₂ emissions considerably below its 1990 level and so had a large number of emission credits for sale. However, this was not the result of Russian environmental policy, but rather the consequence of the collapse of much of Russian industry in the early 1990s and the replacing of dirty inefficient factories with more profitable cleaner ones.
- Only a relatively small number of developed countries agreed to set emission targets at a national level. Developing countries such as China, India, Brazil and Mexico were under no obligation to reduce emissions, although they did have to monitor and report the levels. Rapid economic growth in these countries over the past 20 years means that they are responsible for an increasing

Assume that there is an international agreement (as at the Kyoto summit in December 1997) to cut emissions. If all countries stick to the agreement, the outcome is cell A: a moderate gain to all. What should Congress do? Whatever other countries do (all stick to the agreement, some stick to it, none stick to it), it will be in the USA's interests *not* to stick to it: this is the dominant strategy. Cell D is preferable to Cell A; E is

preferable to B; F is preferable to C. But when *all* countries reason like this, the world ends up in Cell F, with no cut in pollution. Cell F is worse for all countries than Cell A.

Only if countries believe that the other countries will (a) ratify the agreement and (b) stick to it once it is ratified will the agreement be likely to succeed. This requires trust on all sides as well as the ability to monitor the outcomes.

share of global emissions. It is estimated that China and India alone are now responsible for a third of global carbon discharges.

- The USA government, under the George W. Bush presidency, significantly weakened the effectiveness of the treaty by opting out of the protocol. It introduced its own Clear Skies and Global Climate Change Initiatives in February 2002. This provided tax incentives to encourage renewable energy schemes and fuel efficiency schemes, but businesses were not obliged to meet any CO₂ targets.

From Kyoto to Paris

In December 2007, COP13 took place in Bali. As the provisions of the Kyoto agreement ended in 2012, delegates agreed on a new roadmap to make much deeper cuts in emissions. It was hoped that a final accord would be reached in December 2009 at COP15 in Copenhagen. After a fortnight of wrangling between leaders, however, all that resulted was a non-binding 'accord'. This merely recognised the need for keeping global temperature rises to a maximum of 2°C without any specific commitments to achieving that goal.

In December 2010, a modest agreement was accomplished, following a two-week summit held in Cancún in Mexico (COP16). This included the establishment of a 'Green Climate Fund' by rich nations to help poor countries finance climate change investments.

In 2011, Canada became the first country to announce its withdrawal from the Kyoto Accord. It argued that Kyoto was not effective as neither China nor the USA were part of the Accord and several countries outside the EU were falling well short of their Kyoto targets. Japan and Russia announced that they would not adopt any further Kyoto targets in the post-2012 period.

An extension to the Kyoto Protocol to run from 2012 to 2020 was agreed in Doha, Qatar in December 2012 (COP18); only 37 parties (predominately European countries and Australia) had binding targets.

In December 2015, COP21 took place in Paris. After two weeks of intense haggling, the Paris Climate Accord was agreed. This was the first new global climate deal in 18 years.

All parties agreed to the following:

- All countries need to take action to reduce emissions so that global temperatures rise by less than 2°C above their

pre-industrial levels. Further efforts should be made to limit this increase to 1.5°C.

- A recognition that the pledges made by all countries before the conference would only limit the increase in global temperatures to 2.7°C in the best-case scenario.
- Actions need to be taken so that at some point between 2050 and 2100 global emissions are equal to the amount that can be absorbed by natural sinks (i.e. trees, soil, etc.) and carbon-capturing technology.
- By 2020, £66 billion should be raised by richer developed countries to assist poorer developing countries with the cost of switching to renewable energy.

None of these objectives are legally binding. They are aspirational goals rather than commitments. However, unlike the Kyoto Protocol, all the signatories, rather than just the richer nations, have made one important legal obligation.

Each country is now committed to produce and submit a climate change plan for public scrutiny every five years. Common standards of reporting are being introduced so it becomes much easier for the world to scrutinise the actions of each individual country. In particular, it will become far easier to observe (a) how much pollution a country produces; (b) what policies it is using or plans to introduce to reduce its emissions; (c) how well these policies are working.

On 5 October 2016 the threshold for the implementation of the agreement was reached as 55 parties responsible for 55 per cent of total global greenhouse emissions had ratified the treaty. The agreement officially came into force on 4 November 2016. But Donald Trump announced in early 2017 that the USA was pulling out of the agreement. However, he later indicated that he might possibly reverse the decision.

During the past 25 years of intergovernmental climate change conferences, global emissions have continued to rise. It will be interesting to see if the avoidance of 'global shame' proves to be a more effective incentive than any financial penalties.

Explain who are likely to be the 'winners' and 'losers' as a result of talks on carbon dioxide emissions. Use the concepts of game theory to illustrate your argument.

The other major problem area concerns equity. Most countries will feel that they are being asked to do too much and that others are being asked to do too little. Developed countries will want to adopt a grandfathering approach. The starting point with this approach would be current levels of pollution. Every country would then be required to make the same percentage cut. Developing countries, on the other hand, will want the bulk of the cuts, if not all of them, to be

made by the developed countries. After all, the rich countries produce much higher levels of pollutants per capita than do the poor countries, and curbing growth in developing countries would have a far more serious impact on levels of absolute poverty.

How does an international negotiation 'game' differ from the prisoners' dilemma game?

BOX 13.4 TRADING OUR WAY OUT OF CLIMATE CHANGE**The EU carbon trading system**

The EU introduced a carbon Emissions Trading Scheme (EU ETS) in January 2005 as its principal policy to meet environmental targets set by the international treaty, the Kyoto Protocol (which entered into force in February 2005) (see Box 13.3). Article 17 of this treaty supported the use of emissions trading and a similar scheme in the USA had already reduced emissions of both sulphur dioxide and nitrous oxide. The EU ETS created a market in carbon permits or allowances. Its ultimate objective is to give companies greater financial incentives to reduce their emissions of CO₂.

Phases I and II

The first phase of the scheme ran from January 2005 until December 2007. Around 12 000 industrial plants across 27 countries were allocated approximately 2.2 billion CO₂ permits, called Emission Unit Allowances (EUAs). Each EUA issued to a firm gives it the right to emit one tonne of carbon dioxide into the atmosphere. The factories covered by the scheme were collectively responsible for around 40 per cent of the EU's CO₂ emissions each year.

Companies that do not have enough EUAs to match their annual emissions can purchase additional EUAs to cover the difference, while those that reduce their emissions are able to sell any surplus EUAs for a profit. Companies are able to trade directly with each other or via brokers operating throughout Europe.

At the end of December 2007 all existing allowances became invalid and the second Trading Period began, to last until the end of 2012. Although this was run under the same general principles as Trading Period 1, it also allowed companies to use 'Joint Implementation' and 'Clean Development Mechanism' credits earned under the Kyoto Protocol's project-based mechanisms (see Box 13.3). In other words, companies could offset emissions in the EU against emission reductions they achieve in countries outside the EU.

Phase III

Phase III of the EU ETS came into operation on 1 January 2013. It built on the experience gained from operating Phases I and II of the system and included two significant changes.

Move to an EU-wide cap. The cap on total emissions in both Phases I and II of the system were set in a decentralised manner. Each member state had to develop a National Allocation Plan (NAP). The NAP set out the total cap on emissions for that country, the total quantity of EUAs that

would be issued and how they would be assigned to each industrial plant or factory. Each NAP had to be approved by the European Commission before it could be implemented. The numerous NAPs have been replaced in Phase III of the EU ETS by a single EU-wide cap on the volume of emissions and on the total number of EUAs to be issued. The size of this EU-wide cap is to be reduced by 1.74 per cent per year so that permitted emissions in 2020 are 21 per cent lower than 2005.

Move to auctioning permits. In Phase I and II of the EU ETS the majority of EUAs were freely allocated to the plants and factories covered by the scheme. The grandfathering method (see page 402) was used to determine the number of EUAs each factory would receive: i.e. it was based on their current emissions. The European Commission allowed member states to auction up to a maximum of 5 per cent of the EUAs in Phase I and 10 per cent in Phase II. However, this option was seldom chosen.

In Phase III a big increase is planned in the proportion of EUAs that are auctioned. Since 2013 most of the firms in the power sector have already had to purchase all of their allowances by auction. The average in other sectors is planned to increase from 20 per cent in 2013 to 70 per cent by 2020. Only firms in manufacturing and the power industry in certain member states will continue to be allocated the majority of their allowances at no charge.

It has also been recommended by the EU that half of the revenue generated from the auctions should be used to fund measures to reduce greenhouse gas emissions.

In December 2009, the EU also agreed to a '20-20-20' package to tackle climate change. This would involve cutting greenhouse gases by 20 per cent by 2020 compared with 1990 levels, raising the use of renewable energy sources to 20 per cent of total energy usage and cutting energy consumption by 20 per cent.

Much of the emissions reductions would be achieved by tighter caps under the ETS, with binding national targets for non-ETS sectors, such as agriculture, transport, buildings and services. However, over half of the reductions could be achieved by international carbon trading, where permits could be bought from abroad: e.g. under the Clean Development Mechanism.

Assessing the ETS

The introduction of the world's largest market-based policy to address climate change was welcomed by many economists

and policy makers. However, others have raised concerns about both the operation of the scheme and its likely impact on overall emissions.

The size of the cap. What matters crucially for the impact of the scheme is the total number of permits issued by the authorities: i.e. the size of the overall cap. If the supply of the permits is high in the secondary market then the price will be relatively low and firms will lack the necessary incentives to invest in new energy-efficient technology.

Some people have argued that the number of EUAs issued in the past has been far too generous. One reason for this may have been the decentralised manner in which the EUAs were allocated through the NAPs. This gave some countries a strong incentive to game the system by setting an aggregate cap in its NAP that was greater than the volume of emissions actually being produced. By doing this, costs could be kept down for firms operating in that country, which would help to maintain its national economic competitiveness.

Another reason why the number of EUAs may have been too great is because of successful lobbying of governments by firms. In particular, they may have exaggerated claims about the potential negative impact of issuing fewer EUAs on their costs and future competitiveness.

This over-allocation of EUAs clearly seems to have been a problem in Phase I of the scheme. Emission levels across the EU actually rose by 1.9 per cent while the price of EUAs fell from a peak of €30 to just €0.02.

The scrutiny of NAPs by the EU became more rigorous in Phase II of the scheme and the cap on emissions was tightened by 7 per cent. However, there were still big variations between countries, and it appears that the Commission still had limited capacity to check the accuracy of each NAP. Phase III of the system seems to have addressed some of these issues with the removal of the NAPs and the introduction of a single EU-wide cap.

Move from free allocation of permits to auctions. Another major issue with Phases I and II of the scheme was that the majority of EUAs were freely allocated to plants and factories. It was argued by many policy makers that this was important because firms needed time to adjust gradually to a system where they would have to start paying for the pollution they generated. Some people were particularly concerned that selling the permits for a positive price would have large

adverse effects on some firms' costs. This might make it increasingly difficult for them to compete with companies outside the EU. However, after the system was introduced, there were accusations that firms in the power sector had simply used the free allocation of permits to make 'windfall profits'.

The increasing use of auctioning in Phase III of the scheme has been adopted to address this issue. It is also assumed that, after eight years of experience with permits, firms will be better able to adapt to having to buy EUAs.

Transport emissions

From 2012, the EU ETS scheme was also extended to aircraft emissions. Originally the scheme was supposed to cover emissions from all flights either arriving or departing from airports in the EU. Following a huge outcry from the aviation industry, the scheme was temporarily amended so that it would only include flights whose arrival and departure were both at EU airports. This was known as 'Stop the Clock' and an initial cap was set at 86 million tonnes of CO₂.

Plans to bring shipping emissions within the scheme have been delayed. Shipping is a large and growing source of emissions. As a first step towards cutting these, the European Commission has proposed that owners of large ships using EU ports should report their verified emissions from 2018.

Similarly, road transport, responsible for around 20 per cent of all emissions, remains outside the scheme.

Overall, it is still difficult to assess the impact of the EU ETS, even though it has been in operation for over 12 years. Disaggregating the effect of emission allowances from the effects of other economic factors and policy changes is enormously complicated.

The excess supply of allowances remains an issue. The EU has tried to address this problem by introducing *backloading*. This involves withholding allowances from the auction process – 400 million in 2014, 300 million in 2015 and 200 million in 2016. Managing any future supply–demand imbalances will continue to be a major priority for EU policy makers.

Consider a situation where all firms are of identical size and each is allocated credits that allows it to produce 10 per cent less than its current emissions. How would this compare with a situation where permits are allocated to 90 per cent of firms only? Consider both efficiency and equity in your answer.

Section summary

1. One approach to protecting the environment is to use the market. This can be done by extending private property rights. In many cases, however, this approach is impractical. Another approach is to impose charges for using the environment or taxes per unit of output. The problem with these methods is in identifying the appropriate charges or tax rates, since these will vary according to the environmental impact.
 2. Another approach is to use command-and-control systems, such as making certain practices illegal or putting limits on discharges. This is a less sophisticated alternative to taxes or charges, but it is safer when the environmental costs of certain actions are unknown. Other alternatives to market-based approaches include voluntary agreements and education.
 3. Tradable permits are a mix of command-and-control and market-based systems. Firms are given permits to emit a certain level of pollution and then these can be traded.
- A firm that can relatively cheaply reduce its pollution below its permitted level can sell this credit to another firm that finds it more costly to do so. The system is an efficient and administratively cheap way of limiting pollution to a designated level. It can, however, lead to pollution being concentrated in certain areas and can reduce the pressure on firms to find cleaner methods of production.
4. Although governments can make a major contribution to reducing pollution, government action is unlikely to lead to the perfect outcome (however defined). Governments may be more concerned with short-run political considerations and will not have perfect information. What is more, given that many environmental effects spill over national borders, governments may 'play games' internationally to try to reduce the costs to their country of any international action to protect the environment.

13.3 THE ECONOMICS OF TRAFFIC CONGESTION

Traffic congestion is a problem faced by many countries, especially in large cities and at certain peak times. This problem has grown at an alarming rate as people have become increasingly reliant on their cars. Vehicles stuck in traffic jams impose huge costs on countries.

It is not only the motorist that suffers. Congested streets make life less pleasant for the pedestrian, and increased traffic leads to increased accidents and significant problems of pollution.

Between 1960 and 2015 road traffic in Great Britain rose by 338 per cent, whereas the length of public roads rose by only 26 per cent (albeit some roads were widened). Most passenger and freight transport travels by road. In 2015, 89 per cent of passenger kilometres (see Table 13.2) and 76 per cent of freight tonnage kilometres in Great Britain were by

road, whereas rail accounted for just under 10 per cent of passenger traffic and 9 per cent of freight tonnage. The total percentage of passenger kilometres by road peaked at 94 per cent in the mid-1990s before falling to its current figure.

Average weekly household expenditure on transport in the financial year 2015/16 was £72.70, equating to 14 per cent of total expenditure. The vast majority of this was on motoring costs, with only £4.10 and £1.30 spent per week on train and bus/coach travel respectively.

Should the government do anything about the problem? Is traffic congestion a price worth paying for the benefits we gain from using cars? Are there things that can be done to ease the problem without generally inconveniencing the traveller?

Table 13.2 Passenger transport in Great Britain: percentage of passenger kilometres

Year	Cars, vans and taxis	Motor cycles	Buses and coaches	Bicycles	Rail	Air (UK)
1952	26.6	3.2	42.2	10.5	17.4	0.1
1962	56.5	3.3	24.5	3.1	13.2	0.4
1972	75.9	0.9	13.9	0.9	7.9	0.5
1982	80.5	2.0	9.5	1.3	6.1	0.6
1992	86.0	0.7	6.3	0.7	5.6	0.7
2002	85.5	0.7	6.0	0.6	6.2	1.1
2015	82.9	0.6	5.0	0.7	9.8	1.1

We will look later in this section at various schemes and at their relative costs and benefits. But first it is necessary to examine the existing system of allocating road space to see the extent to which it meets or fails to meet society's transport objectives.

The existing system of allocating road space

The allocation of road space depends on both demand and supply. Demand is by individuals who base their decisions on largely private considerations. Supply, by contrast, is usually by central government or local authorities. Let us examine each in turn.

Demand for road space (by car users)

The demand for road space can be seen largely as a *derived* demand. What people want is not the car journey for its own sake, but to get to their destination. The greater the benefit they gain at their destination, the greater the benefit they gain from using their car to get there.

The demand for road space, like the demand for other goods and services, has a number of determinants. If congestion is to be reduced, it is important to know how responsive demand is to a change in any of these: it is important to consider the various elasticities of demand.

Price. This is the *marginal cost* to the motorist of a journey. It includes petrol, oil, maintenance, depreciation and any toll charges.

Are there any costs associated with motoring that would not be included as marginal costs? Explain why.

The price elasticity of demand for motoring tends to be relatively low. There can be a substantial rise in the price of petrol, for example, and there will be only a modest fall in traffic.

Estimates of the short-run price elasticity of demand for road fuel in industrialised countries typically range from -0.1 to -0.5 . Long-run elasticities are somewhat higher, but are still generally inelastic.⁴

The low price elasticity of demand suggests that schemes to tackle traffic congestion that merely involve raising the costs of motoring will have only limited success.

In addition to monetary costs, there are also the time costs of travel. The opportunity cost of sitting in your car is the next best alternative activity you could have been pursuing – relaxing, working, sleeping or whatever. Congestion, by increasing the duration of the journey, increases the opportunity cost.

Income. As incomes rise, car ownership and usage increase substantially. Demand for road space is elastic with respect to income.

Figure 13.4 shows motoring costs as a percentage of UK household expenditure by quintile groups of household income. The higher the household income, the higher the percentage of income spent on motoring. Indeed, the richest quintile's expenditure on motoring is double that of the poorest as a percentage of household expenditure. Clearly, the income elasticity of demand is significantly greater than 1.

This is also reflected in international statistics of car ownership. Figure 13.5 shows the growth of car ownership between 1980 and 2014 in selected European countries. As national incomes have risen, so has the proportion of car

⁴ See: *Road Traffic Demand Elasticities* (Department for Transport, 2015).

Figure 13.4 Motoring costs as % of UK household expenditure: 2015/16

Source: Based on data in Table 3.2 in *Family Spending Reference Tables, 2016* (National Statistics, February 2017).

ownership. People see car transport as a 'luxury good' compared with alternatives such as public transport, walking or cycling. Also, the growth of suburbs has meant that many people travel longer distances to work.

The implication of this is that, if countries continue to experience economic growth, car ownership and usage are likely to increase substantially: a conclusion in line with most forecasts.

Price of substitutes. If bus and train fares came down, people might switch from travelling by car. The cross-price elasticity, however, is likely to be relatively low, given that most people regard these alternatives as a poor substitute for travelling in their own car. Cars are seen as more comfortable and convenient.

The 'price' of substitutes also includes the time taken to travel by these alternatives. The quicker a train journey is compared with a car journey, the lower will be its time cost to the traveller and thus the more people will switch from car to rail.

Price of complements. Demand for road space will depend on the price of cars. The higher the price of cars, the fewer people will own cars and thus the fewer cars there will be on the road.

? *Is the cross-price elasticity of demand for road space with respect to the price of cars likely to be high or low?*

Demand will also depend on the price of complementary services, such as parking. A rise in car parking charges will reduce the demand for car journeys. But here again the cross elasticity is likely to be relatively low. In most cases, the

motorist will either pay the higher charge or park elsewhere, such as in side streets.

? *Go through each of the determinants we have identified so far and show how the respective elasticity of demand makes the problem of traffic congestion difficult to tackle.*

Tastes/utility. Another factor explaining the preference of many people for travelling by car is the pleasure they gain from it compared with alternative modes of transport. Car ownership is regarded by many people as highly desirable, and once accustomed to travelling in their own car most people are highly reluctant to give it up.

One important feature of the demand for road space is that it fluctuates. There will be periods of peak demand, such as during the rush hour or at holiday weekends. At such times, roads can get totally jammed. At other times, however, the same roads may be virtually empty.

Supply of road space

The supply of road space can be examined in two contexts: the short run and the long run.

The short run. In the short run, as we have seen, the supply of road space is constant. When there is no congestion, supply is more than enough to satisfy demand. There is spare road capacity. At times of congestion, there is pressure on this fixed supply. Maximum supply for any given road is reached at the point where there is the maximum flow of vehicles per minute along the road.

The long run. In the long run, the authorities can build new roads or improve existing ones. This will require an assessment of the costs and benefits of such schemes.

Figure 13.5 Increase in car ownership in various European countries

Source: Based on data in Eurostat (tsdpc340).

Identifying a socially efficient level of road usage (short run)

The existing system of *government* provision of roads and *private* ownership of cars is unlikely to lead to an optimum allocation of road space. So how do we set about identifying just what the social optimum is?

In the short run, the supply of road space is fixed. The question of the short-run optimum allocation of road space, therefore, is one of the optimum *usage* of existing road space. It is a question of *consumption* rather than supply. For this reason we must focus on the road user, rather than on road provision.

A socially efficient level of consumption occurs where the marginal social benefit of consumption equals its marginal social cost ($MSB = MSC$). So what are the marginal social benefits and costs of using a car?

Marginal social benefit of road usage

Marginal social benefit equals marginal private benefit plus externalities. Marginal private benefit is the direct benefit to the car user and is reflected in the demand for car journeys, the determinants of which we examined above. External benefits are few. The one major exception occurs when drivers give lifts to other people.

Marginal social cost of road usage

Marginal social cost equals marginal private cost plus externalities. Marginal private costs to the motorist include the costs of petrol, wear and tear, tolls, etc. They also include the time costs of travel. There may also be substantial external costs. These include the following.

Congestion costs: time. When a person uses a car on a congested road, it will add to the congestion. This will therefore slow down the traffic even more and increase the journey time of other car users.

This is illustrated in Table 13.3 (which uses imaginary figures).

Column (1) shows the number of cars travelling along a given road per minute. Column (2) shows the time taken for each car and thus can be seen as the marginal time cost to a motorist of making this journey. It is thus the *private* marginal time cost. With up to three cars per minute there is no congestion and therefore the traffic flows freely, each car taking 5 minutes to complete the journey. As traffic increases beyond this, however, the road becomes progressively more congested, and thus journey times increase. It is not just the additional cars that are forced to travel more slowly, but *all* the cars on the road. The extra cars thus impose a congestion cost on existing users of the road. By the time seven cars per minute are entering the road, journey time has increased to 16 minutes.

Column (3) shows the sum of the journey times of all the motorists on the road. For example, with six cars on the road, each taking 11 minutes, total journey time for all six is 66 minutes. Column (4) shows the increase in total journey time as one more car enters the road. Thus when the seventh car enters the road, total journey time increases from 66 to 112 minutes: an increase of 46 minutes. This is the additional cost to *all* road users: in other words, the marginal *social* cost. But of these 46 minutes, 16 are the private marginal costs incurred by the extra motorist. Only the remaining 30 minutes are *external* costs imposed on other road users. These external costs are shown in column (5).

 Complete Table 13.3 up to 9 cars per minute, assuming that the journey time increases to 24 minutes for the eighth car and 35 minutes for the ninth car.

Time costs can be converted into money costs if we know the value of people's time. If time were valued at 10p per minute, the congestion costs (external costs) imposed by the seventh car would be £3 (i.e. 30 minutes \times 10p per minute). Case Study 13.4 on the student website examines the method used in the UK for estimating the value of time (in the context of evaluating new road schemes).

Table 13.3 Time taken to travel between two points along a given road

Traffic density (cars entering road per minute)	Journey time per car (marginal private time cost: in minutes)	Total journey time for all cars (total time cost: in minutes)	Extra total journey time as traffic increases by one more car (marginal social time cost: in minutes)	Additional time cost imposed on other road users by one more car (marginal external time cost: in minutes)
(1)	(2)	(3) = (1) \times (2)	(4) = Δ (3)	(5) = (4) - (2)
1	5	5	5	0
2	5	10	5	0
3	5	15	5	0
4	6	24	9	3
5	8	40	16	8
6	11	66	26	15
7	16	112	46	30

Congestion costs: monetary. Congestion increases fuel consumption, and the stopping and starting increases the costs of wear and tear. When a motorist adds to congestion, therefore, there will be additional monetary costs imposed on other motorists. A table similar to Table 13.3 could be drawn to illustrate this.

Environmental costs. When motorists use a road, they reduce the quality of the environment for others. Cars emit fumes and create noise. This is bad enough for pedestrians and other car users, but can be particularly distressing for people living along the road. Driving can cause accidents, a problem that increases as drivers become more impatient as a result of delays. Also, as we saw in section 13.1, exhaust gases contribute to global warming and acid rain.

The socially efficient level of road usage

The point where the marginal social benefit of car use is equal to the marginal social cost can be illustrated on a diagram. In Figure 13.6, costs and benefits are shown on the vertical axis and are measured in money terms. Thus any non-monetary costs or benefits (such as time costs) must be given a monetary value. The horizontal axis measures road usage in terms of cars per minute passing a specified point on the road.

For simplicity it is assumed that there are no external benefits from car use and that therefore marginal private and marginal social benefits are the same. The *MSB* curve is shown as downward sloping. The reason for this is that

different road users put a different value on this particular journey. If the marginal (private) cost of making the journey were high, only those for whom the journey had a high marginal benefit would travel along the road. If the marginal cost of making the journey fell, more people would make the journey: people choosing to make the journey at the point at which the marginal cost of using their car had fallen to the level of their marginal benefit. Thus the greater the number of cars in any given time period, the lower the marginal benefit.

The marginal (private) cost curve (*MC*) is likely to be constant up to the level of traffic flow at which congestion begins to occur. This is shown as point *a* in Figure 13.6. Beyond this point, marginal cost is likely to rise as time costs increase and as fuel consumption rises.

The marginal *social* cost curve (*MSC*) is drawn above the marginal private cost curve. The vertical difference between the two represents the external costs. Up to point *b*, external costs are simply the environmental costs. Beyond point *b*, there are also external congestion costs, since additional road users slow down the journey of *other* road users. These external costs get progressively greater as the volume of traffic increases (as column (5) of Table 13.3 illustrated).

The actual level of traffic flow will be at Q_1 , where marginal private costs and benefits are equal (point *e*). The socially efficient level of traffic flow, however, will be at the lower level of Q_2 , where marginal social costs and benefits are equal (point *d*). In other words, the existing system of allocating road space is likely to lead to an excessive level of road usage.

Figure 13.6 Actual and optimum road usage

Identifying a socially optimum level of road space (long run)

In the long run, the supply of road space is not fixed. The authorities must therefore assess what new road schemes (if any) to adopt. This will involve the use of some form of *cost-benefit analysis* (see section 12.4).

The socially efficient level of construction will be where the marginal social benefit from construction is equal to the marginal social cost. This means that schemes should be adopted as long as their marginal social benefit exceeds their marginal social cost.

But how are these costs and benefits assessed in practice? Case Study 13.4 on the student website examines the procedure used in the UK.

Section summary

1. Increased car ownership and car usage have led to a growing problem of traffic congestion.
2. The allocation of road space depends on demand and supply. Demand depends on the price to motorists of using their cars, incomes, the cost of alternative means of transport, the price of cars and complementary services (such as parking), and the comfort and convenience of car transport. The price and cross-price elasticities of demand for car usage tend to be low: many people are unwilling to switch to alternative modes of transport. The income elasticity, on the other hand, is high. The demand for cars and car usage grows rapidly as incomes grow.
3. The short-run supply of road space is fixed. The long-run supply depends on government road construction programmes.
4. The existing system of government provision of roads and private ownership of cars is unlikely to lead to the optimum allocation of road space.
5. In the short run, with road space fixed, allocation depends on the private decisions of motorists. The problem is that motorists create two types of external cost: pollution costs and congestion costs. Thus $MSC > MC$. Because of these externalities, the actual use of road space (where $MB = MC$) is likely to be greater than the optimum (where $MSB = MSC$).
6. In the long run, the socially efficient amount of road space will be where $LRMSB = LRMSC$. New road schemes should be adopted as long as their $LRMSB > LRMSC$. Governments must therefore conduct some form of cost-benefit analysis in order to estimate these costs and benefits.

13.4 URBAN TRANSPORT POLICIES

We now turn to look at different solutions to traffic congestion. These can be grouped into three broad types: direct provision, regulation and legislation, and changing market signals.

Direct provision (supply-side solutions)

The road solution

One obvious solution to traffic congestion is to build more roads. There are, however, serious problems with this approach.

The objective of equity. The first problem concerns *equity*. After all, social efficiency is not the only possible economic objective. For example, when an urban motorway is built, those living beside it will suffer from noise and fumes. Motorway users gain, but the local residents lose. The question is whether this is fair.

The more the government tries to appeal to the car user by building more and better roads, the fewer will be the people who use public transport, and thus the more will public transport decline. Those without cars lose, and these tend to be from the most vulnerable groups – poor, elderly and disabled people, and children.

Building more roads may lead to a *potential* Pareto improvement: in other words, if the gainers had fully to compensate the losers (e.g. through taxes or tolls), they would still have a net gain. The problem is that such compensation is rarely if ever paid. There is thus no actual Pareto improvement.

Congestion may not be solved. Increasing the amount of road space may encourage more people to use cars.

A good example is the London orbital motorway, the M25. In planning the motorway, not only did the government underestimate the general rate of traffic growth, but it also underestimated the direct effect it would have in encouraging people to use the motorway rather than using some alternative route, or some alternative means of transport, or even not making the journey at all. It also underestimated the effect it would have in encouraging people to live further from their place of work and to commute along the motorway. The result is that there is now serious congestion on the motorway and many sections have been widened from the original dual three-lane model to dual four, five and, in some parts, six lanes.

Thus new roads may simply generate extra traffic, with little overall effect on congestion in the long term.

The environmental impact of new roads. New roads lead to the loss of agricultural land, the destruction of many natural habitats, noise, the splitting of communities and disruption to local residents. To the extent that they encourage a growth in traffic, they add to atmospheric pollution and a depletion of oil reserves. It is thus important to take account of these costs when assessing new road schemes. The problem, however, is that these environmental costs are frequently ignored, or only considered as an afterthought and not taken seriously. Part of the problem is that they are difficult to assess, and part is that there is often a strong road lobby which persuades politicians to ignore or play down environmental considerations.

Government or local authority provision of public transport

An alternative supply-side solution is to increase the provision of public transport. If, for example, a local authority ran a local bus service and decided to invest in additional buses, open up new routes and operate a low-fare policy, these services might encourage people to switch from using their cars.

To be effective, this would have to be an attractive alternative. Many people would switch only if the buses were frequent, cheap, comfortable and reliable, and if there were enough routes to take people close to where they wanted to go.

What other types of transport could be directly provided by the government or a local authority?

A policy that has proved popular with many local authorities is to adopt park-and-ride schemes. Here the authority provides free or cheap out-of-town parking and cheap bus services from the car park to the town centre. These schemes are likely to be most effective when used in combination with charges for private cars entering the inner city.

Regulation and legislation

An alternative strategy is to restrict car use by various forms of regulation and legislation.

Restricting car access

One approach involves reducing car access to areas that are subject to high levels of congestion. The following measures are widely used: bus and cycle lanes, 'high occupancy vehicle lanes' (confined to cars with two or more occupants), pedestrian-only areas and no entry to side streets from main roads.

There is a serious problem, with these measures, however. They tend not to solve the problem of congestion, but merely to divert it. Bus lanes tend to make the car lanes more congested; no entry to side streets tends to make the main roads more congested; and pedestrian-only areas often make the roads round these areas more congested, with drivers adopting side streets as 'rat-runs'.

Parking restrictions

An alternative to restricting road access is to restrict parking. If cars are not allowed to park along congested streets, this will improve the traffic flow. Also, if parking is difficult, this will discourage people from using their cars to come into city centres.

Apart from being unpopular with people who want to park, there are some serious drawbacks with parking restrictions:

- People may well 'park in orbit', driving round and round looking for a parking space, and in the meantime adding to congestion.

- People may park illegally. This may add to rather than reduce congestion, and may create a safety hazard.
- People may feel forced to park down side streets in residential areas, thereby causing a nuisance for residents.

Changing market signals

The solution favoured by many economists is to use the price mechanism. As we have seen, one of the causes of traffic congestion is that road users do not pay the full marginal social costs of using the roads. If they could be forced to do so, a social optimum usage of road space could be achieved.

In Figure 13.6 (page 412) this would involve imposing a charge on motorists of $d-c$. By 'internalising' the congestion and environmental externalities in this way, traffic flow will be reduced to the social optimum of Q_2 .

So how can these external costs be charged to the motorist? There are several possible ways.

Extending existing taxes

Three major types of tax are levied on the motorist: fuel tax (duty per litre plus VAT), taxes on new cars and car licences. Could increasing these taxes lead to the optimum level of road use being achieved?

Increasing the rates of new car tax and car licences may have *some* effect on reducing the total level of car ownership, but will probably have little effect on car use. The problem is that these taxes do not increase the *marginal* cost of car use and so do not discourage you from using your car.

Unlike the other two, fuel taxes are a marginal cost of car use. The more you use your car, the more fuel you use and the more fuel tax you pay. They are also mildly related to the level of congestion, since fuel consumption tends to increase as congestion increases. Nevertheless, they are not ideal. The problem is that *all* motorists would pay an increase in fuel tax, even those travelling on uncongested roads. To have a significant effect on congestion, there would have to be a very large increase in fuel taxes and this would be very unfair on those who are not causing congestion, especially those who have to travel long distances. Also, as the fuel protests in recent years have shown, increasing fuel taxes could make the government very unpopular.

Would a tax on car tyres be a good way of restricting car usage?

Introducing new taxes

An alternative to extending existing taxes is to introduce new ones. One that has received much attention in recent times has been the taxing of car parking spaces, particularly those provided by businesses for their employees. The problem with taxing car parking, however, is similar to that of restricting car parking places: people may simply try to park on neighbouring streets (a negative externality imposed on residents), and may spend longer driving

around trying to find a space (thereby adding to congestion in the process).

Road pricing

Taxes are inevitably an indirect means of tackling congestion. Charging people for using roads, on the other hand, where the size of the charge reflects the marginal social cost, is a direct means of achieving an efficient use of road space. The higher the congestion, the higher should be the charge. This would encourage people not only to look for alternative means of transport, but also to travel, wherever possible, at off-peak times.

TC 11
p353

TC 2
p26

Variable tolls. Tolls are used in many countries, and could be adapted to reflect marginal social costs.

One obvious problem, however, is that, even with automatic tolls, there can be considerable tailbacks at peak times. Another problem is that they may simply encourage people to use minor roads into cities, thereby causing congestion on these roads. Cities have networks of streets and thus in most cases it is not difficult to avoid the tolls. Finally, if the tolls are charged to people *entering* the city, they will not affect *local* commuters. But it is these short-distance commuters *within* the city who are most likely to be able to find some alternative means of transport and who thus could make a substantial contribution to reducing congestion.

Area charges. One simple and practical means of charging people to use congested streets is the area charge. People would have to pay (normally by the day) for using their car in a city centre. Earlier versions of this scheme involved people having to purchase and display a ticket on their car, rather like a 'pay-and-display' parking system.

More recently, electronic versions have been developed. The introduction of the London Congestion Charge in February 2003 is an example. Car drivers must pay a standard charge of £11.50 per day to enter the inner London area (or 'congestion zone') any time between 7:00 and 18:00, Monday to Friday. Payment can be made by various means, including post, Internet, telephone, text message and at various shops and petrol stations. Drivers can obtain a £1 discount per day if they use an auto payment system, and are charged £14 if they pay before midnight the following day.

Cars entering the congestion zone have their number plate recorded by camera and a computer check then leads to a penalty charge of £130 being sent to those who have not paid.

A report by Transport for London estimated that traffic levels had fallen by 10 per cent in the first 10 years of the London Congestion Charge, although average traffic speeds have also fallen. One unanticipated benefit of the scheme is that it appears to have reduced the number of traffic accidents by 40 per cent.

The charge is not a marginal one in the sense that it does not vary with the degree of congestion or the amount of time spent or distance travelled by a motorist within the zone. This is an intrinsic problem of area charges. Nevertheless,

their simplicity makes the system easy to understand and relatively cheap to operate.

The London system does not address pollution directly. However, under the 'greener vehicle discount', cars that emitted 100g/km of CO₂ or less were exempt from the charge. This led to a big increase in low-emission diesel cars in London as they qualified for the discount. This prompted Transport for London to replace the 'greener vehicle discount' in April 2013 with the 'Ultra Low Emission Discount'. Vehicles will now have to either be purely electric or emit 75g/km of CO₂ or less to qualify.

The London Mayor, Sadiq Khan, announced that from October 2017 a new additional £10 emissions surcharge will be payable for older vehicles to enter the London Congestion Charge Zone. This *T-Charge* will be applied to cars and vans that do not meet Euro 4 standards.

There does appear to be a growing commitment to combine both congestion and emission external costs within the charge.

Variable electronic road pricing. The scheme most favoured by many economists and traffic planners is that of variable electronic road pricing. It is the approach that can most directly relate the price that the motorist is charged to the specific level of marginal social cost. The greater the congestion, the greater the charge imposed on the motorist. Ideally, the charge would be equal to the marginal congestion cost plus any marginal environmental costs additional to those created on non-charged roads.

Various systems have been adopted in various parts of the world, or are under consideration. One involves devices in the road which record the number plates of cars as they pass. Alternatively, cars may be required to be fitted with sensors. Charges are registered to cars on a central computer and owners are billed. Several cities around the world, including Barcelona, Dallas, Orlando, Lisbon, Oklahoma City and Oslo, are already operating such schemes.

Another system involves having a device installed in the car into which a 'smart card' is inserted. Beacons or overhead gantries automatically charge the cards at times of congestion. Such a system was introduced in 1997 on Stockholm's ring road, and in 1998 in Singapore (see Box 13.5).

With both these systems, the rate can easily be varied electronically according to the level of congestion (and pollution). The rates could be in bands and the current bands displayed by the roadside and/or broadcast on local radio so that motorists knew what they were being charged.

The most sophisticated scheme would involve equipping all vehicles with a receiver. Their position is located by satellites, which then send this information to a dashboard unit, which deducts charges according to location, distance travelled, time of day and type of vehicle. The charges can operate through either smart cards or central computerised billing. It is likely that such schemes would initially be confined to lorries.

BOX 13.5 ROAD PRICING IN SINGAPORE**Part of an integrated transport policy**

Singapore has some 280 vehicles per kilometre of road (this compares with 271 in Hong Kong, 222 in Japan, 77 in the UK, 75 in Germany and 37 in the USA). The average car in Singapore is driven some 17 500 kilometres per year, but with low car ownership (see below), this translates into a relatively low figure for kilometres travelled by car per person. Part of the reason is that Singapore has an integrated transport policy. This includes the following:

- A 171-kilometre-long mass rail transit (MRT) system with five main lines, 102 stations and subsidised fares. Trains are comfortable, clean and frequent. Stations are air-conditioned.
- A programme of building new estates near MRT stations.
- Cheap, frequent buses, serving all parts of the island.
- A modest expansion of expressways.

But it is in respect to road usage that the Singaporean authorities have been most innovative.

Area licences

The first innovation came in 1975 when the Area Licensing Scheme (ALS) was introduced. The city centre was made a restricted zone. Motorists who wished to enter this zone had to buy a ticket (an 'area licence') at any one of 33 entry points. Police were stationed at these entry points to check that cars had paid and displayed. This scheme was extended to the major expressways in 1995 with the introduction of the Road Pricing Scheme (RPS).

The Vehicle Quota System

In 1990, the government also introduced restrictions on the number of new cars, known as the Vehicle Quota System. In order to register and drive a new vehicle in Singapore, the owner has to purchase a Certificate of Entitlement (COE) which is valid for 10 years. The quantity of COEs issued by the government is limited and the number available each year is announced in April. The COEs are then sold to the public via monthly auctions which are operated in a similar manner to those on the eBay system. Buyers specify a maximum price and bids are automatically revised upwards until that maximum price is reached. The price of COEs increases until the quantity demanded is just equal to the number of certificates on offer.

Partly as a result of the quota system, there are only 114 private cars per 1000 population. As you can see from Figure 13.5 on page 410, this is only a fraction of the figure for European countries.

A problem with the licences is that they are a once-and-for-all payment, which does not vary with the amount people use their car. In other words, their marginal cost (for additional miles driven) is zero. Many people feel that, having paid such a high price for their licence, they ought to use their car as much as possible in order to get value for money!

Electronic road pricing

With traffic congestion steadily worsening, it was recognised that something more had to be done. In 1998, a new Electronic Road Pricing Scheme (ERP) replaced the Area Licensing Scheme for restricted areas and the Road Pricing Scheme for expressways. This alternative not only saves on police labour costs, but enables charge rates to be varied according to levels of congestion, times of the day and locality. How does it work?

All vehicles in Singapore are fitted with an in-vehicle unit (IU). Every journey made requires the driver to insert a smart card into the IU. On specified roads, overhead gantries read the IU and deduct the appropriate charge from the card. If a car does not have sufficient funds on its smart card, the car's details are relayed to a control centre and a fine is imposed. The system has the benefit of operating on three-lane highways and does not require traffic to slow down.

The ERP system operates on roads subject to congestion and charges can vary every 5, 20 or 30 minutes according to predicted traffic flows. Rates are published in advance for a three-month period: e.g. from 20 February until 30 April 2017. A review of traffic conditions takes place every quarter and the results can lead to rates being adjusted in future periods. The system is thus very flexible to allow traffic to be kept at the desired level.

One potential problem with charging different rates at different times is that some drivers may substantially speed up or slow down as they approach the gantries to avoid paying higher ERP charges. To try to overcome this problem the ERP rates are adjusted gradually for the first five minutes of a time slot with either new higher or lower charges.

The authorities in Singapore are now testing the use of a Global Navigation Satellite System. This would remove the need for the overhead gantries. It would also make it possible to alter the size of the charge with the length of the congested road the driver has travelled along. There are plans for this system to become operational in 2020.

The ERP system was expensive to set up, however. Cheaper schemes have been adopted elsewhere, such as Norway and parts of the USA. These operate by funnelling traffic into a single lane in order to register the car, but they have the disadvantage of slowing the traffic down.

One message is clear from the Singapore solution. Road pricing alone is not enough. Unless there are fast, comfortable and affordable public transport alternatives, the demand for cars will be highly price inelastic. People have to get to work!

Explain how, by varying the charge debited from the smart card according to the time of day or level of congestion, a socially optimal level of road use can be achieved.

Despite the enthusiasm for such schemes amongst economists, there are nevertheless various problems associated with them:

- Estimates of the level of external costs are difficult to make.
- Motorists have to be informed in advance what the charges will be, so that they can plan the timing of their journeys.
- There may be political resistance. Politicians may therefore be reluctant to introduce road pricing for fear of losing popular support.
- If demand is relatively inelastic, the charges might have to be very high to have a significant effect on congestion.
- The costs of installing road-pricing equipment could be very high.
- If road pricing were introduced only in certain areas, shoppers and businesses would tend to move to areas without the charge.
- A new industry in electronic evasion may spring up!

Subsidising alternative means of transport

An alternative to charging for the use of cars is to subsidise the price of alternatives, such as buses and trains. But cheaper fares alone may not be enough. The government may also have to invest directly in or subsidise an *improved* public transport service: more frequent services, more routes, more comfortable buses and trains.

Subsidising public transport need not be seen as an alternative to road pricing: it can be seen as complementary. If road pricing is to persuade people not to travel by car, the alternatives must be attractive. Unless public transport is seen by the traveller as a close substitute for cars, the elasticity of demand for car use is likely to remain low. This problem is recognised by the UK government, which encourages local authorities to use various forms of road pricing and charges on businesses for employee car parking spaces on condition that the revenues generated are ploughed back into improved public transport. All local authorities have to produce five-year Local Transport Plans covering all forms of transport. These include targets for traffic reduction and increases in the use of public transport.

Subsidising public transport can also be justified on grounds of equity, since it is used most by low-income groups.

Which is preferable: general subsidies for public transport, or cheap fare policies for specific groups (such as children, students and pensioners)?

Conclusions

It is unlikely that any one policy can provide the complete solution. Certain policies or mixes of policies are better suited to some situations than others. It is important for governments to learn from experiences both within their own country and in others, in order to find the optimum solution to each specific problem.

Section summary

1. There are various types of solution to traffic congestion. These include direct provision by the government or local authorities (of additional road space or better public transport); regulation and legislation (such as restricting car access – by the use of bus and cycle lanes, or pedestrian-only areas – and various forms of parking restrictions); changing market signals (by the use of taxes, by road pricing, and by subsidising alternative means of transport).
2. Problems associated with building additional roads include the decline of public transport, attracting additional traffic onto the roads, and environmental costs.
3. The main problem with restricting car access is that it tends merely to divert congestion elsewhere. The main problem with parking restrictions is that they may actually increase congestion.
4. Increasing taxes is effective in reducing congestion only if it increases the marginal cost of motoring. Even when it does, as in the case of additional fuel tax, the additional cost is only indirectly related to congestion costs, since it applies to all motorists and not just those causing congestion.
5. Road pricing is the preferred solution of many economists. By the use of electronic devices, motorists can be charged whenever they add to congestion. This should encourage less essential road users to travel at off-peak times or to use alternative modes of transport, while those who gain a high utility from car transport can still use their cars, but at a price. Variable tolls and area charges are alternative forms of congestion pricing, but are generally less effective than the use of variable electronic road pricing.
6. If road pricing is to be effective, there must be attractive substitutes available. A comprehensive policy, therefore, should include subsidising efficient public transport. The revenues required for this could be obtained from road pricing.

BOX 13.6 THE ECONOMY AND THE ENVIRONMENT

Green growth: a way forward

Recessions are generally bad news: output and jobs are lost, and both consumers and businesses face uncertainty. Yet in the short run, a slump may have positive environmental effects. Between 2007 and 2008 road traffic fell by 0.8 per cent, with further falls of 0.9 and 1.6 per cent in 2009 and 2010 respectively.¹ Probable causes were lower incomes, less freight being transported and fewer people driving to work. Non-renewable resources are depleted more slowly in a downturn, as households reduce consumption, increase recycling and reuse items that they might have discarded in a boom.

In other ways, however, a recession may lead to faster environmental degradation. Businesses are less likely to invest in clean technologies; consumers may put off replacing vehicles with more energy-efficient models; governments may choose to divert resources from environmental initiatives to job creation schemes.

Economic growth and the green agenda

Think back to the first chapter of this book, where we identified the fundamental economic problem of scarcity. We demonstrated how economic growth can provide a solution; allowing us to produce more and so satisfy more of our wants and needs. (We consider economic growth in more detail in Chapters 15 and 23).

In general, economists and politicians have presented economic growth as a 'good thing', resulting in higher levels of welfare and giving society the opportunity to redistribute further to reduce poverty. However, there has been less wholehearted support from the green lobby. Economic growth has been portrayed as fundamentally harmful with a widespread acceptance of the principle that there is a trade-off between growth and degradation of the environment.

The idea that growth may not be beneficial is not a new one. In 1848, John Stuart Mill wrote, 'Towards what ultimate point is society tending by its industrial progress? When the progress ceases, in what condition are we to expect that it will leave mankind?' In 1973, an influential collection of essays by E. F. Schumacher called *Small is Beautiful* was published (see Case Study 1.1 on the student website). This work led the debate on growth and its impact on well-being – a debate that continues today.

If you spend your time thinking that the most important objective of public policy is to get growth up from 1.9 per cent to 2 per cent and even better 2.1 per cent we're pursuing a sort of false god there. We're pursuing it first of all because, if we accept that, we will do things to the climate that will be harmful, but also because all the evidence shows that beyond the sort of standard of living which Britain has now achieved, extra growth does not

END OF CHAPTER QUESTIONS

1. Assume that as traffic density increases along a given stretch of road, there comes a point when traffic begins to slow down. The following table gives the times taken for a car to travel the stretch of road (in minutes) according to the number of cars entering the road per minute.

Cars entering the road	5	6	7	8	9	10	11
Journey time	10	10	11	13	16	22	30

- (a) Copy out the table and add the following rows: (i) total journey time for all cars; (ii) extra journey time as traffic increases by one more car (marginal social time cost); (iii) additional time cost imposed on other road users for each additional car entering the road (marginal external time cost). (See Table 13.3.)

- (b) Assume that time is valued at 10p per minute. On a graph, plot the marginal private time cost (journey time) and the marginal social time cost.
- (c) Assume that electronic road pricing is introduced. What charge should be levied when traffic density reaches (i) 6 cars per minute; (ii) 8 cars per minute; (iii) 11 cars per minute?
- (d) What additional information would you need in order to work out the socially efficient traffic density on this particular stretch of road?
2. Assume that there are several chemical firms in an industry, each one producing different levels of an effluent, whose damage to the environment depends on the location of the firm. Compare the relative merits of using green taxes, tradable permits and controls as means of achieving the socially optimum levels of effluent from these firms.

automatically translate into human welfare and happiness.² (Lord Turner, *Previously Chair of the UK Financial Services Authority*)

In 2010, the New Economics Foundation published a report, titled 'Growth isn't possible. Why we need a new economic direction'. In this they argued that economic growth is constrained by the finite capacity of the earth's resources.³

However, given the levels of poverty seen across the world, a reduced commitment to growth must imply continuing inequality or an acceptance that industrialised countries will experience lower standards of living. This is unthinkable to many, who instead focus on achieving growth in a sustainable manner: one that allows for increased welfare while ensuring the long-term health of the planet. Much of the OECD's work in the environmental arena concentrates on this aspect – hardly surprising, given its remit to support global development. In 2012, it highlighted three issues which governments should consider in formulating growth policies:

- Putting a price on carbon emissions and other pollution.
- Supporting green innovation and ensuring that this spreads across national borders.
- Fostering private investment in capital that will support growth with cleaner technologies.

The OECD acknowledges that various governments across the world are making efforts to promote greener development. The European Union's *Growth Strategy for 2020*, Korea's National Strategy and five-year plan for Green Growth, the green development focus of China's 12th five-year Plan and South Africa's *New Growth Path* and *Green Economy Accord* are just a few examples.

1. The UK government introduced a 'scrappage scheme' in 2009 to run for one year. Under this, motorists were given a £2000 grant towards the cost of a new car. To qualify they had to trade in a car that was more than 10 years old, which would then be scrapped. Explain how this scheme might be justified in the middle of a recession. Should there have been any restrictions on the new cars eligible for the grant?
2. Growth is largely seen as being associated with economic efficiency. Explain how it may also be an important issue when considering equity.
3. Under what circumstances will private investment be attracted to 'green' projects? Is there a role for government here?

1 Transport Statistics Great Britain 2013, Department of Transport.

2 Quoted in *Growth Isn't Possible. Why We Need a New Economic Direction* (New Economics Foundation, 25 January 2010).

3 Ibid.

3. Make out a case from a deep green perspective for rejecting the 'social efficiency' approach to the environment.
4. Why might efforts to address the issue of global warming be hampered by a lack of understanding of probability amongst the general public?
5. In 2007, China overtook the USA as the world's largest emitter of CO₂. Yet USA per capita emissions are three times those of China. What issues arise from this in the formulation of a global policy to reduce CO₂ emissions?
6. Make out a case for adopting a policy of individual tradable carbon permits, allocated to all citizens within a country. Could such a policy be extended globally?
7. Compare the relative merits of increased road fuel taxes, electronic road pricing and tolls as means of reducing urban traffic congestion.
8. Why is the price inelasticity of demand for private car transport a problem when formulating a policy for the reduction of traffic congestion? What could be done to change the price elasticity of demand in a desirable direction?
9. How would you set about measuring the external costs of road transport?
10. Many London councils now have residents' street parking permits, with charges that vary according to the carbon emissions of the registered vehicle. Explain the thinking behind this policy.
11. Since 2008, the UK government has provided free off-peak bus travel for the over-60s in England and Wales. What do you think the impact of this policy has been on car usage? Is there a case for extending the policy to (a) bus travel for pensioners at all times of the day, as is the case in Scotland; (b) bus travel for all?
12. In 2010, the number of air passengers using UK airports fell by 3.4 per cent compared with 2009. In 2015, passengers were 5.5 per cent up compared with 2014. Can we deduce anything about people's attitude to the environment and their behaviour from these data?

Regulation in the UK	436
Increasing competition in the privatised industries	437

In this chapter we continue our examination of government policy to tackle market imperfections. The focus here is on the problem of market power. We examine various policies the government or its agencies can use to prevent firms abusing a monopolistic or oligopolistic position.

In section 14.1 we examine 'competition policy'. We will see that the targets of such policy include the abuse of monopoly power, the problem of oligopolistic collusion, and mergers that will result in the firm having a dominant position in the market.

Then in section 14.2, we look at privatisation and the extent to which privatised industries should be regulated to prevent them abusing their market power. We also consider whether it is possible to introduce enough competition into these industries to make regulation unnecessary.

The relationship between government and business is always likely to be complex. Governments face the twin pressures of having to ensure consumer protection while needing a dynamic and profitable business environment that will ensure high levels of employment, output and growth. In this chapter we see the conflicts that can arise as a consequence.

14.1 COMPETITION POLICY

Competition, monopoly and the public interest

Most markets in the real world are imperfect, with firms having varying degrees of market power. But will this power be against the public interest? This question has been addressed by successive governments in framing legislation to deal with monopolies and oligopolies.

It might be thought that market power is always 'a bad thing', certainly as far as the consumer is concerned. After all, it enables firms to make supernormal profit, which implies they may be 'exploiting' the consumer. The greater the firm's power, the higher will prices be relative to the costs of production. Also, a lack of competition removes the incentive to become more efficient.

But market power is not necessarily a bad thing. Firms may choose not to fully exploit their position of power – perhaps thinking that very high profits would encourage other firms to overcome entry barriers, or perhaps because they are not aggressive profit maximisers. Even if they do make large supernormal profits, they may still charge a lower price than more competitive sectors of the industry because of their economies of scale. Finally, they may use profits for research and development and for capital investment. The consumer might then benefit from new or improved products at lower prices.

Competition policy could ban various structures. For example, there could be restrictions on mergers leading to market share of more than a certain amount. Most countries, however, focus on whether the practices of particular monopolists or oligopolists are anti-competitive. Some practices may be made illegal, such as price fixing by oligopolists; others may be assessed on a case-by-case basis. Such an approach does not presume that the existence of power is against the public interest, but rather that certain uses of that power may be.

 Try to formulate a definition of 'the public interest'.

The targets of competition policy

There are three possible targets of competition policy.

Abuse of the existing power of monopolies and oligopolies: monopoly policy

Monopoly policy seeks to prevent firms from abusing a dominant market position: i.e. misusing their economic power. Although it is referred to as 'monopoly' policy, it also applies to large oligopolists facing very limited competition. For example, most competition agencies consider a market share greater than 50 per cent as strong evidence that a firm has a dominant position. Once a position of

dominance has been identified, the competition agencies usually weigh up the gains and losses to the public of the firm's behaviour.

As we saw in Figure 7.8 (on page 205), faced with the same cost curves as an industry under perfect competition, a monopoly will charge a higher price, produce a lower output and make a larger profit. This is called an **exploitative abuse** – a business practice that directly harms the customer. Other examples include reductions in product quality, limited product ranges and poor levels of customer service. However, a monopolist may achieve substantial economies of scale, with lower costs and a price below the competitive price (see Figure 7.11 on page 207). It may also retain profits for investment and research and development (R&D). This may result in better products and/or lower prices.

Thus the government (or regulatory authority, if separate from the government) has to work out whether a reduction in price would lower R&D and other investment, and whether the consumer would gain in the long run.

Competition authorities have tended to avoid investigating allegations of exploitative abuses because of the challenges involved with correctly identifying and correcting for this type of behaviour. For example, measuring differences between price and costs is very difficult in reality and requires the processing of large amounts of complex information supplied by the firm involved. Regulating prices is also a complicated process. For these reasons, competition agencies have spent most of their time investigating allegations of **exclusionary abuses**.

Exclusionary abuses. These are business practices that limit or prevent effective competition from either actual or potential rivals, for example by creating strategic barriers to entry. Exclusionary abuses may be a necessary condition before firms can implement the more direct exploitative abuses. If a business successfully limits or prevents competition today it may enable the firm to exploit consumers by charging higher prices in the future.

Some of the more frequently cited examples of exclusionary abuses in competition cases include:

- **Predatory pricing.** Prices are set by a dominant firm below its average variable costs with the sole intent of driving its competitor(s) out of business.

Definitions

Exploitative abuse A business practice that directly harms the customer. Examples include high prices and poor quality.

Exclusionary abuses Business practices that limit or prevent effective competition from either actual or potential rivals.

- **Exclusivity rebates/discounts.** Customers are offered special deals if they agree to make 'all or most' of their purchases of the product from the dominant firm. See Box 14.2 for an interesting real-world example.
- **Tying.** This is where a firm controlling the supply of a first product (the tying product), insists that its customers buy a second product (the tied product) from it rather than its rivals.
- **Refusal to supply and margin squeeze.** This occurs where a vertically integrated firm has a dominant position in an upstream market (e.g. components) but faces competition in later stages of the production process (e.g. assembly). If competitors in the downstream market are completely reliant on the supply of some input from the dominant firm in the upstream market, then the dominant firm could *refuse to supply* them. Its aim would be to drive them out of business, thereby giving it a dominant position in the downstream market too. Rather than blatantly refusing to supply its downstream competitors, a more subtle approach for the dominant firm would be to charge high prices for the input so that its rivals are unable to cover their costs and therefore go out of business. This is called **margin squeeze**.
- **Price discrimination.** This would be an abuse if the lower prices are used to drive competitors out of business.
- **Vertical restraints.** This is where a supplying firm imposes conditions on a purchasing firm (or vice versa). For example, a manufacturer may impose rules on retailers about displaying the product or the provision of after-sales service, or it may refuse to supply certain outlets (e.g. perfume manufacturers refusing to supply discount chemist shops).

The growth of power through mergers and acquisitions: merger policy

The aim of merger policy is to have oversight of prospective mergers. The authorities will weigh up gains and losses to the public and the impact on the broader economy, and prevent or modify those that are considered to be against the public interest.

On the plus side, the merged firms may be able to rationalise and reduce costs. Horizontal mergers in particular may allow economies of scale to be gained, with production on fewer sites and more intensive utilisation of capital and labour. Also, a more efficient use may be made of warehousing and transport fleets, with distribution in greater bulk.

There may also be potential benefits with vertical mergers. It may be possible to concentrate various stages in the production process on one site, with consequent savings in transport and handling costs.

There are also cost savings that apply to all types of merger: horizontal, vertical and conglomerate. Central services such as finance and human resources (HR) can be merged and rationalised. Greater financial strength may allow the merged firm to drive down the prices charged by

its suppliers and the combined profits may allow larger-scale investment and R&D.

However, mergers inevitably lead to a greater concentration of economic power, which could be used against the consumer's interests. This is particularly true of horizontal mergers, which will result in fewer firms and reduced consumer choice. But even conglomerate mergers can lead to anti-competitive activities. A conglomerate can use profits gained in one market where it already has monopoly power to **cross-subsidise** prices in a competitive market, thereby driving out competitors.

What are the possible disadvantages of vertical mergers?

In deciding how tough to be with mergers, the government must consider how this will affect firms' behaviour. If the government adopts a liberal policy, this may actually encourage firms to be more efficient. If the managers of a firm are aware that it could be taken over, there is a greater incentive to ensure that the firm is strong and that it is perceived by shareholders to be more profitable than it would be under alternative ownership. This competition for corporate control (see pages 210–11) may lower costs and benefit the consumer. It may, however, make firms keener to exploit any monopoly power, enabling the takeover of other firms, or persuading shareholders not to vote for being taken over.

Government policy towards corporate control will need to ensure that potential mergers encourage competition rather than reduce it.

Oligopolistic collusion: restrictive practice policy

In most countries, the approach towards oligopolistic collusion, known as **restrictive practices**, tends to be more prohibitive than for mergers and monopoly power. This is because there is a much smaller chance that agreements to restrict, limit or prevent competition will ever be in the interests of society. The most likely outcome is higher joint profits for the firms and higher prices for the customer.

Definitions

Tying Where a firm is only prepared to sell a first product (the tying good) on the condition that its consumers buy a second product from it (the tied good).

Margin squeeze Where a vertically integrated firm with a dominant position in an upstream market deliberately charges high prices for an input required by firms in a downstream market to drive them out of business.

Vertical restraints Conditions imposed by one firm on another which is either its supplier or its customer.

Cross-subsidise To use profits in one market to subsidise prices in another.

Restrictive practices Where two or more firms agree to adopt common practices to restrict competition.

Examples of restrictive practices that are commonly cited in competition cases include

- **Horizontal price fixing.** These are direct or indirect agreements between rival firms to fix prices above competitive levels. There are a number of different ways that firms can make price agreements:
 - Set a minimum level below which prices will not be reduced.
 - Adhere to a published price list.
 - Increase prices by a fixed absolute or percentage amount.
 - Charge customers the same amount for delivery.
 - Pass on all additional costs in higher prices.
- **Market sharing.** These are agreements on how to distribute markets or customers between the firms. This could be done by geographical area, type of product or type of customer. For example, two or more supermarket chains could agree to open only one supermarket in each district.
- **Limit production.** Firms agree quotas on how much each should produce.
- **Bid rigging.** In response to a call for tenders, firms agree to discuss bids with one another rather than submitting them independently. They could agree on high-priced bids, with one of the firms (agreed in turn, possibly) submitting a slightly lower price. Or one or more of them may agree not to submit a bid, withdraw a bid, or submit a bid at an artificially high price.
- **Information sharing.** Firms share sensitive information with one another, such as future plans on pricing, product design and output.

Are all such agreements necessarily against the interests of consumers?

Banning formal cartels is relatively easy. Preventing tacit collusion is another matter. It may be very difficult to prove that firms are making informal agreements behind closed doors.

Competition policy in the European Union

Relevant EU legislation is contained in Articles 101 and 102 of the 2009 Treaty of the Functioning of the European Union (TFEU). Additional regulations covering mergers came into force in 1990 and were amended in 2004. Further minor amendments have since been introduced, and many of these focus on specific market regulation.

Definition

Bid rigging Where two or more firms secretly agree on the prices they will tender for a contract. These prices will be above those that would have been submitted under a genuinely competitive tendering process.

Article 101 is concerned with restrictive practices and Article 102 with the abuse of market power. The Articles focus on firms trading between EU members and do not cover monopolies or oligopolies operating solely within a member country. They are implemented by the European Commission (EC), which monitors compliance, investigates behaviour and imposes fines where unlawful conduct is identified.

Firms can appeal against EC judgments to the *General Court* – formerly known as the *Court of First Instance*. The General Court has the power to overturn decisions made by the EC and is able to amend the size of any fines. The EC and/or the firms involved in the case can appeal against decisions made by the *General Court* to the *European Court of Justice*. However, appeals to the *European Court of Justice* can only be made on points of law.

EU restrictive practices policy

Article 101 covers agreements between firms, joint decisions and concerted practices that prevent, restrict or distort competition. In other words, it covers all types of oligopolistic collusion that are against the interests of consumers.

The legislation is designed to prevent collusive *behaviour* not oligopolistic *structures* (i.e. the simple existence of cooperation between firms). For example, agreements between oligopolists are exempt from Article 101 if they meet all of the following conditions: (a) they directly enhance the quality of the good/service for the customer; (b) they are the only way to do so; (c) they do not eliminate competition; (d) consumers receive a fair share of the resulting benefits.

If companies are found guilty of undertaking any anti-competitive practices that are in contravention of Article 101 such as those discussed above, they are ordered to cease the activity with immediate effect and are subject to financial penalties.

Fines. Table 14.1 illustrates the largest fines imposed by the EC on individual companies involved in cartel activity.

Four of the largest seven fines relate to just one case. The EC ruled in July 2016 that the truck producers MAN, Volvo/Renault, Daimler, Iveco and DAF were guilty of operating a cartel.¹ In particular, they colluded over the factory price of

Table 14.1 Highest EC cartel fines per firm

Year	Firm	Case	Amount in €
2016	Daimler	Trucks	1 008 766 000
2016	DAF	Trucks	752 679 000
2008	Saint-Gobain	Car glass	715 000 000
2012	Philips	TV/computer monitor tubes	705 296 000
2012	LG Electronics	TV/computer monitor tubes	687 537 000
2016	Volvo/Renault	Trucks	670 448 000
2016	Iveco	Trucks	494 606 000

¹ 'Commission fines truck producers €2.93 billion for participating in a cartel'. Press release (European Commission, 19 July 2016).

trucks for 14 years and agreed to pass on the compliance costs of stricter EU emissions rules to their customers.

The size of any fine imposed on an organisation depends on a number of factors. Initially, the authorities calculate the annual revenue generated by the firms from the sales of the products directly influenced by the activities that restricted competition. These are referred to as the 'relevant sales'. For example, in the paper envelope case referred to in Box 14.1, the Commission estimated that the company 'Bong' had made sales worth €140 million from the cartel activities it had undertaken with four other companies.

The initial size of the basic fine is then calculated by taking a percentage of the value of these annual relevant sales, up to a maximum of 30 per cent, but typically between 15 and 20 per cent. The percentage chosen is based on the severity of the abuse, which depends on factors such as the market shares of the companies involved and the size of the geographical area affected by the practices.

Once this initial figure has been calculated it is then multiplied by the number of years the firms have been in contravention of Article 101. In the case of the truck manufacturers, this 'duration multiplier' was 14.

An additional amount is then added to the size of the fine and is known as an 'entry fee'. This is once again calculated as a percentage of the value of the firm's relevant sales. However, this figure is not adjusted by a duration multiplier.

The figure is then adjusted for either aggravating or mitigating factors. For example, the fine on a company could be increased if it was a repeat offender or seen as the 'ring-leader', or reduced if it was judged to have been far less actively involved in the cartel's activities.

The final size of the basic fine imposed on a firm is capped and cannot be greater than 10 per cent of that firm's annual total revenue. This is only likely to affect fines where the cartel activities form a large part of the firm's business (as was the case in the paper envelope investigation discussed in Box 14.1).

Reducing fines through co-operation with the Commission. The size of this basic fine can be reduced if members of a cartel provide information that helps the Commission with its investigations. Such firms would be granted a 'Leniency Notice'. To qualify for this they would have to provide detailed information about cartel meetings and exactly how the anti-competitive practices operated. The first company to supply this type of information can be granted full immunity and not have to pay anything (Type 1A leniency) if this is a new case the company is bringing to the Commission's notice. If it is already being investigated by the Commission, the first company to provide detailed information would possibly receive full immunity at the discretion of the Commission (Type 1B leniency). In the truck manufacturing case, MAN was awarded full immunity under Type 1A leniency as it had revealed the existence of the cartel to the Commission in the first place. It, therefore, did not have to pay a fine.

Other companies supplying information can be given reduced fines (Type 2 leniency). The second company to come forward with this type of information can receive a reduction of up to 50 per cent, the third of up to 30 per cent and any firm after this of up to 20 per cent.

Firms can receive a further 10 per cent reduction if they accept the Commission's decision and the size of any financial penalties imposed on them. This is referred to as a Settlement. By speeding up the final decision process it can reduce the administrative costs to the parties involved and avoid the legal costs of any possible appeals.

The aim of all these reductions is to encourage firms to co-operate with the authorities. They further increase the incentive for each firm to cheat on the other members of the cartel to avoid any financial penalties.

EU monopoly policy

Article 102 relates to the abuse of a dominant market position and has also been extended to cover mergers. The implementation of the policy follows a two-stage process.

First, the EC has to define the relevant market: i.e. identify which products and suppliers are close substitutes for one another. Then it has to decide if the firm has a dominant position in this market. To do so it will look at factors such as market shares, the position of competitors, the bargaining strength of customers, measures of profitability and the existence of any significant barriers to entry – see the case in Box 14.2 for an example.

Second, if the evidence confirms that the firm does have a dominant position, the EC will then assess whether the firm is using its market power to restrict competition. As previously discussed, the focus tends to be on exclusionary as opposed to exploitative abuses of power.

If a business is found guilty of engaging in exclusionary abuses that contravene Article 102, such as those discussed on page 422, they are ordered to cease the activities with immediate effect and are subject to financial penalties.

The fines for any infringements of Article 102 are calculated in a very similar manner to those for infringements of Article 101: a percentage is taken of the annual revenue generated from the sale of the products affected by the illegal conduct. This figure is then multiplied by a duration multiplier but, unlike the cartel fine, no entry fee is charged.

Article 102 also contains some guidance on how a dominant firm can defend its behaviour on efficiency grounds. The business has to prove each of the following:

- Any efficiencies are the direct result of the exclusionary conduct.
- The same efficiencies could not be achieved by the firm engaging in different behaviour that is less anti-competitive.
- The efficiencies produced by the exclusionary conduct outweigh any of its negative effects.
- The conduct does not result in the removal of all or most of the competition in the market.

BOX 14.1 FIXING PRICES AT MINI-GOLF MEETINGS?

The EU approach to cartels

In September 2010, the European Commission began an investigation into the market for both standardised and customised paper envelopes in the EU. In December 2014, the Commission found Bong (of Sweden), GPV and Hamelin (of France), Mayer-Kuvert (of Germany) and Tompla (of Spain) guilty of participating in activities that restricted competition in this market. The meetings at which the details of the cartel arrangements were discussed were referred to by the participating firms as 'golf' or 'mini-golf' meetings!

The cartel arrangements directly affected the market for envelopes in Denmark, France, Germany, Norway, Sweden and the UK. The firms were judged to have been involved in the following restrictive practices that were in violation of Article 101:

- allocating customers amongst members of the cartel: i.e. agreeing not to target customers that 'belonged' to other firms;
- agreeing on price increases;
- co-ordinating responses to tenders initiated by major European customers;
- exchanging commercially sensitive information on customers and sales volumes.

Details of the sales of the companies and the fines imposed are given in the table.

The proportion of the value of sales used to calculate the size of the fine was set at 15 per cent in this case (see row 2 of the table). Four out of the five firms began taking part in the

	Bong	GPV group	Hamelin	Meyer-Kuvert	Tompla
1. Value of relevant sales (€)	140 000 000	125 086 629	185 521 000	70 023 181	143 316 000
2. Percentage (15%) of the value of relevant sales (€)	21 000 000	18 762 994	27 828 15	10 503 477	21 497 00
3. Duration multiplier	4.5	4.5	4.416	4.5	4.5
4. Duration multiplier × 15% of sales (€)	94 500 000	84 433 475	122 889 110	47 265 646	96 738 300
5. Plus the entry fee (€) (= row 2)	21 000 000	18 762 994	27 828 150	10 503 477	21 497 400
6. Basic fine (€) (= rows 4 + 5)	115 500 000	103 196 000	150 717 260	57 769 000	118 235 000
7. Final fine	3 118 000	1 651 000	4 996 000	4 991 000	4 729 000

EU merger policy

Under current regulations (2004), mergers and acquisitions (M&As) are prohibited which would significantly reduce competition in the EU.² For example, a merger could be blocked if there were concerns that the newly created firm would have significant market power and lead to higher prices for consumers.

Therefore, the EU investigates 'large' M&As that have an 'EU dimension'. A merger or acquisition is judged as having an 'EU dimension' when no more than two-thirds of each firm's EU-wide business is conducted in a single member state. If a firm does conduct more than two-thirds of its business in one country, then investigation of the merger would be the responsibility of that member state's competition authority.

Thresholds. M&As are deemed 'large' if they exceed one or other of two turnover thresholds.

The first threshold is exceeded if (a) the firms involved have combined worldwide sales greater than €5 billion and (b) at least two of the firms individually have sales of more than €250 million within the EU.

The second threshold is exceeded if (a) the firms involved have combined worldwide sales of more than €2.5 billion; (b) in each of at least three member states, combined sales of all firms involved are greater than €100 million; (c) in each of the three member states, at least two of the firms each have domestic sales greater than €25 million; and (d) EU-wide sales of each of at least two firms is greater than €100 million.

If either of these thresholds is exceeded and the intended merger or acquisition is judged to have an EU dimension, then formal notification of the intention has to be made by the firms to the European Commission. There were 362 notifications in 2016 and the figure has been around 300 per year since 1998.

Investigations. Once a notification is made, the Commission must carry out a preliminary investigation (Phase 1), which is normally completed within 25 days working days. At the end of Phase 1 the majority of cases (over 90 per cent) are usually settled and the merger is either allowed to proceed unconditionally or subject to certain conditions being met. These conditions usually relate to the sale of some of the assets of the newly formed business. See Box 14.3 for an interesting example.

² See http://ec.europa.eu/competition/mergers/overview_en.html

cartel on 8 October 2003 and their involvement in anti-competitive activities lasted until 22 April 2008. Therefore, for these firms the duration multiplier (row 3) was set at 4.5. Hamelin was judged to have entered the cartel a month later than the other participants so the multiplier in its case was set at 4.416. A percentage rate of 15 per cent was also used to calculate the entry fee (row 5). The final figures for the basic amounts of the fine are illustrated in row 7 of the table, which the Commission rounded down to the nearest €1000.

It was considered to be an exceptional case as the sales of envelopes affected by the cartel activities made up a large fraction of each firm's total turnover. Therefore, the unadjusted basic fines would exceed the 10 per cent cap on turnover set by the authorities. The fines were reduced in a way that took account of (a) the value of affected sales for each firm as a proportion of their turnover and (b) the level of involvement in the restrictive practices. Unfortunately, the size of each firm's basic fine, after these adjustments, are not published in the non-confidential report.

Under the Commission's 2006 Leniency Notice we do know that Tompla received a 50 per cent reduction in the size of its adjusted basic fine, Hamelin received a reduction of 25 per cent and Mayer-Kuvert received a reduction of 10 per cent. All five firms obtained an additional 10 per cent reduction for agreeing to the Settlements and not taking their cases to

court. Two firms also claimed that they were unable to pay the fine without getting into serious financial difficulties and were granted a further reduction.

The final sizes of the fines paid by the companies are illustrated in the final row of the table.

Commissioner Margrethe Vestager in charge of competition policy said:

Everybody uses envelopes. When cartelists raise the prices of everyday household objects they do so at the expense of millions of Europeans. The Commission's fight against cartels penalises such behaviour and also acts as a deterrent, protecting consumers from harm. On this case we have closed the envelope, sealed it and returned it to the sender with a clear message: don't cheat your customers, don't cartelise.¹

Why might global cartels be harder to identify and eradicate than cartels solely located within the domestic economy? What problems does this raise for competition policy?

¹ 'Antitrust: Commission on fines five envelope producers over 19.4 million in cartel settlement'. Press release (European Commission, 11 December 2014).

In a small number of cases competition concerns are raised at the end of Phase 1 and a decision is made to refer the proposed merger to a formal, in-depth investigation (Phase 2). In 2016, eight of the 362 notifications made to the EC proceeded to Phase 2. These investigations must normally be completed within 90 working days or 110 in complex cases.

At the end of Phase 2 there are three possibilities: (a) the merger is allowed to proceed with no conditions attached; (b) the merger is allowed to proceed subject to certain conditions being met; (c) the merger is prohibited.

Assessment of the process. The process of EU merger control is thus very rapid and administratively inexpensive. The regulations are also potentially quite tough. M&As are prohibited if they *significantly impede effective competition* (the 'SIEC' test), either by creating or strengthening a dominant firm or by making collusion with other firms, formal or tacit, more likely. But as well as being quite tough, the regulations are also flexible, since they recognise that M&As *may* be in the interests of consumers if they result in cost reductions. In such cases they are permitted.

This flexibility has led to criticism that the Commission has been too easily persuaded by firms, allowing

mergers to go ahead with few, if any restrictions. Indeed, since the current M&A control measures were put in place in 1990 over 6500 M&As have been notified, but only around 250 have been referred to Phase 2 of the process and, of these, only 25 have been prohibited (as of February 2017).

The only M&A prohibited in 2016 related to competition between mobile network operators in the UK. The Commission blocked the acquisition of O2 by Hutchinson (owner of Three) because it believed it would significantly reduce competition: i.e. it would reduce the number of mobile phone operators from four to three and result in customers paying higher prices.

The small number of prohibited mergers highlights a problem for EU policy makers: there is a trade-off between encouraging competition within the EU and supporting European companies to become world leaders. The ability to compete in *world* markets normally requires that companies are large, which may well lead to them having monopoly power within the EU.

To what extent is Article 102 consistent with both these points of view?

BOX 14.2

EXPENSIVE CHIPS?

CASE STUDIES AND APPLICATIONS

The biggest fine in EU monopoly policy history

In May 2004, the European Commission (EC) launched a formal investigation into the business conduct of Intel following complaints submitted by Advanced Micro Devices (AMD) in October 2000 and November 2003. These complaints focused on the behaviour of Intel in the market for microprocessors. These computer chips, also known as Central Processing Units (CPUs), are the most important hardware component in the manufacture of computers. AMD argued that Intel was using its dominance in this market to act in ways that contravened Article 102 of the Treaty on the Functioning of the European Union (TFEU).

EU monopoly policy follows a two-stage process and is similar to the approach adopted by most national competition agencies such as the Competition and Markets Authority in the UK.

Stage 1

The first element in stage 1 of the policy is the identification of the relevant market. This involves survey work to establish which products and suppliers are regarded as close substitutes for one another by the majority of customers.

After carrying out this analysis in the Intel case, the EC concluded that the relevant product market was x86 CPUs. Intel tried, but failed, to convince the authorities that CPUs with a non-x86 architecture should also be included in the definition of the market. All parties did agree that the market for x86 CPUs was global, as computer manufacturers competed on a worldwide basis, CPUs were the same in all regions of the world and the cost of shipping CPUs was small compared to the cost of manufacture.

Having identified the relevant market, the next phase of stage 1 is to assess whether the firm has a dominant position. This involves looking at a number of factors such as market shares, the position of competitors, barriers to entry/expansion and measures of profitability.

Data indicated that Intel's share of the x86 CPU market was approximately 80 per cent over the whole six-year period investigated. The EC typically treats market shares of over 50 per cent as one important indicator of market power. The competition authorities also found evidence of substantial barriers to entry. In particular, the production of CPUs requires considerable sunk investments in R&D, manufacturing facilities and branding. They noted that no new businesses had entered the market in the previous 10 years, while a number had exited, including Rise™ Technology, SGS-Thomson, IBM and Texas Instruments. This left Intel with only one significant rival – AMD. All of this evidence led the EC to conclude that Intel did have a dominant position in the market for x86 CPUs.

Having a dominant position is not in itself unlawful under Article 102. However, the legislation does state that firms in a dominant position have a special responsibility not to abuse their market power by restricting competition either in the market in which they are dominant or in adjacent markets.

Stage 2

In stage 2 of the investigation, the authorities focus on the behaviour of the firm. Final judgements are made about business practices that are potential examples of market abuse. Intel was found guilty of engaging in the following two activities that were seen as examples of exclusionary abuses.

- Discounts were given to four major computer manufacturers (Dell, Lenovo™, HP and NEC) and to the retailer Media-Saturn on the condition that these businesses purchased all or most of their x86 CPUs from Intel.
- Direct payments were made to HP, Acer® and Lenovo on the condition that they postponed or cancelled the launch of products containing x86 CPUs manufactured by AMD.

The fine

The EC imposed a record fine on Intel and ordered the firm to cease the two practices immediately. The size of the fine in monopoly cases is calculated by the EC in the following way.

A proportion of the annual revenue generated by the dominant firm from the sale of the products affected by its illegal conduct is adjusted by a 'duration multiplier' which depends on how many years the abuse lasted.

Typically, it is the annual revenue figure from the final year of the unlawful behaviour that is used in the calculation. For Intel® this was the value of its x86 CPU sales in the whole European Economic Area (EEA) for the business year ending December 2007. Given its confidential nature, this figure was not published in the final report. The proportion of annual revenue was set at 5 per cent. It can be up to a maximum of 30 per cent depending on the seriousness of the infringement. The EC judged that the duration of the exclusionary abuses was from October 2002 to December 2007 – a period of five years and three months. The duration multiplier, however, was set at 5.5 rather than 5.25.

The fine can be reduced if the firm co-operates with the Commission by more than the minimum that is legally required and also terminates the abusive conduct as soon as the Commission intervenes. Neither of these factors applied in the Intel case, so no reductions to the fine were applied.

The final fine was set at €1.06bn.¹ This was the highest financial sanction ever imposed by the EC for abuse of a dominant market position. Intel's annual turnover for the business year ending December 2008 was €25.555bn so the fine was less than 10 per cent of its global turnover – within the limits set by the EC.

Intel challenged the decision by appealing to the General Court. In 2014 (10 years after the investigation began), the General Court announced that it was upholding the EC's decision and Intel was forced to pay the €1.06bn fine.² At the time of writing Qualcomm®, a manufacturer of chipsets for smartphones and tablets, is being investigated by the EC in a very similar case.³

1. What methods are commonly used by competition authorities to define the relevant market?
2. Why might a firm involved in a monopoly case, such as Intel, try to convince the competition authorities to define the relevant market as broadly as possible?
3. Using some examples, explain the difference between exploitative and exclusionary abuse.

¹ 'Commission imposes fine of €1.06 bn on Intel', Press release (European Commission, 13 May 2009).

² 'Commission welcomes General Court judgment upholding its decision', Press release (European Commission, 12 June 2014).

³ 'Commission sends two Statements of Objections to Qualcomm', Press release (European Commission, 8 December 2015).

UK competition policy

There have been substantial changes to UK competition policy since the first legislation was introduced in 1948. The current approach is based on the 1998 Competition Act and the 2002 Enterprise Act, together with Part 3 of the 2013 Enterprise and Regulatory Reform Act.

The Competition Act brought UK policy in line with EU policy, detailed above. The Act has two key sets (or 'chapters') of prohibitions. Chapter I prohibits various restrictive practices, and mirrors EU Article 101. Chapter II prohibits various abuses of monopoly power, and mirrors Article 102. The Enterprise Act strengthened the Competition Act and introduced new measures for the control of mergers.

The 2013 Enterprise and Regulatory Reform Act set up of a new body, the Competition and Markets Authority (CMA), to carry out investigations into particular markets suspected of not working in the best interests of consumers and being in breach of one or more of the Acts. It could make rulings, as we shall see below. Firms affected by a CMA ruling have the right of appeal to the independent Competition Appeal Tribunal (CAT), which can uphold or quash the ruling.

UK restrictive practices policy

The 1998 Competition Act brought UK restrictive practices policy into line with EU policy. In particular, the calculation of fines for anti-competitive behaviour, such as the examples discussed on pages 424–5, was made comparable to the approach used by the European Commission. For example, the size of the available financial penalties was increased so it could be up to 10 per cent of the firm's annual turnover. Also a leniency programme was developed with Type A and B immunity corresponding to EC Type 1A and 1B immunity (see pages 424–5) and Type C immunity corresponding to EC Type 2 immunity.

In December 2016, the CMA ruled that five modelling agencies were guilty of regularly exchanging information and fixing minimum prices for modelling fees.³ Fines totalling £1.5 million were imposed on the businesses involved. The companies launched an appeal so will not qualify for settlement reductions.

In January 2017, two companies involved in the supply of furniture products, Thomas Armstrong (Timber) Ltd and Hoffman Thornwood Ltd, admitted their involvement in market sharing, price fixing and bid-rigging activities.⁴ They were fined a total of £2.8 million. This figure included a 20 per cent reduction as part of the new settlement procedure. A third business involved in the cartel, BHK Ltd, was not fined as it received Type A immunity under the CMA's leniency programme.

The biggest difference between UK and EU policy was created with the passing of the 2002 Enterprise Act. This made it a *criminal* offence for individuals to implement arrangements that enabled price fixing, market sharing, restrictions in production and bid-rigging irrespective of whether there are appreciable effects on competition. Convicted offenders

can receive a prison sentence of up to five years and/or an unlimited fine. Prosecutions can be brought by the Serious Fraud Office or the CMA.

Assessing the policy. When the 2002 Act was introduced it was anticipated that it would result in 6–10 prosecutions per year. In reality, the authorities found the policy more difficult to implement and only three cases were prosecuted between 2002 and 2015, and only one of them successfully: in 2008, three UK executives were jailed for their part in organising a cartel in the marine hose industry.⁵ A case against four BA executives accused of fixing the prices of transatlantic flights collapsed in 2010, while in 2015 the bosses of two companies, Galglass and Kondea, were cleared of fixing the prices of liquid storage tanks.⁶ The boss of the third business involved in the alleged cartel pleaded guilty and received a sentence of six months in prison!

In order to address some of the issues involved with implementing the policy, the 2013 Act included a number of legal amendments to try to make it easier for the CMA to bring successful prosecutions against executives involved in cartel behaviour.

UK monopoly policy

The Chapter II prohibition of the 1998 Competition Act closely mirrors Article 102 of the TFEU. Investigations by the CMA follow the same two-stage process to establish whether the firm (a) has a dominant position and, if so, (b) is using its dominant position to carry out either exploitative or exclusionary abuses. Fines are calculated in a very similar manner to the EC and can be up to 10 per cent of worldwide turnover. One difference between UK and EC policy is that the CMA has the power to ban senior managers from serving as a director of a UK company for up to 15 years.

A recent example of an exploitative abuse case occurred in the pharmaceutical sector. In December 2016, the CMA judged that the pharmaceutical manufacturer Pfizer and distributor Flynn Pharma were guilty of charging excessive and unfair prices for the anti-epilepsy drug Phenytoin Sodium. In September 2012, the price of a 100mg packet of these tablets was increased from £2.83 to £67.50! The CMA imposed a record-high fine on Pfizer of £84.2 million.

In common with other competition authorities, UK agencies have tended to focus on behaviour that is alleged to have excluded competitors from the market. For example, in February 2016 GlaxoSmithKline, the manufacturer of the anti-depressant drug Paroxetine, was fined over £37 million by the CMA for making payments to suppliers of non-branded

versions of this same drug in return for these businesses delaying their entry into the market.

UK merger policy

The framework for merger and acquisition (M&A) policy is set out in the 2002 Enterprise Act. A merger or acquisition can be investigated by the CMA if the resulting company meets one of two conditions: (a) it has a UK turnover that exceeds £70 million or (b) it has a market share of 25 per cent or above. The CMA's assessment is made solely on competition issues. More specifically, M&As can be prevented if they are likely to result in a substantial lessening of competition (SLC).

The final judgement is left to the CMA, apart from in a few exceptional circumstances when a minister can intervene – where the proposed merger or acquisition would have an impact on national security, media plurality or the stability of the financial system. For example, the government intervened in 2008 and allowed the proposed merger between Lloyds TSB and the troubled bank HBOS to go ahead, overruling any objections raised by the competition authorities.

One unusual aspect of UK policy is that there are no obligations on the participating firms to pre-notify the authorities about a merger that meets either of the two conditions. A voluntary notice can be made or the CMA can initiate an investigation following information received from third parties. Around 30 to 40 per cent of merger investigations are typically instigated by the CMA as no notification had been made by the firms involved.

A merger can also be completed before it has been officially cleared by the CMA. If the CMA then decides to prevent it, the firms face the costs of having to split the business back into two separate entities. The 2013 Act increased the CMA's power to force companies to reverse integration activities undertaken prior to an investigation.

The investigation. In other respects UK policy is similar to EU policy. The CMA conducts a preliminary or Phase 1 investigation to see whether competition is likely to be threatened. The 2013 Act introduced a statutory deadline of 40 working days to complete Phase 1 of the process.

At the end of this period the CMA has to decide whether there is a significant chance that the merger would result in a substantial lessening of competition. Sometimes the firms involved will offer to take certain actions to help address any competition concerns. These are known as Undertakings in Lieu (UILs) and usually involve commitments to sell some of the assets of the newly formed business.

If the CMA concludes that there might still be a SLC, it begins Phase 2 of the process, which is a much more in-depth assessment. At the end of this process if no SLC issues are raised, or if they are addressed by any UILs, the merger is allowed to go ahead.

In 2016/17, only five out of the 57 Phase 1 cases were referred for a Phase 2 investigation; 39 cases were cleared unconditionally; nine were cleared after UILs were accepted while one case was judged not to qualify. For example, the

CMA cleared the takeover of the private health-care business, Priory Group, by Acadia Healthcare in November 2016 following a Phase 1 investigation. Acadia had made a UIL to sell 21 hospitals if the merger was cleared.

There is a 24-week statutory time limit for Phase 2 decisions to be made. This can be extended in special circumstances by up to eight weeks. The membership of the team that carries out Phase 2 of the process differs from that which carried out Phase 1 of the investigation. The reasoning behind this is that it is thought to be useful to get a 'fresh pair of eyes' to look at a case. Some M&As are abandoned during the Phase 2 investigations. If the investigations get to the end of Phase 2 the CMA makes one of the following decisions:

- *Unconditional clearance of the merger.* In 2016/17, this happened in 1 out of the 8 cases. For example, in December 2016 the acquisition of LeapFrog by VTech was cleared after a Phase 2 investigation. These two businesses are leading suppliers of toys for learning including tablets for children.
- *Conditional clearance subject to the firms taking certain actions that are legally binding.* These are referred to as 'remedies' and typically involve commitments to sell certain parts of the newly merged business. In 2016/17 this happened in 5 out of the 8 cases. For example, in September 2016 the merger between Ladbrokes and Coral (the second and third largest retail bookmakers in the UK) was given Phase 2 clearance by the CMA with remedies. The newly merged firm had to accept an obligation to sell around 350 to 400 betting shops to a suitable purchaser or purchasers to maintain acceptable levels of competition in some local areas.
- *Prohibition of the merger.* In the 13 years between 2004/5 and 2016/17 only 10 mergers were prohibited out of the 134 Phase 2 investigations that took place. In October 2016, the takeover of Trayport, a company that produces software for utilities trading, by Intercontinental Exchange was prohibited by the CMA.

If anti-monopoly legislation is effective enough, is there ever any need to prevent mergers from going ahead?

Assessment of competition policy

Most commentators agree that it is correct for monopoly policy in both the EU and UK to concentrate on anti-competitive practices and their effects rather than simply on the existence of market dominance. After all, economic power is a problem only when it is abused. When, by contrast, it enables firms to achieve economies of scale, or more finance for investment, the result can be of benefit to consumers. In other words, the assumption that structure determines conduct and performance (see page 190) is not necessarily true, and certainly it is not necessarily true that market power is always bad and competitive industries are always good.

Secondly, most commentators favour the stricter and more prohibitive approach taken towards restrictive practices. The policing and penalties for infringements of Article 101 and Chapter I have become more severe in recent years. For example, the fines imposed by the EC for the period 1990–94 totalled just under €350m. For the period 2010–14 the figure was over €7.5bn.

A problem with any policy to deal with collusion is the difficulty in rooting it out. When firms do all their deals

'behind closed doors' and are careful not to keep records or give clues, then collusion can be very hard to spot. The Leniency Notice was introduced to address this issue.

Merger policy remains the most controversial area of competition policy, with criticisms that far too many are allowed to go ahead. Specific areas of contention with UK policy are whether: (a) firms should be forced to notify the authorities of proposed mergers and be prevented from undertaking any integration activities until the merger is cleared; (b) there

BOX 14.3 MEGABREW

CASE STUDIES AND APPLICATIONS

The merger between the two biggest breweries in the world

On 13 October 2015, the management team of SABMiller (the second largest brewing business in the world) agreed in principle to a \$108 billion takeover offer from AB-InBev (the largest brewing business in the world). Given the size and global nature of these two businesses it soon became obvious that the deal would need to be cleared by numerous competition authorities before it could be completed. This included those of the European Union.

The relevant legislation in Europe that addresses Mergers and Acquisitions (M&As) is the Merger Regulation that came into force on 1 May 2004. Businesses involved in a merger or acquisition that have an 'EU dimension' are obliged to pre-notify the European Commission (EC) and obtain clearance before going ahead with the deal. AB-InBev formally notified the European Authorities of its intention to acquire SABMiller on 30 March 2016.

Once official notification has been received, the EC launches a Phase 1 investigation that usually has to be completed in 25 working days. The investigation focuses on whether the M&A would 'significantly impede effective competition, in the internal market or in a substantial part of it, in particular as a result of the creation or strengthening of a dominant market position' (Article 2(2) and (3)).¹

Although AB-InBev and SABMiller were the biggest two brewers in the world, Heineken® and Carlsberg are the largest in the EU. However, the EC was still concerned that the acquisition of SABMiller by AB-InBev might significantly impede effective competition in member states as it would result in the amalgamation of the third and fourth largest brewers by volume. Unconditional clearance of the deal would have resulted in the same business owning many of the best-selling premium lager brands in Europe including Stella Artois, Beck's, Budweiser, Corona, Peroni, Miller, Pilsner Urquell and Grolsh®.

The investigation

As part of any Phase 1 investigation, the management of the businesses involved can have 'State of Play meetings' with officials from the EC. At these meetings, EC staff can raise any competition concerns they have with the deal and the businesses can respond by offering to take specific actions that they hope will address any issues. The most common action is a commitment to sell off some of the assets of the newly merged business.

Any commitments must be made no later than 20 days following the formal notification of the merger. If a commitment is made it results in the time-frame for the Phase 1 investigation being extended from 25 to 35 working days.

From the beginning of the 'State of Play' meetings, AB-InBev's management team recognised the competition issues of the takeover deal for markets in western Europe. On 8 April 2016, they made a commitment to sell all of SABMiller's businesses in France, Italy, the Netherlands and the UK as a potential remedy for the competition concerns. A price of €2.55 billion for the sale of the assets was agreed with Asahi (the largest Japanese brewery). It included the Peroni, Grolsch and Meantime brands. Following this commitment, the EC extended the deadline for the Phase 1 investigation to 24 May.

At subsequent 'State of Play meetings', EC officials expressed the view that this commitment was not enough to address all their concerns. In particular, they were worried about the impact of the deal on competition in eastern European markets. On 27 April (just inside the 20-working-day deadline) AB-InBev responded by announcing a commitment to sell off all of SABMiller's businesses in the Czech Republic, Hungary, Poland, Romania and Slovakia. This included the following brands: Pilsner Urquell (the best-selling beer in the Czech Republic); Kozel and Tyskie (popular beers in Poland) and Dreher (a best-selling beer in Hungary).

On 24 May the European Commission announced that it would clear the takeover subject to all of the commitments being completed.² In order to get the deal approved by the end of Phase 1 of the investigation, AB-InBev had to agree to sell virtually all of SABMiller's European businesses. In December 2016, it announced the sale of the eastern European businesses to Asahi for a price of €7.3bn.

1. What threshold criteria need be met before a merger is classed as having a European dimension?
2. Discuss the different types of decision made by the European Commission at the end of Phase 1 investigations.
3. Compare and contrast the merger notification systems used in the European Union and the UK.

¹ 'Competition policy', *Fact Sheets on the European Union* (European Parliament).

² 'Commission approves AB InBev's acquisition of SABMiller, subject to conditions', Press release (European Commission, 24 May 2016).

should be a return to a broad public interest test rather than judging mergers purely by their impact on competition.

A review of the whole UK competition regime published by the National Audit Office in February 2016 was critical of the relatively few number of cases investigated. Between 2012 and 2014 the UK authorities issued enforcement fines of £65 million (in 2015 prices). Over the same period the German competition authorities issued fines of £1.4 billion. One explanation for this smaller number of cases may be fear of failure by the CMA. Many firms believe that they have a far greater chance of getting infringement decisions overturned in the UK than in other countries. This fear of successful appeals may deter the CMA from beginning the cases in the first place.

At the time of writing, there is some uncertainty about the impact of the UK's exit from the European Union on competition policy. The current system is referred to as a 'One Stop Shop'. Cases are investigated by either the CMA or the EC but not by both of them. If the UK leaves the Single Market, then both the CMA and EC may have to investigate the same cases. This could result in a big increase in the workload of the CMA. Firms may also face a situation where two different agencies producing contradictory conclusions: i.e. one prohibits while the other clears the same merger.

If two or more firms were charging similar prices, what types of evidence would you look for to prove that this was collusion rather than coincidence?

Section summary

1. Competition policy in most countries recognises that monopolies, mergers and restrictive practices can bring both costs and benefits to the consumer. Generally, though, restrictive practices tend to be more damaging to consumers' interests than simple monopoly power or mergers.
2. European Union legislation applies to firms trading between EU countries. Article 101 applies to restrictive practices. Article 102 applies to dominant firms. There are also separate merger control provisions.
3. UK legislation is covered largely by the 1998 Competition Act, the 2002 Enterprise Act and the 2013 Enterprise and Regulatory Reform Act. The Chapter I prohibition of the 1998 Act applies to restrictive practices and is similar to EU Article 101. The Chapter II prohibition applies to dominant firms and is similar to Article 102. Under the 2002 Act, certain cartel agreements became a criminal offence, and mergers over a certain size must be investigated by the Competition and Markets Authority (CMA).
4. The focus of both EU and UK legislation is on anti-competitive practices rather than on the simple existence of agreements between firms or market dominance. Practices that are found, after investigation, to be detrimental to competition are prohibited and heavy fines can be imposed, even for a first offence.

14.2 PRIVATISATION AND REGULATION

Nationalisation and privatisation

One solution to market failure, advocated by some on the political left, is nationalisation. If industries are not being run in the public interest by the private sector, then bring them into public ownership. This way, so the argument goes, the market failures can be corrected. Problems of monopoly power, externalities, inequality, etc. can be dealt with directly if these industries are run with the public interest, rather than private gain, at heart.

Most nationalisation in the UK took place under the Labour government of 1945–51, when coal, railways, gas and steel were nationalised. The Labour Party at the time saw nationalisation not just as a means of correcting market failures, but as something that was morally desirable. It was seen to be much fairer and less divisive to have a society based on common ownership of the means of production than one where people were divided into separate classes: workers and capitalists.

By the mid-1970s, however, it became increasingly clear that the nationalised industries were inefficient and also a source of much industrial unrest. A change of policy was introduced from the early 1980s, when successive Conservative governments engaged in an extensive programme of 'privatisation', returning virtually all of the **nationalised industries** to the private sector. These, included telecommunications, gas, water, steel, electricity and the railways.

By 1997, the year the Conservatives left office, with the exception of the rail industry in Northern Ireland and the water industry in Northern Ireland and Scotland, the only nationalised industry remaining in the UK was the Post Office (including post offices and mail). The Post Office and

Definition

Nationalised industries State-owned industries that produce goods or services that are sold in the market.

Royal Mail were split in 2012 and Royal Mail was privatised in October 2013. Post Office Ltd remains state owned but, under the 2011 Postal Services Act, there is the option for it to become a mutual organisation in the future.

Other countries have followed similar programmes of privatisation in what has become a worldwide phenomenon. Privatisation has been seen by many governments as a means of revitalising inefficient industries and as a golden opportunity to raise revenues to ease budgetary problems.

In 2008, however, many governments returned to using nationalisation – this time to ‘rescue’ banks which were at risk of going bankrupt. This was facilitated by the EU giving permission for member states to support financial institutions, subject to conditions under EU state aid rules. The use of nationalisation in this *macroeconomic* context of national or international economic crises is examined in section 24.4.

How desirable is privatisation?

Arguments for privatisation

Market forces. The first argument is that privatisation will expose these industries to market forces, from which will flow the benefits of greater efficiency, faster growth and greater responsiveness to the wishes of the consumer. There are three parts to this argument.

- Greater competition in the market. If privatisation involves splitting an industry into competing parts (for example, separate power stations competing to sell electricity to different electricity distribution companies), the resulting competition may drive costs and prices down.
- Greater competition for finance. After privatisation a company has to finance investment through the market: it must issue shares or borrow from financial institutions. In doing so, it will be competing for funds with other companies, and thus must be seen as capable of using these funds profitably.
- Accountability to shareholders. Shareholders want a good return on their shares and will thus put pressure on the privatised company to perform well. If the company does not make sufficient profits, shareholders will sell their shares. The share price will fall and the company will be in danger of being taken over. The market for corporate control (see pages 210–11) thus provides incentives for private firms to be efficient. There has been considerable takeover activity in the water and electricity industries, with most of the regional electricity companies and several of the water companies being taken over, often by non-UK companies.

Reduced government interference. In nationalised industries, managers may frequently be required to adjust their targets for political reasons. At one time they may have to keep prices low as part of a government drive against inflation. At another they may have to increase their prices substantially in order to raise extra revenue for the government and help finance tax cuts. At another they may find their investment programmes cut as part of a government economy drive.

Privatisation frees the company from these constraints and allows it to make more rational economic decisions and plan future investments with greater certainty.

Financing tax cuts. The privatisation issue of shares earns money directly for the government and thus reduces the amount it needs to borrow. Effectively, then, the government can use the proceeds of privatisation to finance tax cuts.

There is a danger here, however, that in order to raise the maximum revenue the government will want to make the industries as potentially profitable as possible. This may involve selling them as monopolies. But this, of course, would probably be against the interests of the consumer.

Potential problems with privatisation

The markets in which privatised industries operate are unlikely to be perfect. What is more, the process of privatisation itself can create problems.

Natural monopolies. The market forces argument for privatisation largely breaks down if a public monopoly is simply replaced by a private monopoly, as in the case of the water companies. Critics of privatisation argue that at least a public-sector monopoly is not out to maximise profits and thereby exploit the consumer.

Some industries have such great economies of scale that there is only room for one firm in the industry. They are natural monopolies. The best examples of natural monopolies are the various grids that exist in the privatised utilities: the national electricity grid, the national gas pipe network, the network of railway lines. These grids account for a relatively high proportion of the total costs of these industries.

In Figure 14.1, assume that the total industry output is Q_1 . With just one company in the industry, long-run average cost is therefore $LRAC_1$. Now assume that the industry is split into two equal-sized companies, each with its own grid. If total output remains at Q_1 , the two firms will produce Q_2 each at the higher long-run average cost of $LRAC_2$.

It is potentially more efficient, therefore, to have a single monopoly supplier whenever there is a natural monopoly. It avoids wasteful duplication.

The problem is that the monopoly producer in a free market could use its power to drive up prices. The long-run profit-maximising position is illustrated in Figure 14.2. The monopolist produces Q_m at a price P_m and at a cost of $LRAC_m$.

If, however, the industry remained nationalised, or if it was privatised but regulated, it could be run as a monopoly and thus achieve the full economies of scale. And yet it could be directed to set a price that just covered costs (including normal profits), and thus make no more profit than a highly competitive industry. In Figure 14.2, it would produce Q_n at a price of P_n . We examine regulation later in this section.

Planning and the co-ordination of industry. Road use and road construction affect the demand for railways and vice versa. Decisions in the coal, electricity, gas and oil industries (and to a large extent in the steel industry) all affect each other. If these industries were nationalised, it should make their decisions easier to co-ordinate in the public interest and could help the sensible planning of the nation's infrastructure. If these industries were under private enterprise, however, either there would be little co-ordination, or alternatively co-ordination might degenerate into oligopolistic collusion, with the consumer losing out. In the extreme case, the same company may have a monopoly in more than one industry. For example, in some regions of the UK, one company runs both buses and trains.

Problems of externalities and inequality. Various industries may create substantial external benefits and yet may be privately unprofitable. A railway or an underground line, for example, may considerably ease congestion on the roads, thus benefiting road as well as rail users. Other industries may cause substantial external costs. Nuclear power stations may produce nuclear waste that is costly to dispose of safely, and/or provides hazards for future generations. Coal-fired power stations emit CO_2 and cause acid rain.

For reasons of equity, it can be argued that various transport services should be subsidised in order to keep them going and/or to keep their prices down. For instance, it can be argued that rural bus services should be kept operating at subsidised prices and that certain people (e.g. pensioners) should be charged lower prices.

Will such externalities and issues of equity be ignored under privatisation? The advocates of privatisation argue that externalities can be dealt with by appropriate taxes, subsidies and regulations even if the industry is privatised. Likewise, questions of fairness and social justice can be dealt with by subsidies or regulations. A loss-making bus service can be subsidised so that it can be run profitably by a private bus company.

Critics argue that externalities are widespread and need to be taken into account by the industry itself and not just by an occasionally intervening government.

In assessing these arguments, a lot depends on the effectiveness of government legislation and regulation.

To what extent can the problems with privatisation be seen as arguments in favour of nationalisation?

Regulation: identifying the optimum price and output

Privatised industries, if left free to operate in the market, will have monopoly power; they will create externalities; and they will be unlikely to take into account questions of fairness. An answer to these problems is for the government or some independent agency to regulate their behaviour so that they produce at the socially optimum price and output.

Exactly what this optimum is depends on what problems need to be taken into account. Take three cases. In the first, the privatised industry is a monopoly (perhaps it is a natural monopoly), but there are no other problems. In the second case, there are also externalities to be considered, and in the third, questions of fairness too.

The privatised industry is a monopoly

The 'first-best' situation: $P = MC$. Assume that all other firms in the economy are operating under perfect competition, and thus producing where $P = MC$. This is the imaginary 'first-best' situation. If this were so, the privatised company should be required to follow the same pricing rule: $P = MC$. As we saw in section 12.1, this will give the Pareto optimal output, where total consumer plus producer surplus is maximised (see pages 348–51).

The theory of the 'second best': $P = MC + Z$. Now let us drop the assumption that the rest of the economy operates under perfect competition. If other industries on average are charging a price, say, 10 per cent above MC , then the theory of the second best suggests that the privatised company

Figure 14.2 Profit-maximising natural monopoly

should also charge a price 10 per cent above MC . At least that way it will not cause a diversion of consumption away from relatively low-cost industries (at the margin) to a relatively high-cost one. The second-best rule is therefore to set $P = MC + Z$, where Z in this case is 10 per cent.

The privatised industry produces externalities

In the first-best situation the privatised industry should produce where price equals marginal social (not private) cost: $P = MSC$. The second-best solution is to produce where $P = MSC + Z$ (where Z is the average of other industries' price above their MSC).

The difficulty for the regulator in applying these rules in practice is to identify and measure the externalities: not an easy task! (See section 12.4.)

The behaviour of the privatised industry involves questions of fairness

If the government wishes the regulator to insist on a price below MC because it wishes to help certain groups (e.g. pensioners, children, rural dwellers, those below certain incomes), what should this price be?

In practice, one of two simple rules could be followed. Either the industry could be required to charge uniform prices, despite higher costs for supplying certain categories of people (this could apply, for example, to rural customers of a privatised postal service); or a simple formula could be used (e.g. half price for pensioners and children). These are often the only practical solutions given the impossibility of identifying the specific needs of individual consumers.

Two further questions arise:

- Should the lower price be subsidised by central or local government, or by the privatised company and hence by other users of the service (i.e. by them paying higher prices)? Justice would suggest that support should come from the community as a whole – the taxpayer – and not just from other users of the service.
- If people require help, should they not be given general tax relief or benefits, rather than specifically subsidised services? For example, should pensioners not be paid better pensions, rather than be charged reduced fares on buses?

1. In the case of buses, subsidies are often paid by local authorities to support various loss-making routes. Is this the best way of supporting these services?
2. In the case of postal services, profitable parts of the service cross-subsidise the unprofitable parts. Should this continue if the industry is privatised?

The long run

In the short run, certain factors of production are fixed in supply. For example, electricity output can be increased by using existing power stations more fully, but the number of power stations is fixed. There will thus be a limit to the

amount of electricity that can be generated in the short run. As that limit is approached, the marginal cost of electricity is likely to rise rapidly. For example, oil-fired power stations, which are more costly to operate, will have to be brought on line.

In the long run, all factors are variable. New power stations can be built. The long-run marginal costs therefore will probably not rise as more is produced. In fact, they may even fall due to economies of scale.

Long-run marginal costs, however, unlike short-run marginal costs, will include the extra capital costs of increasing output. The long-run marginal cost of electricity will thus be all the extra costs of producing one more unit: namely, the extra operating costs (fuel, labour, etc.) plus the extra capital costs (power stations, pylons, etc.).

The rule for the optimum long-run price and output is simple. The regulator should require the industry to produce where price equals long-run marginal social cost ($LRMSC$). This is illustrated in Figure 14.3.

In the short run, optimum price and output are P_S and Q_S where $P =$ (short-run) MSC . This might mean that production is at quite a high cost: existing capital equipment is being stretched and diminishing returns have become serious.

In the long run, then, it will be desirable to increase capacity if $LRMSC < MSC$. Optimum long-run price and output are thus at P_L and Q_L where $P = LRMSC$.

This is the rule for the first-best situation. In the second-best situation, the industry should produce where $P = LRMSC + Z$ (where Z is the average of other industries' price above their $LRMSC$).

? If the regulator imposed such rules, would they cause the firm to make a loss if it faced a downward-sloping $LRMSC$ curve? (Clues: Where would the $LRAC$ curve be relative to the $LRMC$ curve? What would be the effect of externalities and the addition of the Z factor on the price?)

Figure 14.3 Short-run and long-run marginal cost pricing

Regulation in the UK

To some extent the behaviour of privatised industries may be governed by general monopoly and restrictive practice legislation. For example, in the UK privatised firms can be investigated by the Competition and Markets Authority (CMA). In addition to this there may be separate regulatory offices to oversee the structure and behaviour of each of the privatised utilities. In the UK these regulators are as follows: the Office for Gas and Electricity Markets (Ofgem), the Office of Communications (Ofcom) (for telecommunications and broadcasting), the Office of Rail and Road (ORR) and the Office of Water Services (Ofwat).

The regulators set terms under which the industries have to operate. For example, the ORR sets the terms under which rail companies have access to the track and stations. The terms set by the regulator can be reviewed by negotiation between the regulator and the industry. If agreement cannot be reached, the CMA acts as an appeal court and its decision is binding.

The regulator for each industry also sets limits to the prices that certain parts of the industry can charge (see Case Study 14.6 on the student website). These parts are those where there is little or no competition: for example, the charges made to electricity and gas retailers by National Grid, the owner of the electricity grid and major gas pipelines.

Price-setting formulae were largely of the 'RPI minus X' variety (although other factors, including competition and excessive profits, are also taken into account). What the RPI minus X formula means is that the industries can raise their prices by the rate of increase in the retail price index (RPI) (i.e. by the rate of inflation) *minus* a certain percentage (X) to take account of expected increases in efficiency. Thus if the rate of inflation were 3 per cent, and if the regulator considered that the industry (or firm) could be expected to reduce its costs by 2 per cent ($X = 2\%$), then price rises would be capped at 1 per cent. The RPI – X system is thus an example of **price-cap regulation**. The idea of this system of regulation is that it will force the industry to pass cost savings on to the consumer. In 2013, Ofgem replaced RPI – X with RIIO (Revenue = Incentives + Innovation + Outputs). The aim of these price controls is to encourage more innovation.

Whether these price controls will result in marginal cost pricing depends on what the price was in the first place. If the price was equal to marginal cost, and if the X factor is the amount by which the regulator expects the MC curve to shift downwards (after taking inflation into account), then the formula could result in marginal cost pricing.

Why might it equally result in average cost pricing?

Assessing the system of regulation in the UK

The system that has evolved in the UK has various advantages over that employed in the USA and elsewhere, where regulation often focuses on the level of profits (see Case Study 14.6 on the student website).

- It is a discretionary system, with the regulator able to judge individual examples of the behaviour of the industry on their own merits. The regulator has a detailed knowledge of the industry which would not be available to government ministers or other bodies such as the CMA. The regulator could thus be argued to be the best body to decide on whether the industry is acting in the public interest.
- The system is flexible, since it allows for the licence and price formulae to be changed as circumstances change.
- The 'RPI minus X' formula provides an incentive for the privatised firms to be as efficient as possible. If they can lower their costs by more than X, they will, in theory, be able to make larger profits and keep them. There is thus a continuing pressure on them to cut costs. (In countries where profits rather than prices are regulated, there is little incentive to increase efficiency, since any cost reductions must be passed on to the consumer in lower prices, and do not, therefore, result in higher profits.)

There are, however, some inherent problems with the regulation as it has been operated in the UK:

- The 'RPI minus X' formula was designed to provide an incentive for firms to cut costs. But if regulators underestimated the scope for cost reductions resulting from new technology and reorganisation, and set X too low, firms could make excessive profits. Where this has happened, regulators have changed the value of X after only one or two years. Alternatively, one-off price cuts have been ordered, as happened when the water companies were required by Ofwat to cut prices by an average of 10 per cent in 2000. In either case, this then removes the incentive for the industry to cut costs. What is the point of being more efficient if the regulator is merely going to take away the extra profits?
- With RPI minus X reducing firms' profits, the outcome may be reduced investment and innovation. Given the need for greater investment in power generation, in 2013 Ofgem introduced a new system for controlling prices in the distribution part of the energy sector. This is called RIIO (Revenue = Incentives + Innovation + Outputs).

Definition

Price-cap regulation Where the regulator puts a ceiling on the amount by which a firm can raise its price.

This is a new performance-based model which aims to incentivise innovation and a reduction of future costs. It also allows the climate change agenda to be addressed as part of the price control process.

- Regulation has become increasingly complex. This makes it difficult for the industries to plan and may lead to a growth of 'short-termism' as firms are subjected to short-term changes in regulation or government intervention. It is likely to result in resources being wasted as the industry spends time and energy trying to outwit the regulator.
- Alternatively, there is the danger of **regulatory capture**. As regulators become more and more involved in their industry and get to know the senior managers at a personal level, so they are increasingly likely to see the managers' point of view and will thus become less tough.
- The regulators could, instead, be 'captured' by the government. Rather than being totally independent, there to serve the interests of the consumer, they might bend to pressures from the government to do things that might help the government win the next election.

One way in which the dangers of ineffective or over-intrusive regulation can be avoided is to replace regulation with competition wherever this is possible. Indeed, one of the major concerns of the regulators has been to do just this. (See Box 14.4 for ways in which competition has been increased in the electricity industry.)

Increasing competition in the privatised industries

Where natural monopoly exists, competition is impossible in a free market. Of course, the industry could be broken up by the government, with firms prohibited from owning more than a certain percentage of the industry. But this would lead to higher costs of production. Firms would be operating further back up a downward-sloping long-run average cost curve.

But many parts of the privatised industries are not natural monopolies. Generally, it is only the grid that is a natural monopoly. In the case of gas and water, it is the pipelines. It would be wasteful to duplicate these. In the case of electricity, it is the power lines: the national grid and the local power lines. In the case of the railways, it is the track.

Other parts of these industries, however, have generally been opened up to competition (with the exception of water). Thus there are now many producers and sellers of

electricity and gas. This is possible because they are given access, by law, to the national and local electricity grids and gas pipelines.

To help the opening up of competition, regulators have sometimes restricted the behaviour of the established firms (like BT or British Gas), to prevent them using their dominance in the market as a barrier to entry of new firms.

As competition has been introduced into these industries, so price-cap regulation has been progressively abandoned. The intention is ultimately to confine price regulation to the operation of the grids: the parts that are natural monopolies.

Even for the parts where there is a natural monopoly, they could be made contestable monopolies. One way of doing this is by granting operators a licence for a specific period of time. This is known as **franchising**. This has been the approach used for the railways (see Case Study 14.8 on the student website). Once a company has been granted a franchise, it has the monopoly of passenger rail services over specific routes. But the awarding of the franchise can be highly competitive, with rival companies putting in competitive bids, in terms of both price (or, in the case of many of the train operating companies, the level of government subsidy required) and the quality of service.

Another approach is to give all companies equal access to the relevant grid. For example, regional electricity companies have to charge the same price for using their local power lines to both rival companies and themselves.

But despite attempts to introduce competition into the privatised industries, they are still dominated by giant companies, which retain considerable market power. This is a long way from perfect competition and there is scope for price leadership or other forms of oligopolistic collusion. Although regulation through the price formula has been progressively abandoned as elements of competition have been introduced, the regulators have retained an important role in preventing collusion and the abuse of monopoly power.

Definitions

Regulatory capture Where the regulator is persuaded to operate in the industry's interests rather than those of the consumer.

Franchising Where a firm is granted the licence to operate a given part of an industry for a specified length of time.

BOX 14.4 SELLING POWER TO THE PEOPLE

The impact of privatisation and competition in the electricity industry

Competition is generally seen as better than regulation as a means of protecting consumers' interests, but there is evidence that this requires a strong regulatory framework to be retained. The electricity industry provides a good case study on the impact of the introduction of competition into a privatised industry.

The industry before privatisation

Under nationalisation, the industry in England and Wales was organised as a monopoly with the Central Electricity Generating Board (CEGB) supplying 99 per cent of all electricity. It operated the power stations and transmitted the electricity round the country via the national grid. However, the CEGB did not sell electricity directly to the consumer; rather it sold it to 12 regional boards, which in turn supplied it to the consumer.

Privatisation of the industry

Non-nuclear generation in England and Wales was privatised in 1990 as two companies: National Power (with just over 50 per cent of capacity) and PowerGen (with nearly 30 per cent). Nuclear power stations were privatised in 1996.

The 12 regional boards were privatised in 1991 as separate regional electricity companies (RECs), which were responsible for local distribution and supply to consumers. They were also permitted to build their own power stations if they chose. The RECs jointly owned the national grid, but it was run independently. It was eventually sold as a separate company in 1996. The national grid is now managed and operated by National Grid Electricity Transmission plc, a subsidiary of the multinational business National Grid.

The diagram shows the structure of the industry. Electricity is produced by the *generators* (the power stations).

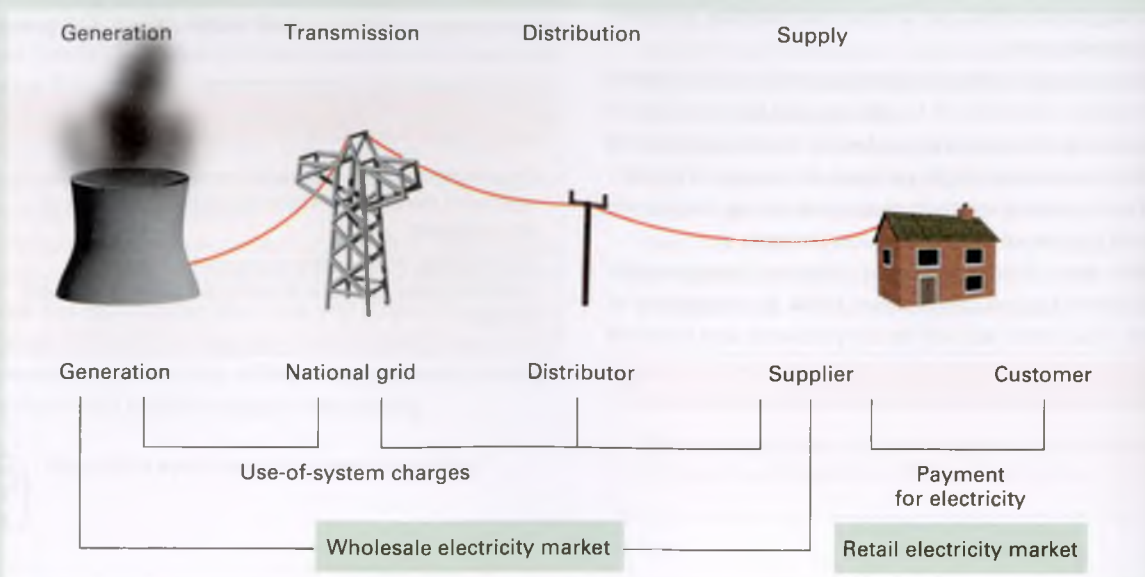

The electricity is *transmitted* along the power lines of the national grid to different parts of the country. It is then transmitted locally by the *distributors*. There are currently 14 licensed distribution network operators (DNOs) in Britain which are responsible for the distribution of electricity from the high voltage transmission grid to businesses and households.

At the time of privatisation an Office of Electricity Regulation (OFFER) was set up to control prices in parts of the industry where there was no competition. OFFER was later merged with the gas regulator to become the Office of Gas and Electricity Markets (Ofgem). Where prices have been controlled, this has been of the *RPI - X* variety (see page 436). For example, the charges paid by the generators and the suppliers to the National Grid Electricity Transmission company are regulated in this way, as this part of the business is considered to be a natural monopoly. The same is true for the DNOs, as each has a natural monopoly in the region for which it is responsible. In 2013 Ofgem replaced the *RPI - X* price controls with Revenue = Incentives + Innovation + Outputs (RIIO). As the name suggests, these set targets to encourage innovation.

The rationale behind introducing the new structure was to increase competition, thereby making regulation increasingly unnecessary. But given the natural monopoly market structure in both transmission and distribution, where was the competition supposed to come from?

It was hoped that competition would be possible at two levels: at the *wholesale* level, with generators competing with each other to sell to suppliers; and at the *retail* level, with suppliers competing to sell to customers. Let us examine each of these markets in turn.

The electricity industry in England and Wales

Competition in the wholesale market for electricity: NETA and BETTA

From 2001 in England and Wales electricity was traded in the wholesale market under the New Electricity Trading Arrangements (NETA). In April 2005, this system was extended to Scotland and renamed the British Electricity Trading and Transmission Arrangements (BETTA). Participants in the market include generators, suppliers, large commercial consumers of electricity and traders (i.e. dealers).

In this market, bulk electricity is traded 'forward' in bilateral contracts between individual buyers and sellers. A forward contract means that a price is agreed today for an amount of electricity to be traded over a particular period in the future, which could be as soon as the next day or could be three or more years hence. The long forward contracts are to allow generators to plan to build extra capacity.

Of course, the future price will be based on anticipated demand, and demand in practice may turn out quite differently. To allow for this, BETTA operates a 'central balancing mechanism'. This is a system of buying and selling additional electricity where necessary to ensure that demand actually balances supply second by second. In practice, only about 2 per cent of electricity has to be traded under the balancing mechanisms; the remainder is traded in the forward contracts.

Concerns were expressed that, with the market dominated by the 'Big Six' major producers, 'liquidity'¹ had declined since 2001 and was low compared to that of many other countries and other commodity markets. A low level of liquidity makes it difficult for firms to enter the market and operate as a non-vertically integrated market participant.

Competition in the retail market for electricity

Since 1999 all customers, whether domestic or business, have been able to choose their supplier. Over that period there have been several new entrants into the supplier market, including various gas companies diversifying into electricity supply.

By 2001, 38 per cent of customers had switched suppliers at least once and the former regional monopoly suppliers' market share had fallen to 70 per cent. In the light of this Ofgem announced that competition was sufficiently developed to allow all regulation of the retail market to be removed by April 2002.

However, the rise of the Big Six, which resulted from mergers and takeovers in the industry, meant that by 2004 they had a 99 per cent share of the retail market. With the rise of smaller independent retailers, this had fallen to 85 per cent by 2016 – still a substantial share.

The CMA inquiry

In 2014, the CMA launched the most comprehensive and wide-ranging review of the energy market since privatisation. This followed a number of investigations carried out by the sector regulator, Ofgem, in response to concerns about the functioning of the energy market. For example, between 2004 and 2014 average domestic electricity prices increased by 75 per cent in real terms. One important issue is whether this was the result of market power or simply reflected rising costs in the sector.

Earlier Ofgem investigations

Ofgem published the results from its first investigation into the market in 2009. The Energy Supply Probe concluded that there was no evidence of collusion in the retail market but proposed a number of remedies to help the market work more effectively. This included improvements in the way information on bills was presented to customers.

In late 2010 Ofgem launched its Retail Market Review (RMR).³ This report recognised that some improvements had been made but that energy bills were still too complex, making it difficult for consumers to find the best deals. For example, there were over 300 different tariffs available to domestic users! The review recommended that tariffs should be calculated on simple per-unit pricing and energy suppliers limited to offering only four different deals – 'the four-tariff rule'.

After carrying out these reviews, Ofgem concluded that its powers as a market regulator were insufficient to determine whether barriers were blocking effective competition. In June 2014, it referred the energy market to the CMA for a full investigation.

The CMA inquiry

The inquiry took two years to complete and the final report was published in June 2016.⁴ Some of its key findings were:

- The wholesale market for electricity was working effectively with no evidence of firms exploiting any market power.
- Vertical integration between the suppliers and generators was not having any negative impact on consumers. Independent electricity generators were able to compete effectively with those that were vertically integrated with the energy suppliers.
- A number of new firms had successfully entered the retail market and had increased their market shares.
- A significant number of customers did not actively engage in the market by shopping around for the best deals. For example, in a survey of 7000 domestic customers carried out as part of the inquiry, 34 per cent of respondents stated that they had never considered switching energy supplier.
- Approximately 70 per cent of the customers of the Big Six were on a standard variable tariff (SVT). Customers are placed on these default pricing schemes if they fail to shop around and actively choose a deal.
- The tariffs available to those people who did shop around closely followed changes in industry costs. However, the gap between SVT and industry costs had increased significantly in recent years.
- The majority of customers using prepayment meters were on SVTs because of low levels of competition. This was partly due to the limitations of non-smart meters.
- The restriction on the number of tariffs imposed by Ofgem following its 2010 review had had a negative impact on competition. It forced some firms to withdraw pricing schemes that had previously benefited many customers.
- A large number of small businesses (those employing fewer than 10 people) were on expensive default schemes. The tariffs available to these businesses were not published by the energy suppliers but were instead the outcome of individual-level negotiation.

In response to these findings, the CMA made the following recommendations:

- The creation of a database that includes the details of customers who have been on the SVT for three years or more. Energy suppliers would have access to this database to offer better deals for these customers. The aim of this reform was to reduce switching costs.
- The 'four-tariff' rule on energy suppliers should be scrapped.
- Energy companies supplying businesses employing fewer than 10 people should publish the different available tariffs to increase transparency and make it easier for these small businesses to choose the best deal.
- A temporary price cap (2017–20) should be introduced for those customers using prepayment meters.

The most controversial aspect of the report was a disagreement amongst its panel members over the policy option of imposing a price cap on SVTs for all customers. Four of the five panel members concluded that it would undermine competition, while the other panel member, Martin Cave, believed that a price cap was required in the short term to address the lack of competitive pressure on SVTs.

The outcome

Ofgem agreed to implement the CMA's recommendations. In February 2017, it announced that a temporary price cap for customers using prepayment meters would come into effect in April 2017. The level of the cap would vary by meter type and region. It would also be reviewed every six months and remain in place until 2020. It also announced that the database would be available in 2018.

Controversy continues about the possibility of introducing a price cap for all customers on SVTs. In March 2017, there was continued speculation that the government might impose price controls and Conservative MP John Penrose called for a 'relative price cap' to be introduced. This would force energy suppliers to price their most expensive tariffs such as the SVT at no more than 6 per cent above their cheapest deal.

In October 2017 the Government published draft legislation for the introduction of a price cap on the most expensive SVTs. It will be interesting to see how competition and regulation in the electricity industry continues to evolve over the next few years.

1. *Wholesale and retail energy markets are expected to deliver on a number of targets including competitive pricing, environmental objectives and equity. Explain why this may present problems.*
2. *Why do you think switching rates have been so low in the retail energy market?*
3. *Assess some of the arguments for and against the use of price caps for all customers on SVTs.*

1 Ofgem defines liquidity as the ability to quickly buy or sell a desired commodity or financial instrument without causing a significant change in its price and without incurring significant transaction costs. An important feature of a liquid market, it says, is that it has a large number of buyers and sellers willing to transact at all times. A high level of liquidity is seen as being good because it enables new players to enter the market and reduces the ability of incumbents to manipulate it (*Utility Week*, 3 September 2009).

3 'Retail market review', *Market Review and Reform* (Ofgem).

4 'Energy Market Investigation: Overview' (Competition and Market Authority, 24 June 2016).

Section summary

1. From around 1983 the Conservative government in the UK embarked on a large programme of privatisation. Many other countries have followed suit.
2. The economic arguments for privatisation include: greater competition, not only in the goods market but in the market for finance and for corporate control; reduced government interference; and raising revenue to finance tax cuts.
3. The economic arguments against privatisation of utilities include the following: the firms are likely to have monopoly power because their grids are natural monopolies; it makes overall planning and co-ordination of the transport and power sectors more difficult; and the industries produce substantial externalities and raise questions of fairness in distribution.
4. Regulators could require firms to charge the socially efficient price. In the first-best world, this will be where price equals marginal social cost. In the real world, this is not the case given that prices elsewhere are not equal to marginal social costs. Ideally, prices should still *reflect* marginal social costs, but there are difficulties in identifying and measuring social costs.
5. In the long run, the optimum price and output will be where price equals long-run marginal social cost. If $LRMSC < MSC$, it will be desirable to invest in additional capacity.
6. Regulation in the UK has involved setting up regulatory offices for the major privatised utilities. These use negotiation and bargaining to persuade the industries to behave in the public interest and set the terms under which firms can operate (e.g. access rights to the respective grid).
7. As far as prices are concerned, the industries have generally been required to abide by an 'RPI minus X' formula, or some variant of it, in all sectors where there is a lack of competition. This means that potential cost reductions are passed on to the consumer while allowing them to retain any additional profits gained from cost reductions greater than X. This has provided them with an incentive to achieve even greater increases in efficiency, but may not have incentivised innovation.
8. Many parts of the privatised industries are not natural monopolies. In these parts, competition has been seen as a more effective means of pursuing the public interest. Various attempts have been made to make the privatised industries more competitive, often at the instigation of the regulator. Nevertheless, considerable market power remains in the hands of many privatised firms, and thus regulators need to be able to retain the ability to prevent the abuse of monopoly power.

END OF CHAPTER QUESTIONS

- Should governments or regulators always attempt to eliminate the supernormal profits of monopolists/oligopolists?
- Compare the relative merits of banning certain types of market *structure* with banning certain types of market *behaviour*.
- Consider the argument that whether an industry is in the public sector or private sector has far less bearing on its performance than the degree of competition it faces.
- If two or more firms are charging similar prices, does this imply that collusion is taking place? What evidence would you need to determine the existence of collusion?
- There exists a view that the UK is too small an economy to benefit from competition in many industries, with firms failing to reach minimum efficient scale. What does this imply for competition policy?
- Should regulators of utilities that have been privatised into several separate companies allow (a) horizontal mergers (within the industry); (b) vertical mergers; (c) mergers with firms in other industries?
- Summarise the relative benefits to consumers of (a) privatising a nationalised industry, (b) keeping it in the public sector but introducing competition.
- If an industry regulator adopts an $RPI - X$ formula for price regulation, is it desirable that the value of X should be adjusted as soon as cost conditions change?
- Examine the case for public ownership of an industry where a natural monopoly exists.
- If price regulation results in lower profits, will this always imply lower investment? How might a government incentivise innovation in a regulated industry?
- Price-cap regulation was abandoned in the gas and electricity industries because the regulator (Ofgem) felt that there was sufficient competition. Consider whether this was a wise decision.

Foundations of Macroeconomics

- | | | |
|-----------|--|------------|
| 15 | An Introduction to Macroeconomic Issues and Ideas | 444 |
| 16 | The Development of Macroeconomic Thinking: a Historical Perspective | 491 |

Why do economies sometimes grow rapidly, while at other times they suffer from recession? Why, if people want to work, do they sometimes find themselves unemployed? Why do economies experience inflation (rising prices), and does it matter if they do? Why do exchange rates change and what will be the impact of such changes on imports and exports? Why do individuals, firms and governments borrow and what are the implications of borrowing and debt for the economic health of countries? These macroeconomic issues affect all countries, and economists are called on to try to find explanations and solutions.

In the next two chapters we will be looking at these issues and giving you a preliminary insight into the causes of these problems and what governments can do to tackle them. In the second of these chapters (Chapter 16) we shall see how macroeconomics has developed over the years as economists have sought to explain the macroeconomic problems of the time – right up to the financial crisis and recession of recent years.

We turn now to macroeconomics. This will be the subject of the second half of this book. As we have already seen, microeconomics focuses on individual markets. It studies the demand for and supply of, for example, oranges, music downloads, petrol and haircuts; bricklayers, doctors, office accommodation and computers. It examines the choices people make between goods, and what determines their relative prices and the relative quantities produced.

In macroeconomics we take a much broader view. We examine the economy as a whole. We still examine demand and supply, but now it is the total level of spending in the economy and the total level of production. In other words, we examine aggregate demand and aggregate supply.

We still examine output, employment and prices, but now it is national output and its rate of growth, national employment and unemployment, and the general level of prices and their rate of increase (i.e. the rate of inflation).

In this chapter, we identify the major macroeconomic issues facing society. Among these is the volatility of the economy. This volatility is perhaps most evident in the fluctuations we see in the economy's output, but we observe it too in other macroeconomic variables, such as unemployment and inflation.

By providing an overview of macroeconomics, this chapter provides the platform necessary to analyse in subsequent chapters some of the key debates of our time.

15.1 AN OVERVIEW OF KEY MACROECONOMIC ISSUES

Macroeconomics examines various issues affecting whole economies. Many of these are the big issues on which elections are won or lost.

Is the economy growing and, if so, how rapidly? How can we avoid, or get out of, recessions? What causes unemployment and how can the rate be got down? Why is inflation sometimes a problem and what can be done to keep rates of inflation at modest levels? Conversely, why do prices sometimes fall, and does this itself create a problem? What will happen to interest rates? How big a problem is government debt? Are financial institutions lending too much or too little? What affects a country's balance of trade in goods and services? How attractive is the country as a destination for investment by foreign businesses?

Major macroeconomic issues

The questions we have just identified give you a flavour of the macroeconomic issues that we will be studying in the following chapters. For simplicity, we will group them under the following headings: economic growth, unemployment, inflation, economic relationships with the rest of the world, the financial well-being of individuals, businesses and government and the relationship between the financial system and the economy. While we will be studying other issues too, such as consumer behaviour and taxation, these still link to these major macroeconomic issues and, more generally, to how economies function.

The purpose of this section is to provide you with some background on these key issues and to look at some key

macroeconomic data. This allows us to put these issues into context before later considering them in more depth.

Economic growth and the business cycle

One of the most basic concerns for macroeconomists is understanding what affects the level of an economy's output and, in turn, what causes it to rise or fall. *Economic growth* is the term economists use to describe the change in the level of an economy's output from period to period. The rate of economic growth measures the percentage change in output. This is usually measured over short periods, such as 12 or 3 months. If we measure the *rate of growth* over a 12-month period we are measuring the economy's annual rate of growth, while if we measure it over a 3-month period we are measuring the quarterly rate of growth.

One of the most important observations to make about economic growth is its *volatility*. This is evident from Figure 15.1, which plots the annual rates of growth of a selection of economies.

Economies suffer from inherent instability. As a result, economic growth and other macroeconomic indicators tend to fluctuate.

Definitions

Rate of economic growth The percentage increase in national output, normally expressed over a 12-month or 3-month period.

Figure 15.1 Growth rates in selected industrial economies

Notes: 2017 to 2020 based on forecasts; eurozone figures are the weighted average of the countries using the euro in any given year; the euro was introduced in 1999; the eurozone figures before 1999 are the weighted average of the original members.

Countries rarely experience stable economic growth; instead, growth rates tend to fluctuate. Understanding the volatility of economic growth and its effects is the focus of much analysis by macroeconomists. After all, fluctuating activity levels are likely to affect the behaviour and well-being of many of us. In 2009, for example, the UK economy shrank by 4.5 per cent, unemployment levels rose from 1.6 million during 2007 to 2.7 million by 2011 and the government experienced a 4.5 per cent fall in its receipts between tax years 2007/8 and 2009/10.

The significance of the volatility of short-term economic growth makes it our next threshold concept. It is the volatility of growth that gives rise to the well-known phenomenon of the *business cycle*. The business cycle refers to the fluctuations we observe in the path traced out from period to period in an economy's output level. Because rates of economic growth affect an economy's output path, the more growth rates vary the more marked are the fluctuations in this path.

To illustrate the effect of fluctuating growth rates on an economy's output path consider Figure 15.2. This shows the volume of output and the annual rate of economic growth in three advanced economies, France, the UK and the USA, since 1990.

The fluctuating nature of economic growth is most starkly illustrated in the late 2000s. In 2009 the volume of output shrunk by around 3 per cent in France and the USA compared with the year before and by 4.5 per cent in the UK. Compare this, for example, with growth rates in the period 1998–2000, when output rose by over 3 per cent per year in all three countries.

The key point here is that if the rate of growth from year to year were constant, then the bars would be the same height and the output level lines would be smoothly upward sloping.¹ Clearly, this is not the case and it is the fluctuations in short-term growth rates, including periods when economic growth is very weak or even negative, that gives rise to the business cycle. In other words, economies experience neither constant growth nor continued expansion.

We will refer frequently to the volatility of economies in the second half of the book. But, given its central importance to much of the subsequent analysis we will provide an overview of economists' thinking on this important issue in section 15.3.

Definitions

Business cycle or trade cycle The periodic fluctuations of national output. Periods of rapid growth are followed by periods of low growth or even decline in national output.

¹ With the index plotted on the vertical axis, a constant growth rate would be shown by a line whose slope gradually increased, as a constant percentage increase would give a steeper line, the higher the index. For example, a 5 per cent annual growth rate from an index of 100 in year 1, would give an index of 105 in year 2, whereas a 5 per cent annual growth rate from an index of 200 in, say, year 10 would give an index of 210 in year 11. Thus the slope between years 10 to 11 would be twice that between years 1 and 2 and yet the growth rate would be identical. If the vertical axis were measured in a *log scale*, then a constant growth rate would be shown as a straight line.

Figure 15.2 Output paths and growth rates of France, UK and USA

Notes: Data for 2017 onwards are based on forecasts.

Source: Based on data in *World Economic Outlook Database* (IMF, October 2017).

THRESHOLD CONCEPT 12

SHORT-TERM GROWTH IN A COUNTRY'S OUTPUT
TENDS TO FLUCTUATETHINKING LIKE AN
ECONOMIST

Countries rarely experience stable economic growth. Instead they experience *business cycles*. Periods of rapid economic growth can be followed by periods of low growth or even negative growth (falling output).

Explaining volatility

Sometimes rising or falling output can be explained by the deliberate actions of governments or central banks (such as the Bank of England). For example, a rise in government spending, a reduction in taxes or a reduction in interest rates may stimulate the economy and raise the rate of economic growth.

But fluctuations in economic growth can often be explained by the working of the market system.

Some economists see the problem as rooted in fluctuations in *aggregate demand*: in other words, in the total demand for the economy's goods and services, whether by individuals or firms (see page 459). What is more, changes in the demands of individuals and firms may interact with each other, affecting the character of the business cycle. For example, a rise in consumer expenditure could stimulate firms to invest in order to build up capacity to meet the extra demand. This, in turn, generates more employment, additional national income and

so more consumption. A similar effect could occur if banks felt able to lend more in response to the growing economy, which would further stimulate the economy as these funds are spent.

Other economists see the problem as rooted in fluctuations in *aggregate supply*: in other words, in the total amount of goods and services firms plan to supply at a given level of prices (see page 462). These 'real-business-cycle' economists argue that changes in aggregate supply occur if the price, availability or effectiveness of the inputs in firms' production processes are in some way affected. One example could be technological changes that boost output and employment. Often such changes come in waves, which would contribute to the observed volatility of output.

But whatever the cause, it is vital to recognise the fundamental instability of market economies. This is what makes the volatility in short-term growth rates a threshold concept.

1. If people believe that the economy's output level is about to fall, how may their actions aggravate the problem?
2. Why will some people suffer more than others from a downturn in economic activity?

Longer-term economic growth

Although growth rates fluctuate, most economies experience positive growth over the longer term. In other words, most economies have output paths that trend upwards over time. We can see this in Figure 15.2, for example. Therefore, we need to distinguish between short-run and long-run economic growth.

While an analysis of short-run growth involves understanding the determinants of the business cycle, analysing long-run economic growth involves understanding what affects a country's capacity to produce. This is because, for growth to be sustained over the longer term, the economy's capacity must increase.

Table 15.1 shows the average annual growth in output by decade since the 1960s for selected countries. As you can see, the differences between countries are quite marked. There are also big differences between the growth rates of individual countries in different periods. Look, for example, at the figures for Japan. From being an 'economic miracle' in the 1960s, by the 1990s Japan had become a laggard, with growth rates well below the OECD average.

The final column of the table takes an even longer-term perspective by focusing on the average annual rate of economic growth from 1960 to 2019. We still observe differences in growth rates, even when averaged over many years.

Table 15.1 Economic growth rates (average % per annum)

	1960s	1970s	1980s	1990s	2000s	2010s	1960–2019

Source: OECD.

While some of the differences may not appear particularly large, it is important to bear in mind that even small differences in the figures have potentially significant implications for economic development and the well-being of nations when you consider that these differences are being compounded year after year.

? Compare economic growth rates in the early 2010s with those in other periods. What explanations can you offer for the differences?

Unemployment

The inherent instability of economies has implications for the number of people in work and so for the number unable to find work. After all, higher levels of economic activity will tend to decrease unemployment numbers, while reduced economic activity will tend to increase them.

In addition, many countries have seen significant effects on the labour market of rapid industrial change, technological advance and globalisation. Hence, labour markets need to be able to adapt to the dynamic environment in which they operate, not only for the sake of those who are made unemployed, but also because it represents a waste of human resources and because unemployment benefits are a drain on government revenues.

Unemployment can be expressed either as a number (e.g. 1.5 million) or as a percentage (e.g. 5 per cent). The most usual definition that economists use for the **number unemployed** is: *those of working age who are without work, but who are available for work at current wage rates*. If the figure is to be expressed as a percentage, then it is a percentage of the total **labour force**. The labour force is defined as *those in employment plus those unemployed*. Thus if 30 million people were employed and 1.5 million people were unemployed, the **unemployment rate** would be:

$$\frac{1.5}{30 + 1.5} \times 100 = 4.76\%$$

When comparing unemployment across countries it is sensible to compare *rates* of unemployment. Table 15.2 shows average unemployment rates across a sample of

countries since the 1960s. It shows how in the 1980s and early 1990s unemployment rates were significantly higher than in the 1960s and 1970s. Then, in the late 1990s and early 2000s, it fell in some countries, such as the UK and USA. In others, such as Germany and France, it remained stubbornly high. However, the global financial crisis and subsequent economic slowdown meant that unemployment rates were to rise generally in the late 2000s and into the early 2010s.

We take a preliminary look at the nature and causes of unemployment in section 15.5.

? Have unemployment rates generally risen or fallen over the decades or is there no discernible pattern? Does the answer vary by country?

Inflation

By inflation we mean a general rise in prices throughout the economy. Government policy here is to keep inflation both low and stable. One of the most important reasons for this is that it will aid the process of economic decision making. For example, businesses will be able to set prices and wage rates, and make investment decisions with far more confidence.

The **rate of inflation** measures the annual percentage increase in prices. Typically, when we hear about inflation it is in relation to *consumer* prices. The UK government publishes

Definitions

Number unemployed (economist's definition) Those of working age who are without work, but who are available for work at current wage rates.

Labour force The number employed plus the number unemployed

Unemployment rate The number unemployed expressed as a percentage of the labour force.

Rate of inflation The percentage increase in prices over a 12-month period.

a consumer prices index (CPI) each month, and the rate of inflation is the percentage increase in that index over the previous 12 months. This index is used throughout the EU, where it generally goes under its full title of the harmonised index of consumer prices (HICP). The HICP covers virtually 100 per cent of consumer spending (including cross-border spending) and uses sophisticated weights for each item (see Appendix 1, page A:7 for an analysis of weighting in indices).

In most developed countries, governments now have a target for the rate of consumer price inflation. This is frequently around 2 per cent, as is the case in the UK, USA and eurozone. Central banks, such as the Bank of England, the US Federal Reserve Bank (the Fed) and the European Central Bank, then adjust interest rates to try to keep inflation on target (we see how this works in Chapter 22). The advent of inflation-rate targeting has tended to narrow differences in inflation rates between countries, as have the increasing economic ties between countries.

Table 15.3 helps to show how, in recent years, people in many developed economies have become accustomed to inflation rates of around 2 or 3 per cent. Yet it was many years ago that inflation in most developed countries was in double figures. Many countries saw relatively high rates of inflation during the 1970s, with the inflation rate in the UK, for example, reaching 24 per cent in 1975.

Today inflation rates are significantly lower and some countries have experienced periods of negative inflation rates or what is sometimes called 'deflation'.

We will take a preliminary look at the factors affecting rates of inflation in section 15.6.

Would it matter if all prices rose by 20 per cent, but everyone's income also rose by 20 per cent? (We consider this issue in section 15.6.)

Foreign trade and global economic relationships

A country's macroeconomic environment is shaped not only by domestic conditions but also by its economic relationships with other countries. These relationships evolve

as the global economy develops and the world order changes. Take, for example, the rapid economic growth observed over the past couple of decades or more in economies like China and India, just to name a couple.

International economic relationships also evolve as countries or groups of countries come together to shape their economic relationships with other economies. Following the UK referendum on EU membership in 2016, the decision to leave meant that, over time, a new set of economic relationships between the UK and its foreign partners would emerge.

One way of viewing the economic relationship between a country and other economies is through its *balance of payments account*. This records all transactions between the residents of that country and the rest of the world. These transactions enter as either debit items or credit items. The debit items include all payments *to* other countries: these include the country's purchases of imports, the investments it makes abroad and the interest and dividends paid to people abroad who have invested in the country. The credit items include all receipts *from* other countries: these include the sales of exports, inflows of investment into the country and earnings of interest and dividends from abroad.

The sale of exports and any other receipts earn foreign currency. The purchase of imports or any other payments abroad requires foreign currency. If a country starts to spend more foreign currency than it earns, then its balance of payments will go into deficit. If the government does nothing to correct the

Definitions

Balance of payments account A record of the country's transactions with the rest of the world. It shows the country's payments to or deposits in other countries (debits) and its receipts or deposits from other countries (credits). It also shows the balance between these debits and credits under various headings

Table 15.3 Average consumer price inflation rates (%)

balance of payments deficit, the *exchange rate* of the country's currency must fall. The exchange rate is the rate at which one currency exchanges for another. For example, the exchange rate of the pound into the dollar might be £1 = \$1.40.

A falling exchange rate (e.g. from \$1.40 to \$1.20) is a problem because it pushes up the price of imports and so reduces people's purchasing power and can fuel inflation. This was the situation facing the UK in the aftermath of the vote to leave the European Union, when the pound fell sharply. Exchange-rate fluctuations can also be problematic because they can cause great uncertainty for traders and can damage international trade and economic growth.

What are the underlying causes of balance of payments problems? How do the balance of payments and the exchange rate relate to the other macroeconomic issues? What are the best policies for governments to adopt? We take an initial look at these questions in section 15.7 and then examine them in more detail in Chapters 25 and 26.

Financial well-being

The financial system is an integral part of most economies. Financial markets, financial institutions and *financial instruments* have become increasingly important in determining the financial well-being of nations, organisations, government and people. The increasing importance of the financial system to economies is known as *financialisation*.

The most immediate evidence of financialisation is the extent to which many of us interact with financial institutions and our use of financial instruments. Financialisation is most frequently associated with the level of indebtedness of *economic agents*, such as households and firms, to banks. In the UK, for example, by the end of 2016 households had debt outstanding borrowed from banks and building societies to the value of £1.3 trillion.

The importance of financial stability and the problem of financial distress. It is important for policy makers to ensure the stability of the financial system and the general financial well-being of economic agents. This importance was most starkly demonstrated by the events surrounding the financial crisis of 2007–9, when many banks looked as if they might become bankrupt. The crisis showed starkly how the financial distress of banks and other financial institutions can lead to global economic turmoil. Because of the global interconnectedness of financial institutions and markets, problems can spread globally like a contagion.

And it was not just financial institutions that were distressed in the late 2000s; we also witnessed financially distressed households and businesses, many of which were burdened by unsustainable levels of debt.

Subsequently, the financial distress was to affect government too, especially in advanced economies. Governments were burdened by growing levels of debt as they spent more to offset rapidly weakening private-sector spending. At the same time, tax revenues fell because of weakening economic growth. The consequence has been a prolonged period

during which many governments have felt it necessary to tighten their budgets. And this constraint on government spending has been a brake on economic growth.

Financial accounts. In thinking about financial well-being or distress, three key accounts can be considered. These are compiled for the main sectors of the economy: the household, corporate and government sectors, and the whole economy.

First, there is the *income account* which records the various *flows* of income (a credit) alongside the amounts either spent or saved (debits). Economic growth refers to the annual real growth in a country's income flows (i.e. after taking inflation into account).

Next, there is the *financial account*. There are two elements here. First, we can record financial *flows*, which determine the net acquisition of financial wealth by each sector. These comprise new saving, borrowing or repayments. Reductions in the flows of borrowing, in countries like the UK and USA, were very important in explaining the credit crunch and subsequent deep recession of the late 2000s/early 2010s.

The other element of the financial account is its *balance sheet*. A balance sheet is a record of *stocks* of *assets* and *liabilities* of individuals or institutions. An asset is something owned by or owed to you. A liability is a debt: i.e. something you owe to someone else. In the case of the financial account, we have a complete record of the stocks of financial assets (arising from saving) and financial liabilities (arising from borrowing) of a sector, and include things such as currency, bank deposits, loans, bonds and shares. The flows of borrowing during the 2000s meant that many individual and organisations experienced a significant increase in stocks of financial liabilities.

Definitions

Exchange rate The rate at which one national currency exchanges for another. The rate is expressed as the amount of one currency that is necessary to purchase *one unit* of another currency (e.g. £1.20 = £1).

Financial instruments Tradable financial assets, such as shares ('equities'), bonds, foreign currency and bank account deposits.

Financialisation A term used to describe the process by which financial markets, institutions and instruments becoming increasingly significant in economies.

Economic agents People or institutions making economic decisions. These could be individuals as consumers, workers, borrowers or savers, or firms, governments or other public institutions.

Balance sheet A record of the stock of assets and liabilities of an individual or institution.

Asset Possessions of an individual or institution, or claims held on others.

Liability Claims by others on an individual or institution; debts of that individual or institution.

Finally, there is the *capital account*, which looks at flows and stocks of *physical* assets and liabilities. Again, there are two elements. The first records the capital *flows* of the various sectors, which occur when acquiring or disposing of physical assets, such as property and machinery. The second records the *stock* of physical wealth held by the various sectors.

The national balance sheet. This is a measure of the wealth of a country (i.e. the nation's financial and physical stock of net assets). It shows the *composition* of a country's wealth and the contribution of each of the main *sectors* of the economy.

The balance of a sector's or country's stock of financial and non-financial assets over its financial liabilities is referred to as its *net worth*. An *increase* in the net worth of the sectors or the whole country implies greater financial well-being. However, during the 2000s many sectors experienced increases in net worth as asset values rose, despite the rising stock of financial liabilities. Subsequently, the increase in the stock of liabilities was not financially sustainable and asset prices were to fall.

These various accounts are part of an interconnected story detailing the financial well-being of a country's households, companies and government. To illustrate how, consider what would happen if, over a period of time, you were to spend more than the income you receive. This would result in your income account deteriorating. To finance your excess spending you could perhaps draw on any financial wealth that you have accumulated through saving. Alternatively, you might fund some of your spending through a loan from a financial institution, such as a bank. Either way, your financial balance sheet will deteriorate. Or you may dispose of some physical assets, such as property. However your excess spending is financed, your capital balance will deteriorate: your net worth declines.

The importance of balance-sheet effects in influencing behaviour and, hence, economic activity has been increasingly recognised by both economists and policy makers, especially since the financial crisis of 2007–9. Understanding these effects and their consequences is crucial in devising the most appropriate policies.

Balance sheets affect people's behaviour. The size and structure of governments', institutions' and individuals' liabilities (and assets too) affect economic well-being and can have significant effects on behaviour and economic activity.

Government macroeconomic policy

From the above issues we can identify a series of macroeconomic policy objectives that governments might typically pursue:

- High and stable economic growth.
- Low unemployment.
- Low inflation.
- The avoidance of balance of payments deficits and excessive exchange rate fluctuations.
- A stable financial system and the avoidance of excessively financially distressed sectors of the economy, including government itself.

Unfortunately, these policy objectives may conflict. For example, a policy designed to accelerate the rate of economic growth may result in a higher rate of inflation, a balance of payments deficit and excessive lending. Governments are thus often faced with awkward policy choices.

Societies face trade-offs between economic objectives.

For example, the goal of faster growth may conflict with that of greater equality; the goal of lower unemployment may conflict with that of lower inflation (at least in the short run). This is an example of *opportunity cost*: the cost of achieving one objective may be achieving less of another. The existence of trade-offs means that policy makers must make choices.

Definitions

Net worth The market value of a sector's stock of financial and non-financial wealth.

Section summary

1. Macroeconomics, like microeconomics, looks at issues such as output, employment and prices; but it looks at them in the context of the whole economy.
2. Economies are inherently volatile, as evidenced by fluctuations in short-term economic growth rates. These fluctuations cause an economy's output path to fluctuate, generating what economists call the business cycle.
3. Among the macroeconomic goals that are generally of most concern to governments are: economic growth, reducing unemployment, reducing inflation, avoiding balance of payments and exchange rate problems, a stable financial system and the avoidance of excessively financially distressed economic agents.
4. Unfortunately, these goals are likely to conflict. Governments may thus be faced with difficult policy choices.

15.2 MEASURING NATIONAL INCOME AND OUTPUT

A consistent theme of section 15.1 was the inherent volatility of economies. One of the principal ways in which we observe this is through the volatility of national income or output. But just how do we measure national income or output? The measure we use is called **gross domestic product (GDP)**.

This section focuses on how GDP is calculated. It also looks at difficulties in interpreting GDP statistics. Can the figures be meaningfully used to compare one country's standard of living with another? The appendix to this chapter goes into more detail on the precise way in which the statistics for GDP are derived.

The three ways of measuring GDP

GDP can be calculated in three different ways, which should all result in the same figure. These three methods can be understood in the context of the *circular flow of income model*, which we introduced in Chapter 1 (see page 17). This model allows us to trace the resources and, as its name suggests, the income flows that pass between the major groups in the economy.

A simplified version of the model is shown in Figure 15.3. In the diagram, the economy is divided into two major groups: *firms* and *households*. Each group has two roles. Firms are producers of goods and services; they are also the employers of labour and other factors of production. Households (which include all individuals) are the consumers of goods and services; they are also the suppliers of labour and various other factors of production.

The first method of measuring GDP is to add up the value of all the goods and services produced in the country, industry by industry. In other words, we focus on firms and add up all their production. This first method is known as the *product method*.

The production of goods and services generates incomes for households in the form of wages and salaries, profits, rent and interest. The second method of measuring GDP, therefore, is to add up all these incomes. This is known as the *income method*.

The third method focuses on the expenditures necessary to purchase the nation's production. In this simple model of the circular flow of income, whatever is produced is sold. The value of what is sold must therefore be the value of what is produced. The *expenditure method* measures this sales value.

Because of the way the calculations are made, the three methods of calculating GDP *must* yield the same result. In other words,

$$\begin{aligned}\text{national product} &= \text{national income} \\ &= \text{national expenditure}\end{aligned}$$

In the appendix to this chapter, we look at each of the three methods in turn, and examine the various factors that have to be taken into account to ensure that the figures are accurate.

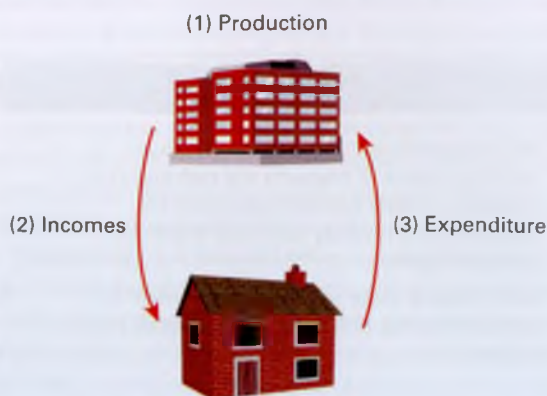

Taking account of inflation

If we are to make a sensible comparison of one year's national income with another, we must take inflation into account. For example, if this year national income is 10 per cent higher than last year, but at the same time prices are also 10 per cent higher, then the average person will be no better off at all. There has been no *real* increase in income (see discussion in Appendix 1 at the end of the book on page A:6).

An important distinction here is between **nominal GDP** and **real GDP**. *Nominal* GDP, sometimes called 'money GDP', measures GDP in the prices ruling at the time and thus takes no account of inflation. *Real* GDP, sometimes called 'GDP at constant prices', measures GDP in the prices that ruled in some particular year – the *base year*. Thus we could measure each year's GDP in, say, 2015 prices. This would enable us to see how much *real* GDP had changed from one year to another. In other words, it would eliminate increases in money GDP that were merely due to an increase in prices.

The official statistics give both nominal and real figures. (Case Study 15.1 on the student website shows in more detail how real GDP figures are calculated.) Figure 15.4 shows nominal GDP and GDP at constant 2015 prices since 1955 in the

Figure 15.3 The circular flow of income

Definitions

Gross domestic product (GDP) The value of output produced within the country over a 12-month period.

Nominal GDP GDP measured at current prices.

Real GDP GDP after allowing for inflation: i.e. GDP measured in *constant* prices, in other words in terms of the prices ruling in some base year.

Figure 15.4 Nominal and constant-price GDP, UK 1955–2016

Source: Based on *Time Series Data*, series YBHA and ABMI (Office for National Statistics).

UK. If we had mistakenly used the nominal GDP figures to compare the size of output between these two dates we would have thought that the economy was over 100 times larger. In fact, the real figures show the UK economy was actually only 4.3 times larger in 2016 than in 1955.

As well as revealing the extent of long-term economic growth, the real figures also show the *variability* of economic

growth from year to year. We can see falls in output in the mid-1970s, early 1980s and early 1990s that are not directly observable from nominal GDP. Instead, nominal GDP continued to increase because of rising price levels. However, in 2009 output fell by over 4.2 per cent, which meant that even nominal GDP fell. In other words, price rises were not enough to offset a substantial decline in the volume of output.

THRESHOLD CONCEPT 13

THE DISTINCTION BETWEEN REAL AND NOMINAL VALUES

THINKING LIKE AN ECONOMIST

Which would you rather have: (a) a pay rise of 5 per cent when inflation is 2 per cent, or (b) a pay rise of 10 per cent when inflation is 9 per cent? Which debt would you rather have: (a) one where the interest rate is 10 per cent and inflation is 8 per cent, or (b) one where the interest rate is 5 per cent and the inflation rate is 1 per cent?

To answer these questions, you need to distinguish between real and nominal values. *Nominal values* are measured in current prices and take no account of inflation. Thus in the questions above, the nominal pay rises are (a) 5 per cent and (b) 10 per cent; the nominal interest rates are (a) 10 per cent and (b) 5 per cent. In each case it might seem that you are better off with alternative (b).

But if you opted for answers (b), you would be wrong. Once you take inflation into account, you would be better off in each case with alternative (a). What we need to do is to use real values. Real values take account of inflation. Thus in the first question, although the nominal pay rise in alternative (a) is 5 per cent, the real pay rise is only 3 per cent, since 2 of the 5 per cent is absorbed by higher prices. You are only 3 per cent better off in terms of what you can buy. In alternative (b) the real pay rise is

only 1 per cent, since 9 of the 10 per cent is absorbed by higher prices. Thus in real terms, alternative (a) is better.

In the second question, although in alternative (a) you are paying 10 per cent in nominal terms, your debt is being reduced in real terms by 8 per cent and thus you are paying a real rate of interest of only 2 per cent. In alternative (b), although the nominal rate of interest is only 5 per cent, your debt is being eroded by inflation by only 1 per cent. The real rate of interest is thus 4 per cent. Again, in real terms, you are better off with alternative (a).

The distinction between real and nominal values is a threshold concept, as understanding the distinction is fundamental to assessing statistics about the economy.

It's easy to make the mistake of using nominal figures when we should really be using real ones. This is known as 'money illusion': the belief that a rise in money terms represents a real rise.

When comparing two countries' GDP growth rates, does it matter if we use nominal figures, provided we use them for both countries?

Taking account of population: the use of per capita measures

The figures we have been looking at up to now are *total* GDP figures. Although they are useful for showing how big the total output or income of one country is compared with another, we are often more interested in output or income *per head*. Luxembourg obviously has a much lower total national income than the UK, but it has a higher GDP per head. In 2009 China overtook Japan to become the second largest economy in the world, and some estimate that it will become the biggest economy by 2025. But these are total figures. Despite China's rapid growth, it is estimated that by 2020 GDP per capita in China will still be only around 20 per cent of that of the USA.

Other per capita measures are sometimes useful. For example, measuring GDP per head of the *employed* population allows us to compare how much the average worker produces. A country may have a relatively high GDP per head of population, but also have a large proportion of people at work. Its output per worker will therefore not be so high.

 By what would we need to divide GDP in order to get a measure of labour productivity per hour?

Taking account of exchange rates: the use of PPP measures

There is a big problem with comparing GDP figures of different countries. They are measured in the local currency and

thus have to be converted into a common currency (e.g. dollars or euros) at the current exchange rate. But the exchange rate may be a poor indicator of the purchasing power of the currency at home. For example, £1 may exchange for, say, 150 yen. But will £1 in the UK buy the same amount of goods as ¥150 in Japan? The answer is almost certainly no.

To compensate for this, GDP can be converted into a common currency at a *purchasing-power parity rate*. This is a rate of exchange that would allow a given amount of money in one country to buy the same amount of goods in another country after exchanging it into the currency of the other country. For example, the OECD publishes PPP rates against the US dollar for all OECD currencies. Using such rates to measure GDP gives the *purchasing-power standard (PPS) GDP*.

Box 15.1 compares GDP with PPS GDP for various countries.

Definitions

Purchasing-power parity (PPP) exchange rate An exchange rate corrected to take into account the purchasing power of a currency. \$1 would buy the same in each country after conversion into its currency at the PPP rate.

Purchasing-power standard (PPS) GDP GDP measured at a country's PPP exchange rate.

BOX 15.1 WHICH COUNTRY IS BETTER OFF?

CASE STUDIES AND APPLICATIONS

Comparing national income statistics

Using PPS GDP figures can give a quite different picture of the relative incomes in different countries than using simple GDP figures. The table shows the GDP per head and PPS GDP per head in various countries. The figures are expressed as a percentage of the average of the EU-15 countries (i.e. those that were members prior to the entry of 10 new members in May 2004).

Thus in 2017, GDP per head in Denmark was estimated to be 45 per cent higher than the EU-15 average. But, because of higher Danish prices, the average person in Denmark could buy only 15 per cent more goods and services. By contrast, GDP per head in the Czech Republic was only 51 per cent of the EU-15 average but, because of lower prices in the Czech Republic, the average person there could buy 82 per cent as much as the average citizen of the EU-15 countries.

 Referring to the figures in the table, which countries' actual exchange rates would seem to understate the purchasing power of their currency?

GDP per head as a percentage of the EU-15 average, 2017

	GDP per head	GDP (PPS) per head
Poland	34.8	65.6
Greece	49.4	62.7
Czech Republic	50.8	82.1
Portugal	54.3	71.6
Spain	73.0	85.5
Italy	82.3	88.4
France	99.6	97.0
UK	104.7	99.1
Japan	107.0	96.9
Germany	113.8	113.4
Canada	120.6	105.4
Netherlands	122.9	118.8
Sweden	139.9	114.7
Denmark	145.4	115.4
Australia	152.9	113.3
USA	163.4	133.5
Ireland	172.0	169.5
Luxembourg	284.6	251.3

Notes: Figures based on forecasts; EU-15 = the 15 members of the EU prior to the accession of additional countries in May 2004.

Do GDP statistics give a good indication of a country's standard of living?

If we take into account both inflation and the size of the population, and use figures for *real* per capita PPS GDP, will this give us a good indication of a country's standard of living? The figures *do* give quite a good indication of the level of production of goods and the incomes generated from it, provided we are clear about the distinctions between the different measures.

But when we come to ask the more general question of whether the figures give a good indication of the welfare or happiness of the country's citizens, then there are serious problems in relying exclusively on GDP statistics.

Problems of measuring national output

The main problem here is that the output of some goods and services goes unrecorded and thus the GDP figures will understate the nation's output. There are two reasons why items are not recorded.

Non-marketed items. If you employ a decorator to paint your living room, this will be recorded in the GDP statistics. If, however, you paint the room yourself, it will not. Similarly, if a nanny is employed by parents to look after their children, this childcare will form part of GDP. If, however, a parent stays at home to look after the children, it will not. The exclusion of these 'do-it-yourself' and other home-based activities means that the GDP statistics understate the true level of production in the economy.

If over time there is an *increase* in the amount of do-it-yourself activities that people perform, the figures will also understate the *rate of growth* of national output. On the other hand, if in more and more families both partners go out to work and employ people to look after their children, this will overstate the rate of growth in output. The childcare that was previously unrecorded now enters into the GDP statistics.

? If we were trying to get a 'true' measure of national production, which of the following activities would you include: (a) washing-up; (b) planting flowers in the garden; (c) playing an educational game with children in the family; (d) playing any game with children in the family; (e) cooking your own supper; (f) cooking supper for the whole family; (g) reading a novel for pleasure; (h) reading a textbook as part of studying; (i) studying holiday brochures? Is there a measurement problem if you get pleasure from the do-it-yourself activity itself as well as from its outcome?

The 'underground' or 'shadow' economy. The underground economy consists of illegal and hence undeclared transactions. These could be transactions where the goods or services are themselves illegal, as with drugs, guns and prostitution. Alternatively, they could be transactions that are illegal only in that they are not declared for tax purposes. For example, to avoid paying VAT, a garage may be prepared to repair your car slightly more cheaply if you pay cash. Another example is that of 'moonlighting', where

people do extra work outside their normal job and do not declare the income for tax purposes. For example, an electrician employed by a building contractor during the day may rewire people's houses in the evenings, again for cash. Unemployed people may do casual jobs that they do not declare, to avoid losing benefits.

Problems of using GDP statistics to measure welfare

GDP is essentially an indicator of a nation's *production*. But production may be a poor indicator of society's well-being for the following reasons.

Production does not equal consumption. Production is desirable only to the extent that it enables us to *consume* more. If GDP rises as a result of a rise in *investment*, this will not lead to an increase in *current* living standards. It will, of course, help to raise *future* consumption.

The same applies if GDP rises as a result of an increase in exports. Unless there is a resulting increase in imports, it will be consumers abroad that benefit, not domestic consumers.

Production has human costs. If production increases, this may be due to technological advance. If, however, it increases as a result of people having to work harder or longer hours, its net benefit will be less. Leisure is a desirable good, and so too are pleasant working conditions, but these items are not included in the GDP figures.

GDP ignores externalities. The rapid growth in industrial society is recorded in GDP statistics. What the statistics do not record are the environmental side effects: the polluted air and rivers, the ozone depletion, the problem of global warming. If these external costs were taken into account, the *net* benefits of industrial production might be much less.

? Name some external benefits that are not included in GDP statistics.

The production of certain 'bads' leads to an increase in GDP. Some of the undesirable effects of growth may in fact *increase* GDP! Take the examples of crime, stress-related illness and environmental damage. Faster growth may lead to more of all three. But increased crime leads to more expenditure on security; increased stress leads to more expenditure on health care; and increased environmental damage leads to more expenditure on environmental clean-up. These expenditures *add* to GDP. Thus, rather than reducing GDP, crime, stress and environmental damage actually increase it.

Total GDP figures ignore the distribution of income. If some people gain and others lose, we cannot say that there has been an unambiguous increase in welfare. A typical feature of many rapidly growing countries is that some people grow very rich while others are left behind. The result is a growing inequality. If this is seen as undesirable, then clearly total GDP statistics are an inadequate measure of welfare.

Conclusions

If a country's citizens put a high priority on a clean environment, a relaxed way of life, greater self-sufficiency, a less materialistic outlook, more giving rather than selling, and greater equality, then such a country will probably have a lower GDP than a similarly endowed country where the pursuit of wealth is given high priority. Clearly, we cannot

conclude that the first country will have a lower level of well-being.

However, this does not mean that we should reject GDP statistics as a means of judging economic performance. While GDP statistics are not a good measure of economic welfare, they are an effective measure of *output* or *income*, and should be seen in that context.

BOX 15.2 CAN GDP MEASURE NATIONAL HAPPINESS?

EXPLORING
ECONOMICS

An alternative perspective on well-being

The domains of national well-being

GDP is not a complete measure of economic welfare; nor is it meant to be. Consequently, there is considerable interest in alternative methods of establishing the level of human well-being and happiness.

In 2010 the UK's Office for National Statistics launched its *Measuring National Well-being (MNW) programme*.¹ The principal aim was to develop a set of national statistics which would both help people to gain a better understanding of well-being and allow well-being to be monitored. The data, for instance, would enable policy makers to make more informed policy decisions by better understanding the impact of their choices across society.

The MNW programme has identified a series of 'domains' with associated measures. There are 10 domains: personal well-being, our relationships, health, what we do, education and skills, where we live, personal finance, the economy, governance and the natural environment. These 10 domains produce a series of indicators – 43 as of 2016.

In the three-year period to September 2016 the ONS reported that of the 35 measures where data allowed for comparison, 22 measures had improved, 5 showed no overall change and 8 deteriorated.

Domains such as 'personal finance' and 'where we live' included several indicators showing improvement. For example, real median disposable income rose, the number of people reporting financial hardship fell and the number accessing the natural environment weekly rose.

Meanwhile the number of crimes against the person (per thousand of the population) had risen and the numbers reporting satisfaction with their job and with the amount of leisure time fell.

Personal well-being and social capital

Since 2011, adults in the UK over 16 have been asked the following four questions in an attempt to monitor individual well-being:
