- Overall, how satisfied are you with your life nowadays?
- Overall, to what extent do you feel the things you do in your life are worthwhile?
- Overall, how happy did you feel yesterday?
- Overall, how anxious did you feel yesterday?

Respondents give their answers using a scale of 0 to 10 where 0 is 'not at all' and 10 is 'completely'.

Since 2013 the ONS has published regional indicators of personal well-being. In its review of personal well-being in financial year 2015/16,² the ONS reports that the average level of personal well-being was highest in Northern Ireland. One possible explanation, it argues, might be higher levels of feelings of belonging to a neighbourhood and a sense that people are prepared to help others. These are elements of what is known as **social capital**. Social capital captures social connections and networks which affect the cohesiveness of societies. Our social connections, whether through relationships with family and friends, local communities or wider society, help to bind societies together.

As well as affecting personal well-being, social capital is important for national well-being and has economic significance. Examples of the impact of social capital include the economic value of the informal care of the sick and vulnerable, the provision of local amenities through volunteers or social enterprise, the economic benefits from membership of clubs, societies and other organisations, including the social bonds that are created.

Our understanding of both national and individual well-being continues to evolve. However, it is, of course, debatable how close any measures of well-being can come to measuring such a thing. Further, how should the results of such investigations help governments devise policy? Will governments be any closer to measuring the costs and benefits of any policy decisions?

1. *Is well-being the same as happiness or utility?*
2. *For what reasons might a person have a high income but a poor level of well-being?*

Definitions

Social capital (OECD definition) Networks, together with shared norms, values and understandings, that facilitate co-operation within or among groups.

Section summary

1. National income is usually expressed in terms of gross domestic product. This is simply the value of domestic production over the course of the year. It can be measured by the product, expenditure or income methods.
2. Real national income takes account of inflation by being expressed in the prices of some base year.
3. In order to compare living standards of different countries, national income has to be expressed per capita and at purchasing-power parity exchange rates.
4. Even if it is, there are still problems in using national income statistics for comparative purposes. Certain items will not be included: items such as non-marketed products, services in the family and activities in the underground economy. Moreover, the statistics include certain 'bads' and ignore externalities, and they also ignore questions of the distribution of income.

15.3 THE BUSINESS CYCLE

The distinction between actual and potential growth

Economies are volatile as evidenced by the volatility of growth. They experience not only periods of expansion but also periods when growth is negative – when output levels contract. For many, the defining feature of the business cycle is the very absence of growth in times of recession.

The published statistics on growth show **actual growth**: the percentage change in national output over a period of time. As we saw in section 15.1, this is commonly measured over a year (12 months) or a quarter (3 months).

We should be careful to distinguish between actual growth and potential growth. **Potential growth** is the speed at which the economy *could* grow. It is the percentage annual increase in the economy's *capacity* to produce: the rate of growth in *potential output*.

Potential output (i.e. potential GDP) is the level of output when the economy is operating at 'normal capacity utilisation'. This allows for firms having a planned degree of spare capacity to meet unexpected demand or for hold-ups in supply. It also allows for some unemployment as people move from job to job. Because potential output is normal-capacity output, it is somewhat below full-capacity output, which is the absolute maximum that could be produced with firms working flat out.

The output gap. The difference between actual and potential output is known as the **output gap**. Thus if actual output exceeds potential output, the output gap is positive: the economy is operating above normal capacity utilisation. If actual output is below potential output, the output gap is negative: the economy is operating below normal capacity utilisation. Box 15.3 looks at the output gap since 1970 for five major industrial economies.

Assume that the actual growth rate is less than the potential growth rate. This will lead to an increase in spare capacity and probably an increase in unemployment. In turn, the output gap will become less positive or perhaps more negative, depending on the economy's starting point.

In contrast, if the actual growth rate were to exceed the potential growth rate, there would be a reduction in spare capacity and the output gap would become less negative or more positive. However, periods when actual growth exceeds potential growth can only be temporary. In the long run, the actual growth rate will be limited to the potential growth rate.

Factors affecting potential output and potential growth

Although our focus in section 15.3 is on short-term volatility and hence on actual growth, it is worth briefly considering the principal factors that contribute to potential economic growth. We look at this in much more depth in Chapter 23.

Explanations tend to focus on the role of the economy's resources. This is the 14th of our threshold concepts, which states that long-term growth in a country's output depends on a growth in the quantity and/or productivity of its resources.

First, there is the issue of quantity. An increase in resources, whether they are natural resources, labour or capital, enables the economy's potential output to increase.

Definitions

Actual growth The percentage increase in national output actually produced.

Potential growth The percentage increase in the capacity of the economy to produce.

Potential output The sustainable level of output that could be produced in the economy: i.e. one that involves a 'normal' level of capacity utilisation and does not result in rising inflation.

Output gap The difference between actual and potential output. When actual output exceeds potential output, the gap is positive. When actual output is less than potential output, the gap is negative.

Second, there is the issue of the effectiveness or productivity of resources. An increase in the effectiveness of the resources used, perhaps through advances in technology, improved labour skills or improved organisation, also enables growth in potential output.

Although the growth in potential output varies to some extent over the years – depending on the rate of advance of technology, the level of investment and the discovery of new raw materials – it nevertheless tends to be much steadier than the growth in actual output.

How might the volatility of an economy affect the growth of potential output?

The hypothetical business cycle

Actual growth tends to fluctuate. In some years, countries will experience high rates of economic growth: the country experiences a boom. In other years, economic growth is low or even negative: the country experiences a slowdown or recession.² This cycle of expansion and slowdown causes fluctuations in the path of output.

Figure 15.5 illustrates a hypothetical business cycle. While it is a stylised representation of the business cycle, it is useful for illustrating four identifiable ‘phases’ of the cycle.

² In official statistics, a recession is defined as when an economy experiences falling real GDP (negative growth) for two or more successive quarters.

1. *The upturn.* In this phase, a contracting or stagnant economy begins to recover, and growth in actual output resumes, or begins to accelerate.
2. *The expansion.* During this phase, there is rapid economic growth: the economy is booming. A fuller use is made of resources, and the gap between actual and potential output narrows.
3. *The peaking out.* During this phase, growth slows down or even ceases.
4. *The slowdown, recession or slump.* During this phase, there is little or no growth or even a decline in output. Increasing slack develops in the economy. The economy is operating with a negative output gap.

A word of caution: do not confuse a high level of output with a high rate of growth in output. The level of output is highest in phase 3. The rate of growth in output is highest in phase 2 (i.e. where the curve is steepest).

Figure 15.5 shows a decline in actual output in recession. Redraw the diagram, only this time show a mere slowing down of growth in phase 4.

Long-term output trend

A line can be drawn showing the trend of national output over time (i.e. ignoring the cyclical fluctuations around the trend). This is shown as the dashed line in Figure 15.5. If, over time, firms on average operate with a ‘normal’ degree of capacity utilisation (a zero output gap), the trend output

THRESHOLD CONCEPT 14

LONG-TERM GROWTH IN A COUNTRY'S OUTPUT DEPENDS ON A GROWTH IN THE QUANTITY AND/OR PRODUCTIVITY OF ITS RESOURCES

THINKING LIKE AN ECONOMIST

In the short term, economic growth is likely to be influenced by changes in aggregate demand. If the economy is in recession, an expansion in aggregate demand will help to bring the economy out of recession and move it closer to full employment.

Actual output, however, cannot continue growing faster than potential output over the longer term. Firms will start reaching capacity and actual growth will then have to slow. The rate of potential growth thus places a limit to the rate of actual growth over the longer term.

What then determines the rate of growth in potential output? The answer lies on the supply side. It depends on the rate of growth of factors of production. There are two key elements here. The first is growth in the *quantity* of factors: growth in the size of the workforce, of the available land and raw materials, and of the stock of capital. The second is productivity growth. This involves elements such as growth in the educational attainments and skills of the workforce, growth in technology, and growth in the efficiency with which resources are used.

To recognise the importance of resources and their productivity in determining long-term growth is a threshold concept. It helps in understanding the importance of designing appropriate supply-side policies: policies that focus on increasing aggregate supply rather than managing aggregate demand. It is easy to worry too much about the short term.

This is not to say that the short term should be neglected. The famous economist John Maynard Keynes argued that it was fundamentally important to focus on aggregate demand and the short term to avoid severe economic fluctuations, with the twin problems of high unemployment in recessions and high inflation in periods of unsustainably high growth. He used the famous phrase, ‘In the long term we’re all dead.’

But although we all have to die sometime, we may have many years left to reap the benefits of appropriate supply-side policy. And even if we don’t, our children will.

1. Give some examples of supply-side policy (see Chapter 23 for some ideas if you are stuck).
2. If there is an increase in aggregate supply, will this result in an increase in potential growth?

line will be the same as the potential output line. Also, if the average level of capacity that is unutilised stays constant from one cycle to another, the trend line will have the same slope as the full-capacity output line. In other words, the trend (or potential) rate of growth will be the same as the rate of growth of capacity.

If, however, the level of unutilised capacity changes from one cycle to another, then the trend line will have a different slope from the full-capacity output line. For example, if unemployment and unused industrial capacity rise from one peak to another, or from one trough to another, the trend line will move further away from the full-capacity output line (i.e. it will be less steep).

? *If the average percentage (as opposed to the average level) of capacity that was unutilised remained constant, would the trend line have the same slope as the potential output line?*

The business cycle in practice

The hypothetical business cycle illustrated in Figure 15.5 is nice and smooth and regular. Drawing it this way allows us to make a clear distinction between each of the four phases. In practice, however, business cycles are highly irregular. They are irregular in two important ways:

- *The length of the phases.* Some booms are short-lived, lasting only a few months or so. Others are much longer, lasting perhaps several years. Likewise some recessions are short while others are long.
- *The magnitude of the phases.* Sometimes in phase 2 there is a very high rate of economic growth, perhaps 4 per cent per annum or more. On other occasions in phase 2 growth is much gentler. Sometimes in phase 4 there is a recession, with an actual decline in output, as occurred in 2008–9. On other occasions, phase 4 is merely a 'pause', with growth simply being low.

An international business cycle

All countries tend to experience business cycles. Typically the timing is similar from one country to another. In other words, there is an international business cycle. Figure 15.6 shows the annual rate of growth in real GDP in the global economy alongside that in the UK and USA. Global growth rates varied from 5.6 per cent in 2007 to just below zero in 2009.

Figure 15.6 illustrates how global economic volatility is mirrored, at least in part, by the economic volatility in the UK and USA. More generally, this suggests that countries' business cycles have both a national and a global component. With increased global economic ties, many countries have seen the global component increase in its relative importance.

Aggregate demand and the business cycle

The focus of much of the analysis of business cycles is on fluctuations in *aggregate demand* (AD). This is the total spending on goods and services made within the country ('domestically produced goods and services'). It consists of spending by four groups of people: consumers on goods and services (C), firms on investment (I), the government on goods, services and investment (such as education, health and new roads) (G) and people abroad on this country's exports (X). From these four we have to subtract any imports (M) since aggregate demand refers only to spending on *domestic* firms. Thus

$$AD = C + I + G + X - M$$

Periods of rapid growth are associated with periods of rapid expansion of aggregate demand. Periods of recession are associated with a decline in aggregate demand.

Fluctuations in private-sector expenditure

When analysing the role played by the private sector as a source of economic volatility, it makes sense to begin by looking at consumer spending. This is because, by value, it is the largest expenditure component of aggregate demand. In the UK, for example, it frequently accounts for over 60 per cent of national income. This means that even small fluctuations in consumer expenditure can be significant for aggregate demand. As Figure 15.7 shows, annual rates of economic growth mirror fairly closely those in real household consumption.

Definitions

Aggregate demand Total spending on goods and services produced in the economy. It consists of four elements, consumer expenditure (C), investment (I), government expenditure (G) and the expenditure on exports (X), less any expenditure on foreign goods and services (M). Thus $AD = C + I + G + X - M$.

BOX 15.3 OUTPUT GAPS**A measure of excess or deficient demand**

If the economy grows, how fast and for how long can it grow before it runs into inflationary problems? On the other hand, what minimum rate must be achieved to avoid rising unemployment?

To answer these questions, economists have developed the concept of 'output gaps'.¹ The output gap is the difference between actual output and potential output, i.e. normal-capacity output.

If actual output is below potential output (the gap is negative), there will be a higher than normal level of unemployment as firms are operating below their normal level of capacity utilisation. There will, however, be a downward pressure on inflation, resulting from a lower than normal level of demand for labour and other resources.

If actual output is above potential output (the gap is positive), there will be excess demand and a rise in inflation.

Generally, the gap will be negative in a recession and positive in a boom. In other words, output gaps follow the course of the business cycle.

Measuring the output gap

But how do we measure the output gap? There are two principal statistical techniques.

De-trending techniques. This approach is a purely mechanical exercise which involves smoothing the actual GDP figures. In doing this, it attempts to fit a trend growth path. This is illustrated by the dashed line in Figure 15.5. The main disadvantage of this approach is that it is not grounded in economic theory and therefore does not account for those factors likely to determine normal-capacity output.

Production function approach. Many institutions, such as the European Union, use an approach which borrows ideas from economic theory. Specifically, this uses the idea of a production function which relates output to a set of inputs. Estimates of potential output are generated by using statistics

on the size of a country's capital stock (see Box 23.1), the potential available labour input and, finally, the productivity or effectiveness of these inputs in producing output.

In addition to these statistical approaches, use could be made of *business surveys*. In other words, we ask businesses directly about normal capacity working and current levels of output. However, survey-based evidence can provide only a broad guide to rates of capacity utilisation and whether there is deficient or excess demand.

International evidence

The chart shows output gaps for five countries from 1970 estimated using a production function approach. What is apparent from the chart is that all the countries have experienced significant output gaps, both positive and negative. This is consistent with a core theme of this chapter and one to which we will return repeatedly throughout the second half of the book: economies are inherently volatile. In other words, countries experience business cycles.

The chart shows that the characteristics of countries' business cycles can differ, particularly in terms of depth and duration. But we also see evidence of an international business cycle (see page 459), which results from national cycles appearing to share characteristics. This global component of countries' business cycles is clearly evident in the late 2000s and into the 2010s. Increasing global interconnectedness from financial and trading links meant that the financial crisis of the late 2000s spread like a contagion.

While output gaps vary from year to year, over the longer term the average output gap tends towards zero. As we can see from the table, this means that for our selection of countries from 1970 the actual rate of economic growth is approximately the same as the potential rate.

Figure 15.6 UK and global economic growth

Figure 15.7 Annual growth of UK consumption, investment and output

Note: Annual growth rates are calculated using constant-price data.

Source: Based on data in *Quarterly National Accounts*, series KG27, KG7T and IHYR (National Statistics).

Yet this still leaves many important questions to be addressed. What factors affect consumption? Which are most important? How do changes in consumption then affect the macroeconomic environment? Are the effects always the same? These are questions we will examine in section 17.1.

Another component of aggregate demand is investment. If we look again at Figure 15.7, we can see that fluctuations in the annual rate of growth of real investment spending (also known as gross capital formation) are considerably greater than those in output (real GDP).

It appears then that the volatility of investment is one of the factors contributing to the ups and downs of the business cycle. However, this does not mean that the fluctuations in investment are the primary cause of the economy's short-term volatility. They can be, but, as we will discuss in Chapter 17, some economists emphasise more the role that investment plays in *amplifying* the business cycle. The argument here is that investment decisions are affected by the growth in national income. Rising national income may encourage firms to invest to meet increasing demand. But this also has the effect of increasing aggregate demand, which further boosts national income. In contrast, an economy experiencing weak growth, or one where national income is contracting, might see investment levels fall, perhaps very sharply. This, of course, weakens aggregate demand, further amplifying already weak or negative economic growth.

The role of the financial sector

One sector that clearly plays a crucial role in affecting economic activity is the financial sector. While we will focus in detail on the markets, institutions and products and services which comprise the financial sector in Chapter 18, the economic significance of the sector means that it will be referred to frequently in subsequent chapters.

Given the financial crisis of the late 2000s, the interest in the role that the financial sector might play in affecting the business cycle is unsurprising. Some economists argue that the financial sector is a major *source* of economic volatility.

Some go as far as to say that the behaviour of financial institutions through their lending and investments generates unsustainable economic growth which inevitably ends with an economic downturn.

Other economists argue that the financial sector *amplifies* economic shocks. The argument here is not that financial institutions are the source of fluctuations in economic growth but rather that they magnify the shocks that affect the economy. They can do this by boosting lending when growth is strong or reducing lending when growth is weak.

Aggregate supply and the business cycle

While much of the economic analysis of business cycles stresses the importance of fluctuations in aggregate demand, economists recognise that fluctuations in *aggregate supply* can also cause fluctuations in output. Sudden sharp changes to input prices, such as in the price of oil, can be one such cause.

Some economists go further and argue that shifts in aggregate supply are the *primary* source of economic volatility. They argue that these aggregate supply shocks affect the economy's potential output. Consequently, the business cycle is the result of fluctuations in potential output, which in turn affect actual output.

They argue that economies are frequently affected by supply shocks, many of which might be described as 'technological shocks'. As well as changes to input prices, these could include changes to production methods, the regulatory climate or the political environment. These shocks affect production processes and levels of productivity. Some of these changes affect potential output positively, some negatively.

Definitions

Aggregate supply The total amount that firms plan to supply at any given level of prices.

Section summary

1. Actual growth must be distinguished from potential growth. The actual growth rate is the percentage annual increase in the output that is actually produced, whereas potential growth is the percentage annual increase in the capacity of the economy to produce (whether or not this capacity is utilised).
2. Actual growth will fluctuate with the course of the business cycle. The hypothetical business cycle can be broken down into four phases: the upturn, the expansion, the peaking out, and the slowdown or recession. In practice, the length and magnitude of these phases will vary: the cycle is thus irregular.
3. Countries' business cycles may have both national and international components. The international component has tended to increase over time as countries have become increasingly interconnected, for example through trade and growing financial ties.
4. Explanations of the business cycle tend to focus on fluctuations originating in aggregate demand. This requires a deeper understanding of the behaviour of the components of aggregate demand, including that of private-sector behaviour.
5. However, fluctuations in aggregate supply can also result in economic instability. Some economists go further and argue that business cycles can result from fluctuations in potential output caused by frequent technology shocks.

15.4 THE CIRCULAR FLOW OF INCOME

As we have seen, the economic choices of people, businesses and organisations can have profound effects for the macro-economy. One model which allows us to develop an understanding of the impact of these choices for economic growth and which does so by focusing on aggregate demand is the *circular flow of income model*.

We encountered the circular flow model in section 15.2 when looking at how we measure GDP. Consider Figure 15.8. As before, the economy is divided into two major groups: *firms* and *households*. Each group has two roles. Firms are producers of goods and services; they are also the employers of labour and other factors of production. Households (which include all individuals) are the consumers of goods and services; they are also the suppliers of labour and various other factors of production. In the diagram there is an inner flow and various outer flows of incomes between these two groups.

Before we look at the various parts of the diagram, a word of warning. Do not confuse *money* and *income*. Money is a *stock* concept. At any given time, there is a certain quantity of money in the economy (e.g. £1 trillion). But that does not tell us the level of national *income*. Income is a *flow* concept (as is expenditure). It is measured as so much *per period of time*. The relationship between money and income depends on how rapidly the money *circulates*: its 'velocity of circulation'. (We will examine this concept in detail later on: see pages 495 and 588.) If there is £1 trillion of money in the economy and each £1 on average is paid out as income twice per year, then annual national income will be £2 trillion.

The inner flow, withdrawals and injections

The inner flow

Firms pay money to households in the form of wages and salaries, dividends on shares, interest and rent. These payments are in return for the services of the factors of production – labour, capital and land – that are supplied by households. Thus on the left-hand side of the diagram, money flows directly from firms to households as 'factor payments'.

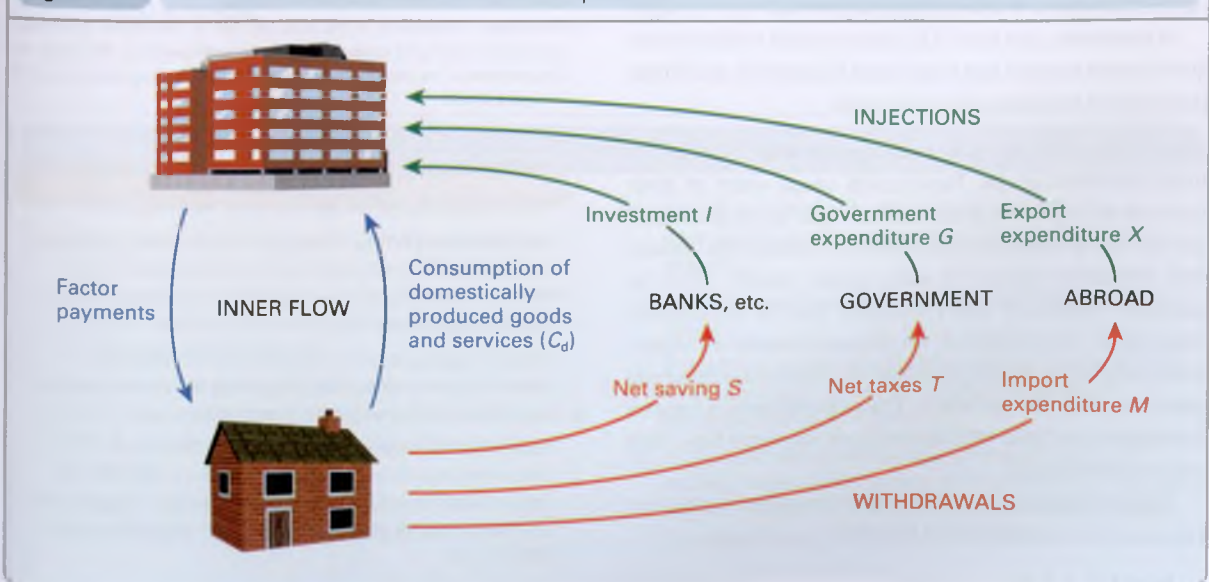

Households, in turn, pay money to domestic firms when they consume domestically produced goods and services (C_d). This is shown on the right-hand side of the inner flow. There is thus a circular flow of payments from firms to households to firms and so on.

If households spend *all* their incomes on buying domestic goods and services, and if firms pay out *all* this income they receive as factor payments to domestic households, and if the velocity of circulation does not change, the flow will continue at the same level indefinitely. The money just goes round and round at the same speed and incomes remain unchanged.

 Would this argument still hold if prices rose?

In the real world, of course, it is not as simple as this. Not all income gets passed on round the inner flow; some is *withdrawn*. At the same time, incomes are injected into the flow from outside. Let us examine these withdrawals and injections.

Figure 15.8 The circular flow of national income and expenditure

Withdrawals (*W*)

Only part of the incomes received by households will be spent on the goods and services of domestic firms. The remainder will be withdrawn from the inner flow. Likewise, only part of the incomes generated by firms will be paid to UK households. The remainder of this will also be withdrawn. There are three forms of *withdrawals* (or '*leakages*' as they are sometimes called).

Net saving (S). Saving is income that households choose not to spend but to put aside for the future. Savings are normally deposited in financial institutions such as banks and building societies. This is shown in the bottom centre of the diagram. Money flows from households to 'banks, etc.'. What we are seeking to measure here, however, is the net flow from households to the banking sector. We therefore have to subtract from saving any borrowing or drawing on past savings by households to arrive at the *net saving* flow. Of course, if household borrowing exceeded saving, the net flow would be in the other direction: it would be negative.

Net taxes (T). When people pay taxes (to either central or local government), this represents a withdrawal of money from the inner flow in much the same way as saving; only, in this case, people have no choice. Some taxes, such as income tax and employees' national insurance contributions (called social contributions in some countries), are paid out of household incomes. Others, such as VAT and excise duties, are paid out of consumer expenditure. Others, such as corporation tax, are paid out of firms' incomes before being received by households as dividends on shares. For simplicity, however, taxes are shown in Figure 15.8 as leaving the circular flow at just one point.

When, however, people receive *benefits* from the government, such as unemployment benefits, child benefit and pensions, the money flows the other way. Benefits are thus equivalent to a 'negative tax'. These benefits are known as *transfer payments*. They transfer money from one group of people (taxpayers) to others (the recipients).

In the model, 'net taxes' (*T*) represents the *net* flow to the government (central and local) from households and firms. It consists of total taxes minus benefits.

Import expenditure (M). Not all consumption is of totally home-produced goods. Households spend some of their incomes on imported goods and services, or on goods and services using imported components. Although the money that consumers spend on such goods initially flows to domestic retailers, it will eventually find its way abroad, either when the retailers or wholesalers themselves import them, or when domestic manufacturers purchase imported inputs to make their products. This expenditure on imports constitutes the third withdrawal from the inner flow. This money flows abroad.

Total withdrawals are simply the sum of net saving, net taxes and the expenditure on imports:

$$W = S + T + M$$

Injections (*J*)

Only part of the demand for firms' output arises from consumers' expenditure. The remainder comes from other sources outside the inner flow. These additional components of aggregate demand are known as *injections (J)*. This important insight means that we can write aggregate demand as:³

$$AD = C_d + J$$

There are three types of injection.

Investment (I). This is the money that firms spend after obtaining it from various financial institutions – either past savings or loans, or through a new issue of shares. They may invest in plant and equipment or may simply spend the money on building up stocks of inputs, semi-finished or finished goods.

Government purchases (G). When the government spends money on goods and services produced by firms, this counts as an injection. Examples of such government expenditure include spending on roads, hospitals and schools. (Note that government expenditure in this model does not include state benefits, hence, the use of the term 'government purchases'. Benefits are transfer payments, as we saw above. They are the equivalent of negative taxes and have the effect of reducing the *T* component of withdrawals.)

Export expenditure (X). Money flows into the circular flow from abroad when residents abroad buy our exports of goods and services.

Total injections are thus the sum of investment, government expenditure and exports:⁴

$$J = I + G + X$$

³ Note that this definition of aggregate demand ($AD = C_d + J$) is equivalent to the one we gave on page 459, i.e. $AD = C + I + G + X - M$, since both the terms C_d and J exclude expenditure on imports.

⁴ We assume, for simplicity in this equation that all investment, government expenditure and export expenditure is on domestic products. Where any part of these three is on imports, we need to subtract this imported element to arrive at I, G or X .

Definitions

Withdrawals (*W*) (or leakages) Incomes of households or firms that are not passed on round the inner flow. Withdrawals equal net saving (*S*) plus net taxes (*T*) plus import expenditure (*M*): $W = S + T + M$.

Transfer payments Moneys transferred from one person or group to another (e.g. from the government to individuals) without production taking place.

Injections (*J*) Expenditure on the production of domestic firms coming from outside the inner flow of the circular flow of income. Injections equal investment (*I*) plus government purchases (*G*) plus expenditure on exports (*X*).

The relationship between withdrawals and injections

There are indirect links between saving and investment, taxation and government expenditure, and imports and exports, via financial institutions, the government (central and local) and foreign countries respectively. If more money is saved, there will be more available for banks and other financial institutions to lend out. If tax receipts are higher, the government may be keener to increase its expenditure. Finally, if imports increase, incomes of people abroad will increase, which will enable them to purchase more of our exports.

These links, however, do not guarantee that $S = I$ or $G = T$ or $M = X$. Firms may wish to invest (I) more or less than people wish to save (S); governments can spend (G) more than they receive in taxes (T) or vice versa; and exports (X) can exceed imports (M) or vice versa.

A major point here is that the decisions to save and invest are made by different people, and thus they plan to save and invest different amounts. Likewise the demand for imports may not equal the demand for exports. As far as the government is concerned, it may choose not to make $T = G$. It may choose not to spend all its tax revenues: to run a 'budget surplus' ($T > G$). Or it may choose to spend more than it receives in taxes – to run a budget deficit ($G > T$) – by borrowing or printing money to make up the difference.

Thus planned injections (J) may not equal planned withdrawals (W).

In terms of the UK economy, are the following net injections, net withdrawals or neither? If there is uncertainty, explain your assumptions.

- Firms are forced to take a cut in profits in order to give a pay rise.*
- Firms spend money on research.*
- The government increases personal tax allowances.*
- The general public invests more money in banks and building societies.*

- UK investors earn higher dividends on overseas investments.*
- The UK government purchases US military aircraft.*
- People draw on their savings to finance holidays abroad.*
- People draw on their savings to finance holidays in the UK.*
- The government runs a budget deficit (spends more than it receives in tax revenues) and finances it by borrowing from the general public.*
- The government runs a budget deficit and finances it through new money created by the central bank.*

Equilibrium in the circular flow

We saw earlier in the chapter how fluctuations in aggregate demand cause short-term growth rates to fluctuate. The circular flow of income model helps us understand the process.

If planned injections do not equal planned withdrawals, aggregate demand will change and so too will national income. Take the case where injections exceed withdrawals. Perhaps there has been a rise in business confidence so that investment has risen. Or perhaps there has been a tax cut so that withdrawals have fallen. As we have seen, the excess of injections over withdrawals will lead to a rise in national income.

But as national income rises, so households will not only spend more on domestic goods (C_d), but also save more (S), pay more taxes (T) and buy more imports (M). In other words, withdrawals will rise too. This will continue until they have risen to equal injections. At that point, national income will stop rising, and so will withdrawals. Equilibrium has been reached. Thus equilibrium is where:

$$W = J$$

Similarly, if withdrawals exceed injections, the resulting fall in national income will lead to a fall in withdrawals. Again, this will continue until $W = J$.

Section summary

- The circular flow of income model depicts the flows of money round the economy. The inner flow shows the direct flows between firms and households. Money flows from firms to households in the form of factor payments, and back again as consumer expenditure on domestically produced goods and services.
- Not all incomes get passed on directly round the inner flow. Some is withdrawn in the form of net saving, some is paid in net taxes, and some goes abroad as expenditure on imports.
- Likewise, not all expenditure on domestic firms is by domestic consumers. Some is injected from outside the inner flow in the form of investment expenditure, government purchases and expenditure on the country's exports.
- Planned injections and withdrawals are unlikely to be the same.
- If injections exceed withdrawals, national income will rise and the economy grows. The reverse will happen if withdrawals exceed injections.
- If injections exceed withdrawals, the resulting rise in national income will lead to a rise in withdrawals. This will continue until $W = J$. At this point, the circular flow will be in equilibrium.

15.5 UNEMPLOYMENT

Understandably one of the most emotive of all macroeconomic issues is that of unemployment, not least because of the very personal costs to those affected by unemployment. Box 15.4 considers in more detail these and the broader costs to the economy of unemployment.

In this section, we look briefly at the potential causes of unemployment. What does the volatility of economies mean for unemployment? Is unemployment merely the result of the business cycle? If not, what other factors might be important? Before addressing these questions we do two things. First, we look at how we measure unemployment. Second, we look at evidence on the composition of unemployment and the duration that people are unemployed.

Claimant unemployment and standardised unemployment

Two common measures of unemployment are used in official statistics. The first is *claimant unemployment*. This is simply a measure of all those in receipt of unemployment-related benefits. Claimant statistics have the advantage of being very easy to collect. However, they exclude all those of working age who are available for work at current wage rates, but who are *not* eligible for benefits. The net effect is that the claimant statistics tend to understate the true level of unemployment. They are also sensitive to government changes in the eligibility conditions for unemployment-related benefits.

Because of the weaknesses of claimant statistics many governments use the *standardised unemployment rate* as the main measure of unemployment. In this measure, the unemployed are defined as people of working age who are without work, available to start work within two weeks and *actively seeking employment* or waiting to take up an appointment.

This is the measure used by the International Labour Organization (ILO) and the Organisation for Economic Cooperation and Development (OECD), two international organisations that publish unemployment statistics for many countries. The figures are compiled from the results of national labour force *surveys*. A representative cross-section of the population is asked whether they are employed, unemployed (using the above definition) or economically inactive. From their replies, national rates of unemployment can be extrapolated. In the UK, the Labour Force Survey is conducted quarterly.

As we have seen, the standardised rate is likely to be higher than the claimant rate to the extent that it includes people seeking work who are nevertheless not entitled to claim benefits. However, it will be lower to the extent that it excludes those who are claiming benefits and yet who are not actively seeking work.

Generally, the standardised rate is significantly higher than the claimant rate. Over the five-year period from 2012 to 2016, for example, the average claimant count rate in the UK was 3.7 per cent while the average standardised unemployment rate (for all aged 16 and over) was 6.8 per cent.

How does the ILO/OECD definition differ from the economist's definition? What is the significance of the phrase 'available for work at current wage rates' in the economist's definition?

The composition of unemployment

Unemployment rates can vary enormously between countries and between different groups within countries. In part, this is likely to reflect structural factors. Countries and regions within countries can, for example, have very different labour markets. Countries often have very different policies on unemployment, training schemes, redundancy, etc., and demonstrate very different attitudes of firms towards their workers.

Table 15.4 highlights differences between countries, age groups and men and women for the period from 2009 to 2016.

In many countries, female unemployment has traditionally been higher than male unemployment. Causes have included differences in education and training, discrimination by employers, more casual or seasonally related employment among women and other social factors. In many countries, as highlighted by Table 15.4, the position has changed in recent years. One important reason has been the decline in many of the older industries, such as coal and steel, which employed mainly men.

Table 15.4 does, however, show some stark differences in unemployment rates across different age groups. Rates in the under-25 age group are higher than the average, and substantially so in many countries. Higher youth unemployment rates can be explained by the suitability (or unsuitability) of the qualifications of school leavers, the attitudes of employers to young people, and the greater willingness of young people to spend time unemployed looking for a better job or

Definitions

Claimant unemployment Those in receipt of unemployment-related benefits.

Standardised unemployment rate The measure of the unemployment rate used by the ILO and the OECD. The unemployed are defined as persons of working age who are without work, are available to start work within two weeks and either have actively looked for work in the last four weeks or are waiting to take up an appointment.

BOX 15.4 THE COSTS OF UNEMPLOYMENT

EXPLORING
ECONOMICS

Who loses and by how much?

The most obvious cost of unemployment is to the unemployed themselves. There is the direct financial cost of the loss in their earnings. Then there are the personal costs of being unemployed. The longer people are unemployed, the more dispirited they may become. Their self-esteem is likely to fall, and they are more likely to succumb to stress-related illness.

Beyond the unemployed themselves, there are the costs to their family and friends. Personal relations can become strained, and there may be an increase in domestic violence and the number of families splitting up.

Then there are the broader costs to the economy. Unemployment represents a loss of output. In other words, actual output is below potential output. Apart from the loss of disposable income to the unemployed themselves, this underutilisation of resources leads to lower incomes for other people too:

- The government loses tax revenues, since the unemployed pay no income tax and national insurance and, given that the unemployed spend less, they pay less VAT and excise duties. The government also incurs administrative costs associated with the running of benefit offices. It may also have to spend extra on health care, the social services and the police.
- Firms lose the profits that could have been made if there had been full employment.
- Other workers lose any additional wages they could have earned from higher national output.

What is more, the longer people remain unemployed, the more deskilled they tend to become. This scarring effect reduces potential as well as actual income.

? *Why have the costs to the government of unemployment benefits not been included as a cost to the economy?*

Finally, there is some evidence that higher unemployment leads to increased crime and vandalism. This obviously imposes a cost on the sufferers.

The costs of unemployment are to some extent offset by benefits. If workers voluntarily quit their jobs to look for better ones, then they must reckon that the benefits of a better job more than compensate for their temporary loss of income. From the nation's point of view, a workforce that is prepared to quit jobs and spend a short time unemployed will be a more adaptable, more mobile workforce – one that is responsive to changing economic circumstances. Such a workforce will lead to greater allocative efficiency in the short run and more rapid economic growth over the longer run.

Long-term involuntary unemployment is quite another matter. The costs clearly outweigh any benefits, both for the individuals involved and for the economy as a whole. A demotivated, deskilled pool of long-term unemployed is a serious economic and social problem.

? *Which of the above costs would be recorded as a reduction in GDP?*

waiting to start a further or higher education course. The difference in rates is less in Germany, which has a well-established apprenticeship system.

The duration of unemployment

A few of the unemployed may never have had a job and maybe never will. For most, however, unemployment lasts only a certain period. For some it may be just a few days while they are between jobs. For others it may be a few months. For others – the long-term unemployed – it could be several years. Figure 15.9 shows the composition of standardised unemployment in the UK for all aged 16 and over by duration.

What determines the average duration of unemployment? There are three important factors here.

The number unemployed (the size of the stock of unemployment). Unemployment is a ‘stock’ concept (see Box 10.10). It measures a *quantity* (i.e. the number unemployed) at a particular *point in time*. The higher the stock of unemployment, the longer will tend to be the duration of unemployment. There will be more people competing for vacant jobs.

The rate of inflow and outflow from the stock of unemployment. The people making up the unemployment total are constantly changing. Each week some people are made redundant or quit their jobs. They represent an inflow to the stock of unemployment. Other people find jobs and thus represent an outflow from the stock of unemployment. The various inflows and outflows are shown in Figure 15.10.

Unemployment is often referred to as ‘the pool of unemployment’. This is quite a good analogy. If the water flowing into a pool exceeds the water flowing out, the level of water in the pool will rise. Similarly, if the inflow of people into unemployment exceeds the outflow, the level of unemployment will rise.

The duration of unemployment will depend on the *rate* of inflow and outflow. The rate is expressed as the number of people per period of time. The bigger the flows are relative to the total number unemployed, the less will be the average duration of unemployment. This is because people move into and out of the pool more quickly, and hence their average stay will be shorter.

1. If the number unemployed exceeded the total annual outflow, what could we conclude about the average duration of unemployment?
2. Make a list of the various inflows to and outflows from employment from and to (a) unemployment; (b) outside the workforce.

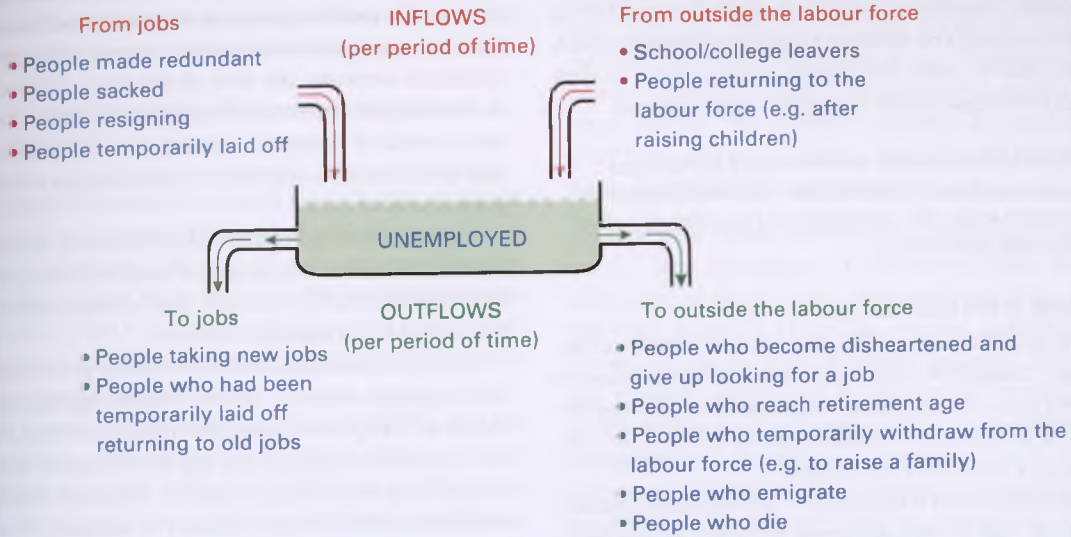

The phase of the business cycle. The duration of unemployment also depends on the phase of the business cycle. At the onset of a recession, unemployment will rise, but as yet the average length of unemployment is likely to have been relatively short. Once a recession has lasted for a period of time, however, people will on average have been out of work longer, and this long-term unemployment is likely to persist even when the economy is pulling out of recession.

Figure 15.9 UK standardised unemployment by duration

Source: Based on data from dataset UNEM01 SA: Unemployment by age and duration (seasonally adjusted) (ONS).

Figure 15.10 Flows into and out of unemployment

* LOOKING AT THE MATHS

The average duration of unemployment (D_U) will equal the stock of unemployment (U) as a proportion of the outflow (F) from unemployment.

$$D_U = \frac{U}{F}$$

Thus the bigger the stock of unemployment relative to the outflow from it, the longer will unemployment last. Taking the UK figures

for 2015, where the number unemployed (U) was 1.78 million and the total outflow from unemployment (F) was 3.44 million:

$$D_U = \frac{1.781}{3.44} = 0.533$$

Thus the average duration of unemployment was 0.533 years or 195 days. By contrast, in 2012, the average duration was $2.572/3.945 = 0.652$ years or 239 days.

Causes of unemployment

There are various possible causes of unemployment. It is important when thinking about policies to tackle unemployment to understand its determinants. The following are among those most commonly identified by economists.

Real wage rates

Nominal wage rates are the actual value of wage rates paid to workers. The real wage rate is the wage rate expressed in terms of its purchasing power to workers and the purchasing cost to employers. In other words, the real wage is the nominal wage corrected for inflation.

$$W_r = \frac{W_n}{P}$$

where W_r is the real wage rate; W_n is the nominal wage rate; and P is the price index (e.g. the CPI).

Real-wage unemployment occurs when trade unions use their monopoly power to drive wages *above* the

market-clearing level. It could also be caused by the government setting the national minimum wage too high.

A rise in real wage rates increases the effective cost to firms of employing workers. This is because the wage rates paid by firms have increased *relative* to the prices of their goods and services. Excessive real wage rates were blamed by the Conservative governments under Thatcher and Major for the high unemployment of the 1980s and 1990s. The possibility of higher real-wage unemployment was also one of the reasons for their rejection of a national minimum wage.

Definition

Real-wage unemployment Disequilibrium unemployment caused by real wages being driven up above the market-clearing level.

One effect of high real wage rates, however, may help to reduce real-wage unemployment. The extra wages paid to those who are still employed could lead to extra consumer expenditure. Higher real wage rates increase the purchasing power of workers. This addition to aggregate demand could, in turn, lead to firms demanding more labour, as they attempt to increase output to meet the extra demand.

? *If the higher consumer expenditure and higher wages subsequently led to higher prices, what would happen to (a) real wages; (b) unemployment (assuming no further response from unions)?*

The phase of the business cycle

We have seen throughout this chapter how volatile economies are. Changes in output associated with the business cycle will result in changes in employment and unemployment. In a recession, unemployment is likely to rise, whereas in a boom, it is likely to fall.

Demand-deficient is the name we give to unemployment associated with falling aggregate demand. As aggregate demand falls, firms find that they are unable to sell their current level of output. For a time they may be prepared to build up stocks of unsold goods, but sooner or later they will start to cut back on production and cut back on the amount of labour they employ.

As aggregate demand begins to grow again and firms increase output, so demand-deficient unemployment will start to fall again. Because demand-deficient unemployment fluctuates with the business cycle, it is sometimes referred to as **cyclical unemployment**. Figure 15.11 shows the fluctuations in unemployment in industrialised economies. If you compare this figure with Figure 15.1 on page 445, you can see how unemployment tends to rise in recessions and fall in booms.

Demand-deficient unemployment is also referred to as ‘Keynesian unemployment’, after John Maynard Keynes (see pages 492 and 498 below and Case Study 16.6 on the student website for a profile of the great economist), who saw a deficiency of aggregate demand as the cause of the high unemployment between the two world wars. Today, many economists are known as ‘Keynesian’. Although there are many strands of Keynesian thinking, these economists all see aggregate demand as important in determining a nation’s output and employment.

The more that aggregate demand fluctuates, the more significant the cyclical component of unemployment becomes. But what affects the amount that unemployment rises following a fall in aggregate demand?

One consideration is the magnitude and persistence of the fall in aggregate demand. This will affect the aggregate demand for labour. A large or enduring downturn could result in a large rise in unemployment as the aggregate demand for labour falls. On the other hand, a small or transitory downturn is more likely to have a smaller impact on unemployment.

Another consideration is the extent to which, if at all, the real average wage rate falls. A fall in real wage rates reduces the effective cost to firms of employing workers and thus helps to offset some of the fall in employment that arises from the general reduction in firms’ demand for labour. The UK has a relatively ‘flexible’ labour market with many

Definition

Demand-deficient or cyclical unemployment
Disequilibrium unemployment caused by a fall in aggregate demand with no corresponding fall in the real wage rate.

Figure 15.11 Standardised unemployment rates in selected industrial economies

people on zero-hour, part-time or 'self-employed' contracts and having no union representation. In the recession that followed the financial crisis in the late 2000s, many workers faced cuts in real wages, but unemployment rose less than in some other countries with less flexible labour markets.

Is it only in the interest of workers to resist falls in real wage rates?

For some Keynesian economists, however, the problem is much more fundamental than a downward stickiness in real wages. For them the problem is that the low level of aggregate demand causes an *equilibrium* in the *goods* market at an output that is too low to generate full employment. Firms' supply is low (below the full-employment level of supply) because aggregate demand is low.

This low-level equilibrium in the goods market, and the corresponding disequilibrium in the labour market, may *persist*. This is the result of a lack of confidence on the part of firms. After all, why should firms produce more and take on more workers if they believe that the recession will persist and that they will therefore not sell any more? The economy remains trapped in a low-output equilibrium. In such cases, a fall in real wages would not cure the unemployment. In fact, it might even make the problem worse.

If this analysis is correct, namely that a reduction in wages will reduce the aggregate demand for goods, what assumption must we make about the relative proportions of wages and profits that are spent (given that a reduction in real wage rates will lead to a corresponding increase in rates of profit)?

Information

Frictional (search) unemployment occurs when people leave their jobs, either voluntarily or because they are sacked or made redundant, and are unemployed for a period of time while they are looking for a new job. They may not get the first job they apply for, despite a vacancy existing and despite their being suitably qualified.

The problem is that information is imperfect. Employers are not fully informed about what labour is available; workers are not fully informed about what jobs are available and what they entail. Both employers and workers, therefore, have to search: employers searching for the right labour and workers searching for the right jobs.

One obvious remedy for frictional unemployment is to provide better job information through government job centres, private employment agencies or the media. Another much more controversial remedy is for the government to reduce the level of unemployment benefit. This will make the unemployed more desperate to get a job and thus prepared to accept a lower wage.

Structural change

Structural unemployment occurs where the structure of the economy changes. Many countries have witnessed rapid structural change over recent years. This has seen

employment in some industries expand while in others it has contracted. There are two main reasons for this.

A change in the pattern of demand. Some industries experience declining demand. This may be due to a change in consumer tastes as certain goods go out of fashion; or it may be due to competition from other industries or from competition overseas. For example, consumer demand may shift away from coal and to other fuels. This will lead to structural unemployment in mining areas.

A change in the methods of production (technological unemployment). New techniques of production often allow the same level of output to be produced with fewer workers (see Case Study 15.11 on the student website). This is known as 'labour-saving technical progress'. Unless output expands sufficiently to absorb the surplus labour, people will be made redundant. This creates **technological unemployment**. An example is the loss of jobs in the banking industry caused by the increase in the number of cash machines and by the development of telephone and Internet banking.

Structural unemployment often occurs in particular regions of the country when industries located in those regions decline or introduce labour-saving technology. When it does, it is referred to as **regional unemployment**.

The level of structural unemployment depends on three factors:

- The degree of **regional concentration** of industry. The more that industries are concentrated in particular regions, the greater will be the level of structural unemployment if particular industries decline. For example, the collapse in the South Wales coal-mining industry led to high unemployment in the Welsh valleys.
- The **speed of change** of demand and supply in the economy. The more rapid the rate of technological change or the shift in consumer tastes, the more rapid will be the rate of redundancies.

Definitions

Frictional (search) unemployment Equilibrium unemployment that occurs as a result of imperfect information in the labour market. It often takes time for workers to find jobs (even though there are vacancies) and in the meantime they are unemployed.

Structural unemployment Equilibrium unemployment that arises from changes in the pattern of demand or supply in the economy. People made redundant in one part of the economy cannot immediately take up jobs in other parts (even though there are vacancies).

Technological unemployment Structural unemployment that occurs as a result of the introduction of labour-saving technology.

Regional unemployment Structural unemployment occurring in specific regions of the country.

■ **The immobility of labour.** The less able or willing workers are to move to a new job, the higher will be the level of structural unemployment. In Chapter 10 we made the distinction between geographical and occupational immobility (see pages 281–2). Geographical immobility is a particular problem with regional unemployment. Occupational immobility is a particular problem with technological unemployment where old skills are no longer required.

There are two broad approaches to tackling structural unemployment: *market-orientated* and *interventionist*.

A market-orientated approach involves encouraging people to look more actively for jobs, if necessary in other parts of the country. It involves encouraging people to adopt a more willing attitude towards retraining, and if necessary to accept some reduction in wages.

An interventionist approach involves direct government action to match jobs to the unemployed. Two examples are providing grants to firms to set up in areas of high unemployment (regional policy), and government-funded training schemes.

Policies to tackle structural unemployment are examined in detail in sections 23.5 and 23.6.

Seasonal factors

Seasonal unemployment occurs when the demand for certain types of labour fluctuates with the seasons of the year. This problem is particularly severe in holiday areas, such as Cornwall, where unemployment can reach very high levels in the winter months. Policies for tackling seasonal unemployment are similar to those for structural unemployment.

Section summary

1. Who should be counted as 'unemployed' is a matter for some disagreement. The two most common measures of unemployment are claimant unemployment (those claiming unemployment-related benefits) and ILO/OECD standardised unemployment (those available for work and actively seeking work or waiting to take up an appointment). Standardised unemployment measures are based on labour force surveys.
2. The 'stock' of unemployment will grow if the inflow of people into unemployment exceeds the outflow (to jobs or out of the labour market altogether). The more rapid these flows, the shorter the average duration of unemployment.
3. In most countries, unemployment is unevenly distributed across geographical regions, between women and men, between age groups and between different ethnic groups.
4. The costs of unemployment include the financial and other personal costs to the unemployed person, the costs to relatives and friends, and the costs to society at large in terms of lost tax revenues, lost profits and lost wages to other workers, and in terms of social disruption.
5. When thinking about possible policies to tackle unemployment it is important to understand its causes.
6. Possible causes include excessive real wages (real-wage unemployment), deficient aggregate demand (demand-deficient or cyclical unemployment), poor information in the labour market and hence a time lag before people find suitable jobs (frictional unemployment), structural change in the economy (structural unemployment – specific types being technological and regional unemployment), or seasonal fluctuations in the demand for labour (seasonal unemployment).

15.6 INFLATION

The rate of inflation refers to the annual percentage increase in price levels. By this is meant the percentage increase in a specific price index.

Different inflation rate measures

As we saw in section 15.1, the term 'rate of inflation' is typically used to refer to the annual percentage change in *consumer* prices. The index that is normally used is the consumer prices index (CPI), which is used throughout the EU. Sometimes in the UK an older measure is used, the retail price index (RPI). Unlike CPI, RPI includes housing costs. The CPI is seen as more sophisticated as it is based on a geometric mean of the basket of goods making up the index, whereas the RPI is based on an arithmetic mean. The effect is to make

the RPI typically around 1.2 percentage points higher than the CPI. People whose incomes are increased in line with inflation will thus fare better if this is based on the RPI rather than the CPI.⁵

⁵ See Julian Champkin, 'RPI versus CPI: what's the difference? Why does it matter? Will it make you poorer or richer?', *Significance* (RSS/ASA, 10 January 2013).

Definition

Seasonal unemployment Unemployment associated with industries or regions where the demand for labour is lower at certain times of the year.

A broader measure of inflation relates to the rate at which the prices of all domestically produced goods and services are changing. The price index used in this case is known as the **GDP deflator** (see Case Study 15.1 on the student website). Figure 15.12 shows inflation rates for selected industrialised countries using the GDP deflator.

LOOKING AT THE MATHS

The inflation rate (π) is calculated from the following formula:

$$\pi_t = \frac{P_t - P_{t-1}}{P_{t-1}} \times 100$$

where P_t is the price index for year t and P_{t-1} is the price index for the previous year. Thus if the price index for year 1 is 140.0 and that for year 2 is 149.1, then inflation in year 2 is

$$\pi = \frac{149.1 - 140.0}{140.0} \times 100 = 6.5\%$$

It is also possible to give the rates of inflation for other prices. For example, indices are published for commodity prices, for food prices, for house prices, for import prices, for prices after taking taxes into account and so on. Their respective rates of inflation are simply their annual percentage increases. Likewise it is possible to give the rate of inflation of wage rates ('wage inflation').

Figure 15.13 shows three inflation rate measures for the UK from 2001. Of the three inflation rates, the annual growth of average weekly earnings shows the most variability. This has implications for the purchasing power of workers. We can see, for example, a marked erosion of purchasing

power in 2009 following the financial crisis and again, to some degree, during 2014 and 2017.

Before we proceed, a word of caution: be careful not to confuse a rise or fall in *inflation* with a rise or fall in *prices*. A rise in inflation means a *faster* increase in prices. A fall in inflation means a *slower* increase in prices (but still an increase as long as inflation is positive). (See Box A1.1 on page A:11.)

Make a list of those who are most likely to gain and those who are most likely to lose from inflation.

Causes of inflation

Demand-pull inflation

Demand-pull inflation is caused by continuing rises in aggregate demand. Firms will respond to a rise in demand partly by raising prices and partly by increasing output. Just how much they raise prices depends on how much their costs rise as a result of increasing output. The closer actual output gets to potential output, and the less slack there is in the economy, the more will firms respond to a rise in

Definitions

GDP deflator The price index of all final domestically produced goods and services, i.e. all those items that contribute towards GDP.

Demand-pull inflation Inflation caused by persistent rises in aggregate demand

Figure 15.12 Inflation rates in selected industrial economies

Figure 15.13 Selection of annual UK inflation rates

Notes: AWE is the average regular weekly pay (including bonuses) over the latest three months.

Source: Based on *Time Series Data*, series IHYU, D7G7 and KAC3 (ONS).

demand by raising their prices. On the other hand, the greater the spare capacity, the more will firms respond by raising output and the less by raising prices.

Sometimes there may be a *single* increase in demand (or a 'demand shock'). This could be due, for example, to an increased level of government expenditure. The effect is to give a *single* rise in the price level. Although this causes inflation in the short run, once the effect has taken place, inflation will fall back to zero. For inflation to persist, there must be *continuing* increases in aggregate demand and thus continuing rises in the price level. If inflation is to rise, the rate of increase in aggregate demand must also rise.

Demand-pull inflation is typically associated with a booming economy. Many economists therefore argue that it is the counterpart of demand-deficient unemployment. When the economy is in recession, demand-deficient unemployment is high, but demand-pull inflation is low. When, on the other hand, the economy is near the peak of the business cycle, demand-pull inflation is high, but demand-deficient unemployment is low.

Cost-push inflation

Cost-push inflation is associated with continuing rises in costs which occur *independently* of aggregate demand.

If firms face a rise in costs, they will respond partly by raising prices and passing the costs on to the consumer, and partly by cutting back on production. Just how much firms raise prices and cut back on production depends on the impact of price changes on aggregate demand. The less responsive is aggregate demand to price changes, the less will sales fall as a result of any price rise. This allows firms to pass on more of the rise in their costs to consumers as higher prices. On the other hand, the more sensitive aggregate

demand is to price changes, the less able are firms to pass on their higher costs to consumers: hence prices rise by less.

Note that the effect on output and employment is the opposite of demand-pull inflation. With demand-pull inflation, output and hence employment tends to rise. With cost-push inflation, however, output and employment tends to fall.

As with demand-pull inflation, we must distinguish between *one-off* increases in cost (a 'supply shock') from *continuing* increases. If there is a one-off increase in costs, there will be a one-off rise in the price level. For example, if the government raises the excise duty on petrol and diesel, there will be a single rise in fuel prices and hence in firms' fuel costs. This will cause *temporary* inflation while the price rise is passed on through the economy. Once this has occurred, prices will stabilise at the new level and the rate of inflation will fall back to zero again. If cost-push inflation is to continue over a number of years, therefore, then costs must *continually* increase. If cost-push inflation is to *rise*, the rate of increase in costs must also rise.

Sources of cost-push inflation. Rises in costs may originate from a number of different sources, such as trade unions pushing up wages, firms with monopoly power raising prices in order to increase their profits, or increases in international commodity prices. With the process of globalisation and

Definition

Cost-push inflation Inflation caused by persistent rises in costs of production (independently of demand).

BOX 15.5

THE COSTS OF INFLATION

EXPLORING
ECONOMICS

Who loses and by how much?

A lack of growth is obviously a problem if people want higher living standards. Unemployment is obviously a problem, both for the unemployed themselves and also for society, which suffers a loss in output and has to support the unemployed. But why is inflation a problem? If prices go up by 10 per cent, does it really matter? Provided your wages kept up with prices, you would have no cut in your living standards.

If people could correctly anticipate the rate of inflation and fully adjust prices and incomes to take account of it, then the costs of inflation would indeed be relatively small. For us as consumers, they would simply be the relatively minor inconvenience of having to adjust our notions of what a 'fair' price is for each item when we go shopping. For firms, they would again be the relatively minor costs of having to change price labels, or prices in catalogues or on menus, or adjust slot machines. These are known as **menu costs**.

In reality, people frequently make mistakes when predicting the rate of inflation and are not able to adapt fully to it. This leads to the following problems, which are likely to be more serious the higher the rate of inflation becomes and the more the rate fluctuates.

Redistribution. Inflation redistributes income away from those on fixed incomes and those in a weak bargaining position, to those who can use their economic power to gain large pay, rent or profit increases. It redistributes wealth to those with assets (e.g. property) that rise in value particularly rapidly during periods of inflation, and away from those with types of savings that pay rates of interest below the rate of inflation and hence whose value is eroded by inflation. Elderly people who rely on the interest from their savings may be particularly badly hit by rapid inflation.

Uncertainty and lack of investment. Inflation tends to cause uncertainty among the business community, especially when the rate of inflation fluctuates. (Generally, the higher the rate of inflation, the more it fluctuates.) If it is difficult for firms to predict their costs and revenues, they may be discouraged from investing. This will reduce the rate of economic growth. On the other hand, as will be explained below, policies to

reduce the rate of inflation may themselves reduce the rate of economic growth, especially in the short run. This may then provide the government with a policy dilemma.

Balance of payments. Inflation is likely to worsen the balance of trade. If a country suffers from relatively high inflation, its exports will become less competitive in world markets. At the same time, imports will become relatively cheaper than home-produced goods. Thus exports will fall and imports will rise. This is known as an international substitution effect. As a result, the balance of trade will deteriorate and/or the exchange rate will fall. Both of these effects can cause problems.

Resources. Extra resources are likely to be used to cope with the effects of inflation. Accountants and other financial experts may have to be employed by companies to help them cope with the uncertainties caused by inflation.

The costs of inflation may be relatively mild if inflation is kept to single figures. They can be very serious, however, if inflation gets out of hand. If inflation develops into 'hyperinflation', with prices rising perhaps by several hundred per cent or even thousands per cent per year, the whole basis of the market economy will be undermined. Firms constantly raise prices in an attempt to cover their soaring costs. Workers demand huge pay increases in an attempt to stay ahead of the rocketing cost of living. Thus prices and wages chase each other in an ever-rising inflationary spiral. People will no longer want to save money. Instead they will spend it as quickly as possible before its value falls any further. People may even resort to barter in an attempt to avoid using money altogether. (Case Study 15.14 on the student website looks at historical cases of hyperinflation in Germany in the 1920s, Serbia in the 1990s and Zimbabwe in the 2000s.)

1. Do you personally gain or lose from inflation? Why?
2. Make a list of those who are most likely to gain and those who are most likely to lose from inflation.

increased international competition, cost-push pressures have tended to decrease in recent years. One major exception has been the oil shocks that have occurred from time to time. For example, the near tripling of oil prices from \$51 per barrel in January 2007 to \$147 per barrel in July 2008, and again from \$41 a barrel in January 2009 to \$126 a barrel in April 2011, put upward pressure on costs and prices around the world.

Temporary supply shocks can come from bad harvests. Longer-term supply-side problems can come from the depletion of natural resources, such as the gradual running down

of North Sea oil, pollution of the seas and hence a decline in incomes for nations with large fishing industries, and, perhaps the most devastating of all, the problem of 'desertification' in sub-Saharan Africa.

Menu costs of inflation The costs associated with having to adjust price lists or labels.

BOX 15.6 THE PHILLIPS CURVE**Is higher inflation the price for lower unemployment?**

If inflation tends to be higher when the economy is booming and if unemployment tends to be higher in recessions, does this mean that there is a 'trade-off' between inflation and unemployment: that lower unemployment tends to be associated with higher inflation, and lower inflation with higher unemployment? Such a trade-off was observed by the New Zealand economist Bill Phillips (see Case Study 15.15 on the student website), and was illustrated by the famous *Phillips curve*.

The original Phillips curve

In 1958, Phillips showed the statistical relationship between wage inflation and unemployment in the UK from 1861 to 1957. With wage inflation (w) on the vertical axis and the unemployment rate (U) on the horizontal axis, a scatter of points was obtained. Each point represented the observation for a particular year. The curve that best fitted the scatter has become known as the 'Phillips curve'. It is illustrated in Figure (a) and shows an inverse relationship between inflation and unemployment.¹

Given that wage increases over the period were approximately 2 per cent above price increases (made possible because of increases in labour productivity), a similar-shaped, but lower curve could be plotted showing the relationship between *price* inflation and unemployment.

The curve has often been used to illustrate the effects of changes in aggregate demand. When aggregate demand rose (relative to potential output), inflation rose and

unemployment fell: there was an upward movement along the curve. When aggregate demand fell, there was a downward movement along the curve.

There was also a second reason given for the inverse relationship. If wages rose, the unemployed might have believed that the higher wages they were offered represented a *real* wage increase. That is, they might not have realised that the higher wages would be 'eaten up' by price increases: they might have suffered from *money illusion*. They would thus have accepted jobs more readily. The average duration of unemployment therefore fell. This is a reduction in *frictional* unemployment.

The Phillips curve was bowed in to the origin. The usual explanation for this is that, as aggregate demand expanded, at first there would be plenty of surplus labour, which could meet the extra demand without the need to raise wages very much. But as labour became increasingly scarce, firms would find they had to offer increasingly higher wages to obtain the labour they required, and the position of trade unions would be increasingly strengthened.

The *position* of the Phillips curve depended on *non-demand* factors causing inflation and unemployment: frictional and structural unemployment; and cost-push, structural and expectations-generated inflation. If any of these non-demand factors changed so as to raise inflation or unemployment, the curve would shift outwards to the right. The relative stability of the curve over the hundred years or so observed by Phillips suggested that these non-demand factors had changed little.

The Phillips curve seemed to present governments with a simple policy choice. They could trade off inflation against unemployment. Lower unemployment could be bought at the cost of higher inflation, and vice versa. Unfortunately, the experience since the late 1960s has suggested that no such simple relationship exists beyond the short run.

The breakdown of the Phillips curve

From about 1967 the Phillips curve relationship seemed to break down. The UK, and many other countries in the Western world too, began to experience growing unemployment *and* higher rates of inflation.

Figure (b) shows price inflation (π) and (standardised) unemployment in the UK from 1960. From 1960 to 1967 a curve similar to the Phillips curve can be fitted through the data (the red line). From 1968 to the early 1990s, however, no simple picture emerges. Certainly the original Phillips

(a) *The original Phillips curve***The interaction of demand-pull and cost-push inflation**

Demand-pull and cost-push inflation can occur together, since wage and price rises can be caused both by increases in aggregate demand and by independent causes pushing up costs. Even when an inflationary process *starts* as either demand-pull or cost-push, it is often difficult to separate the two. An initial cost-push inflation may encourage the government to expand aggregate demand to offset rises in unemployment. Alternatively, an initial demand-pull

curve could no longer fit the data; but whether the curve shifted to the right and then back again somewhat (the broken lines), or whether the relationship broke down completely, or whether there was some quite different relationship between inflation and unemployment, is not clear by simply looking at the data.

Since 1997, the Bank of England has been targeting inflation (see section 22.3). For much of this period the 'curve' would seem to have become a virtually horizontal straight line. However, from the late 2000s, against a backdrop of significant economic volatility and uncertainty, the range of inflation rates increased despite inflation rate targeting. A contributory factor to this was the volatility experienced in commodity prices. In the middle of the 2010s, for example, inflation fell

below the target as commodity prices fell reflecting sluggish demand in the eurozone and elsewhere.

Over the years, there has been much debate among economists about the relationship between inflation and unemployment. The controversy will be examined in later chapters and particularly in Chapter 21. One thing does seem clear, however: the relationship is different in the short run and the long run.

Assume that there is a trade-off between unemployment and inflation, traced out by a 'Phillips curve'. What could cause a leftward shift in this curve?

1 Phillips' estimated equation was $\omega = -0.9 + 9.638U^{-1.394}$.

inflation may strengthen the power of certain groups, which then use this power to drive up costs.

Expectations and inflation

Workers and firms take account of the *expected* rate of inflation when making decisions.

Imagine that a union and an employer are negotiating a wage increase. Let us assume that both sides expect a rate of

inflation of 5 per cent. The union will be happy to receive a wage rise somewhat above 5 per cent. That way the members would be getting a *real* rise in incomes. The employers will be happy to pay a wage rise somewhat below 5 per cent. After all, they can put their price up by 5 per cent, knowing that their rivals will do approximately the same. The actual wage rise that the two sides agree on will thus be somewhere around 5 per cent.

Now let us assume that the expected rate of inflation is 10 per cent. Both sides will now negotiate around this benchmark, with the outcome being somewhere round about 10 per cent. Thus the higher the expected rate of inflation, the

higher will be the level of pay settlements and price rises, and hence the higher will be the resulting *actual* rate of inflation.

Just how expectations impact on inflation depends on how they are formed. We examine this in Chapter 21.

Section summary

1. Demand-pull inflation occurs as a result of increases in aggregate demand. This can be due to monetary or non-monetary causes.
2. Cost-push inflation occurs when there are increases in the costs of production independent of rises in aggregate demand. If there is a single supply-side shock, the inflation will peter out. For cost-push inflation to persist, there must be continuous increases in costs.
3. Cost-push and demand-pull inflation can interact to form spiralling inflation.
4. Expectations play a crucial role in determining the rate of inflation. The higher people expect inflation to be, the higher it will be.

15.7 THE OPEN ECONOMY

All countries trade with and have financial dealings with the rest of the world. In other words, all countries are *open economies*. Indeed, over time the economies of nations have become ever more intimately linked. Key drivers of this global interconnectedness of economies are globalisation, financialisation and improved communications.

Global interconnectedness means economic events in one part of the world, such as changes in interest rates or a downturn in economic growth, can have myriad knock-on effects for the international community at large – from the international investor, to the foreign exchange dealer, to the domestic policy maker, to the business which exports or imports, or which has subsidiaries abroad. Consequently, the international component of countries' business cycles has tended to become ever more important.

The balance of payments account

The flows of money between residents of a country and the rest of the world are recorded in the country's *balance of payments account*.

Receipts of money from abroad are regarded as *credits* and are entered in the accounts with a positive sign. *Outflows* of money from the country are regarded as *debits* and are entered with a negative sign.

There are three main parts of the balance of payments account: the *current account*, the *capital account* and the *financial account*. Each part is then subdivided. We shall look at each part in turn, and take the UK as an example. Table 15.5 gives a summary of the UK balance of payments for 2016, while also providing an historical perspective.

The current account

The *current account* records payments for imports and exports of goods and services, plus incomes flowing into and out of the country, plus net transfers of money into and out of the country. It is normally split into four subdivisions.

The trade in goods account. This records imports and exports of physical goods (previously known as 'visibles'). Exports result in an inflow of money and are therefore a credit item. Imports result in an outflow of money and are therefore a debit item. The balance of these is called the *balance on trade in goods* or *balance of visible trade* or *merchandise balance*. A *surplus* is when exports exceed imports. A *deficit* is when imports exceed exports.

The trade in services account. This records imports and exports of services (such as transport, tourism and insurance). Thus the purchase of a foreign holiday would be a debit, since it represents an outflow of money, whereas the purchase by an overseas resident of a UK insurance policy would be a credit to the UK services account. The balance of these is called the *services balance*.

Definitions

Open economy One that trades with and has financial dealings with other countries.

Balance of payments account The record of all the economic transactions between the residents of a specific country with the rest of the world for a specific time period, typically a year or a quarter. It records all the inflows and outflows of money under various headings. Inflows are recorded as credits; outflows are recorded as debits.

Current account of the balance of payments The record of a country's imports and exports of goods and services, plus incomes and transfers of money to and from abroad.

Balance on trade in goods or balance of visible trade or merchandise balance Exports of goods minus imports of goods.

The balance of both the goods and services accounts together is known as the **balance on trade in goods and services** or simply the **balance of trade**.

Income flows. These consist of wages, interest and profits flowing into and out of the country. For example, dividends earned by a foreign resident from shares in a UK company would be an outflow of money (a debit item).

Current transfers of money. These include government contributions to and receipts from the EU and international organisations, and international transfers of money by private individuals and firms for the purpose of *consumption*. Transfers out of the country are debits. Transfers into the country (e.g. money sent from Greece to a Greek student studying in the UK) would be a credit item.

The **current account balance** is the overall balance of all the above four subdivisions. A **current account surplus** is where credits exceed debits. A **current account deficit** is where debits exceed credits. Figure 15.14 shows the current account balances of a selection of countries as a proportion of their GDP since 1960. The chart shows how global imbalances on the current account have tended to increase over time, particularly since the 1980s. In conjunction with Table 15.5 we can also see that the UK has consistently run a current account deficit over the past three decades or so. This has been driven by a large trade deficit in goods.

? Why are the US and UK current balances approximately a 'mirror image' of the Japanese and German current balances?

The capital account

The **capital account** records the flows of funds, into the country (credits) and out of the country (debits), associated with the acquisition or disposal of fixed assets (e.g. land or intangibles, such as patents and trademarks), the transfer of funds by migrants, the payment of grants by the government for overseas projects, debt forgiveness by the government and the receipt of money for capital projects (e.g. from the EU's Agricultural Guidance Fund).

As Table 15.5 shows, the balance on the capital account is small in comparison to that on the current and financial accounts.

The financial account¹

The **financial account** of the balance of payments records cross-border changes in the holding of shares, property, bank deposits and loans, government securities, etc. In

other words, unlike the current account, which is concerned with money *incomes*, the financial account is concerned with the purchase and sale of *assets*. Case Study 15.16 on the student website considers some of the statistics behind the UK's financial account.

Investment (direct and portfolio). This account covers primarily long-term investment.

- Direct investment.** This involves a significant and lasting interest in a business in another country. If a foreign company invests money from abroad in one of its branches or associated companies in the UK, this represents an inflow of money when the investment is made and is thus a credit item. (Any subsequent profit from this investment that flows abroad will be recorded as an *investment income outflow* on the current account.) Investment abroad by UK companies represents an outflow of money when the investment is made. It is thus a debit item.

Note that what we are talking about here is the acquisition or sale of assets: e.g. a factory or farm, or the takeover of a whole firm, not the imports or exports of equipment.

- Portfolio investment.** This relates to transactions in debt and equity securities which do not result in the investor having any significant influence on the operations of a particular business. If a UK resident buys shares (equity securities) in an overseas company, this is an outflow of funds and is hence a debit item.

Other financial flows. These consist primarily of various types of short-term monetary movement between the UK and the rest of the world. Deposits by overseas residents in banks in the UK and loans to the UK from abroad are credit items, since they represent an inflow of money. Deposits by UK residents in overseas banks and loans by UK banks to

overseas residents are debit items. They represent an outflow of money.

Short-term monetary flows are common between international financial centres to take advantage of differences in countries' interest rates and changes in exchange rates.

1. Why may inflows of short-term deposits create a problem?
2. Where would interest payments on short-term foreign deposits in UK banks be entered on the balance of payments account?

Note that in the financial account, credits and debits are recorded *net*. For example, UK investment abroad consists of the net acquisition of assets abroad (i.e. the purchase *less* the sale of assets abroad). Similarly, foreign investment in the UK consists of the purchase *less* the sale of UK assets by foreign residents. Note that in either case the flow could be in the opposite direction. For example, if UK residents purchased fewer assets abroad than they sold, this item would be a net credit, not a debit (there would be a net return of money to the UK).

By recording financial account items net, the flows seem misleadingly modest. For example, if UK residents deposited an extra £100bn in banks abroad but drew out £99bn, this would be recorded as a mere £1bn net outflow on the other financial flows account. In fact, *total* financial account flows vastly exceed current plus capital account flows.

Flows to and from the reserves. The UK, like all other countries, holds reserves of gold and foreign currencies. From time to time the Bank of England (acting as the government's agent) will sell some of these reserves to purchase sterling on the foreign exchange market. It does this normally as a means of supporting the rate of exchange (see below). Drawing on reserves represents a *credit* item in the

balance of payments accounts: money drawn from the reserves represents an *inflow* to the balance of payments (albeit an outflow from the reserves account). The reserves can thus be used to support a deficit elsewhere in the balance of payments.

Conversely, if there is a surplus elsewhere in the balance of payments, the Bank of England can use it to build up the reserves. Building up the reserves counts as a debit item in the balance of payments, since it represents an outflow from it (to the reserves).

When all the components of the balance of payments account are taken together, the balance of payments should exactly balance: credits should equal debits. As we shall see below, if they were not equal, the rate of exchange would have to adjust until they were, or the government would have to intervene to make them equal.

When the statistics are compiled, however, a number of errors are likely to occur. As a result, there will not be a balance. To 'correct' for this, a *net errors and omissions* item is included in the accounts. This ensures that there will be an exact balance. The main reason for the errors is that the statistics are obtained from a number of sources, and there are often delays before items are recorded and sometimes omissions too.

? With reference to the above, provide an assessment of the UK balance of payments in each of the years illustrated in Table 15.5.

Figure 15.15 graphically summarises the main accounts of the UK's balance payments: current, capital and financial accounts. It presents each as a percentage of national income (see also right-hand column of Table 15.5). In conjunction with the net errors and omissions item, which averages close to zero over the long run, we can see how the accounts

combine to give a zero overall balance. For much of the period since the late 1980s, current account deficits have been offset by surpluses on the financial account.

What causes deficits to occur on the various parts of the balance of payments? The answer has to do with the demand for and supply of sterling on the foreign exchange market. Thus before we can answer the question, we must examine this market and in particular the role of the rate of exchange.

Exchange rates

An exchange rate is the rate at which one currency trades for another on the foreign exchange market.

If you live in the UK and go abroad, you will need to exchange your pounds into euros, dollars, Swiss francs or whatever. You will get the money at the exchange rate in operation at the time you draw it from a cash machine abroad or from a bank: for example, €1.15 to the pound, or \$1.25 to the pound.

It is similar for firms. If an importer wants to buy, say, some machinery from Japan, it will require yen to pay the Japanese supplier. It will thus ask the foreign exchange section of a bank to quote it a rate of exchange of the pound into yen. Similarly, if you want to buy some foreign stocks and shares, or if companies based in the UK want to invest abroad, sterling will have to be exchanged into the appropriate foreign currency.

Likewise, if Americans want to come on holiday to the UK or to buy UK assets, or US firms want to import UK goods or to invest in the UK, they will require sterling. They will get it at an exchange rate such as £1 = \$1.25. This means that they will have to pay \$1.25 to obtain £1 worth of UK goods or assets.

Exchange rates are quoted between each of the major currencies of the world. These exchange rates are constantly

Figure 15.15 UK balance of payments as a percentage of GDP

changing. Minute by minute, dealers in the foreign exchange dealing rooms of the banks are adjusting the rates of exchange. They charge commission when they exchange currencies. It is important for them, therefore, to ensure that they are not left with a large amount of any currency unsold. What they need to do is to balance the supply and demand of each currency: to balance the amount they purchase to the amount they sell. To do this, they will need to adjust the price of each currency, namely the exchange rate, in line with changes in supply and demand.

Not only are there day-to-day fluctuations in exchange rates, but also there are long-term changes in them. Figure 15.16 shows the average quarterly exchange rates between the pound and various currencies since 1980.

One of the problems in assessing what is happening to a particular currency is that its rate of exchange may rise against some currencies (weak currencies) and fall against others (strong currencies). In order to gain an overall picture of its fluctuations, therefore, it is best to look at a weighted average exchange rate against all other currencies. This is known as the *exchange rate index*. The weight given to each currency in the index depends on the percentage of UK trade in goods and services done with countries using that currency. The weights are revised annually. Figure 15.16 also shows the sterling exchange rate index based on 2005 = 100.

? From looking at Figure 15.16, how has the pound 'fared' compared with the US dollar and the yen from 1980? What conclusions can be drawn about the relative movements between these currencies?

Note that all the exchange rates must be consistent with each other. For example, if £1 exchanged for \$1.50 or 150 yen, then \$1.50 would have to exchange for 150 yen directly

(i.e. \$1 = 100 yen), otherwise people could make money by moving around in a circle between the three currencies in a process known as *arbitrage*.

The determination of the rate of exchange in a free market

In a free foreign exchange market, the rate of exchange is determined by demand and supply. This is known as a *floating exchange rate*, and is illustrated in Figure 15.17.

For simplicity, assume that there are just two countries: the UK and the USA. When UK importers wish to buy goods from the USA, or when UK residents wish to invest in the USA, they will *supply* pounds on the foreign exchange market in order to obtain dollars. The higher the exchange rate, the more dollars they will obtain for their pounds. This will effectively make US goods cheaper to buy, and investment more profitable. Thus the *higher* the exchange rate, the *more*

Definitions

Exchange rate index A weighted average exchange rate expressed as an index, where the value of the index is 100 in a given base year. The weights of the different currencies in the index add up to 1

Arbitrage Buying an asset in a market where it has a lower price and selling it again in another market where it has a higher price and thereby making a profit.

Floating exchange rate When the government does not intervene in the foreign exchange markets, but simply allows the exchange rate to be freely determined by demand and supply.

Figure 15.16 Sterling exchange rates against selected currencies

Notes: The euro was introduced in 1999, with notes and coins circulating from 2001. The euro figures prior to 1999 (in grey) are projections backwards in time based on the average exchange rates of the currencies that made up the euro.

Source: Based on data in *Time Series Data* (ONS).

Figure 15.17 Determination of the rate of exchange

pounds will be supplied. The supply curve of pounds, therefore, typically slopes upwards.

When US residents wish to purchase UK goods or to invest in the UK, they will require pounds. They demand pounds by selling dollars on the foreign exchange market. The lower the dollar price of the pound (the exchange rate), the cheaper it will be for them to obtain UK goods and assets, and hence the more pounds they are likely to demand. The demand curve for pounds, therefore, typically slopes downwards.

The equilibrium exchange rate is where the demand for pounds equals the supply. In Figure 15.17 this is at an exchange rate of $\text{£}1 = \$1.30$. But what is the mechanism that equates demand and supply?

If the current exchange rate were above the equilibrium, the supply of pounds being offered to the banks would exceed the demand. For example, in Figure 15.17, if the exchange rate were \$1.40, there would be an excess supply of pounds of $a - b$. The banks, wishing to make money by exchanging currency, would have to lower the exchange rate in order to encourage a greater demand for pounds and reduce the excessive supply. They would continue lowering the rate until demand equalled supply.

Similarly, if the rate were below the equilibrium, say at \$1.20, there would be a shortage of pounds of $c - d$. The banks would find themselves with too few pounds to meet all the demand. At the same time, they would have an excess supply of dollars. The banks would thus raise the exchange rate until demand equalled supply.

In practice, the process of reaching equilibrium is extremely rapid. The foreign exchange dealers in the banks are continually adjusting the rate as new customers make

new demands for currencies. What is more, the banks have to watch each other closely since they are constantly in competition with each other and thus have to keep their rates in line. The dealers receive minute-by-minute updates on their computer screens of the rates being offered around the world.

Shifts in the currency demand and supply curves

Any shift in the demand or supply curves will cause the exchange rate to change. This is illustrated in Figure 15.18, which shows the euro/sterling exchange rate. If the demand and supply curves shift from D_1 and S_1 to D_2 and S_2 respectively, the exchange rate will fall from $\text{€}1.40$ to $\text{€}1.20$. A fall in the exchange rate is called a **depreciation**. A rise in the exchange rate is called an **appreciation**.

But why should the demand and supply curves shift? The following are the major possible causes of a depreciation:

- **A fall in domestic interest rates.** UK rates would now be less competitive for savers and other depositors. More UK residents would be likely to deposit their money abroad (the supply of sterling would rise), and fewer people abroad would deposit their money in the UK (the demand for sterling would fall).

Definitions

Depreciation A fall in the free-market exchange rate of the domestic currency with foreign currencies.

Appreciation A rise in the free-market exchange rate of the domestic currency with foreign currencies.

Figure 15.18 Floating exchange rates: movement to a new equilibrium

- **Higher inflation in the domestic economy than abroad.** UK exports will become less competitive. The demand for sterling will fall. At the same time, imports will become relatively cheaper for UK consumers. The supply of sterling will rise.
- **A rise in domestic incomes relative to incomes abroad.** If UK incomes rise, the demand for imports, and hence the supply of sterling, will rise. If incomes in other countries fall, the demand for UK exports, and hence the demand for sterling, will fall.
- **Relative investment prospects improving abroad.** If investment prospects become brighter abroad than in the UK, perhaps because of better incentives abroad, or because of worries about an impending recession in the UK, again the demand for sterling will fall and the supply of sterling will rise.

BOX 15.7 DEALING IN FOREIGN EXCHANGE

CASE STUDIES AND APPLICATIONS

A daily juggling act

Imagine that a large car importer in the UK wants to import 5000 cars from Japan costing ¥15 billion. What does it do?

It will probably contact a number of banks' foreign exchange dealing rooms in London and ask them for exchange rate quotes. It thus puts all the banks in competition with each other. Each bank will want to get the business and thereby obtain the commission on the deal. To do this it must offer a higher rate than the other banks, since the higher the ¥/£ exchange rate, the more yen the firm will get for its money. (For an importer a rate of, say, ¥160 to £1 is better than a rate of, say, ¥140.)

Now it is highly unlikely that any of the banks will have a spare ¥15 billion. But a bank cannot say to the importer, 'Sorry, you will have to wait before we can agree to sell them to you.' Instead the bank will offer a deal and then, if the firm agrees, the bank will have to set about obtaining the ¥15 billion. To do this, it must offer to obtain pounds for Japanese who are supplying yen at a sufficiently low ¥/£ exchange rate.

(The lower the ¥/£ exchange rate, the fewer yen the Japanese will have to pay to obtain pounds.)

The banks' dealers thus find themselves in the delicate position of wanting to offer a *high* enough exchange rate to the car importer in order to gain its business, but a *low* enough exchange rate in order to obtain the required amount of yen. The dealers are thus constantly having to adjust the rates of exchange in order to balance the demand and supply of each currency.

In general, the more of any foreign currency that dealers are asked to supply (by being offered sterling), the lower will be the exchange rate they will offer. In other words, a higher supply of sterling pushes down the foreign currency price of sterling (see Figure 15.18).

Assume that a firm based in the USA wants to import Scotch whisky from the UK. Describe how foreign exchange dealers will respond.

- **Speculation that the exchange rate will fall.** If businesses involved in importing and exporting, and also banks and other foreign exchange dealers, think that the exchange rate is about to fall, they will sell pounds *now* before the rate does fall. The supply of sterling will thus rise. People thinking of buying pounds will wait until the rate does fall and hence, in the meantime, the demand for sterling will fall. Speculation thus helps to bring about the very effect people had anticipated (see pages 70–73).
- **Longer-term changes in international trading patterns.** Over time the pattern of imports and exports is likely to change as (a) consumer tastes change, (b) the nature and quality of goods change and (c) the costs of production change. If, as a result, UK goods become less competitive than, say, German or Japanese goods, the demand for sterling will fall and the supply will rise. These shifts, of course, are gradual, taking place over many years.

11.10
p70

 Go through each of the above reasons for shifts in the demand for and supply of sterling and consider what would cause an appreciation of the pound.

Exchange rates and the balance of payments

10.5
p22

In a free foreign exchange market, the balance of payments will *automatically* balance. But why?

The credit side of the balance of payments constitutes the demand for sterling. For example, when people abroad buy UK exports or assets, they will demand sterling in order to

pay for them. The debit side constitutes the supply of sterling. For example, when UK residents buy foreign goods or assets, the importers of them will require foreign currency to pay for them. They will thus supply pounds. A floating exchange rate ensures that the demand for pounds always equals the supply. It thus also ensures that the credits on the balance of payments are equal to the debits: that the balance of payments balances.

This does not mean that each part of the balance of payments account will separately balance, but simply that any current account deficit must be matched by a capital plus financial account surplus and vice versa.

For example, suppose initially that each part of the balance of payments *did* separately balance. Then let us assume that interest rates rise. This will encourage larger short-term financial inflows as people abroad are attracted to deposit money in the UK: the demand for sterling would shift to the right (e.g. from D_2 to D_1 in Figure 15.18). It will also cause smaller short-term financial outflows as UK residents keep more of their money in the country: the supply of sterling shifts to the left (e.g. from S_2 to S_1 in Figure 15.18). The financial account will go into surplus. The exchange rate will appreciate.

As the exchange rate rises, this will cause imports to be cheaper and exports to be more expensive. The current account will move into deficit. There is a movement up along the new demand and supply curves until a new equilibrium is reached. At this point, any financial account surplus is matched by an equal current (plus capital) account deficit.

Section summary

1. The balance of payments account records all payments to and receipts from foreign countries. The current account records payments for imports and exports, plus incomes and transfers of money to and from abroad. The capital account records all transfers of capital to and from abroad. The financial account records inflows and outflows of money for investment and as deposits in banks and other financial institutions; it also includes dealings in the country's foreign exchange reserves.
2. The whole account must balance, but surpluses or deficits can be recorded on any specific part of the account.
3. The rate of exchange is the rate at which one currency exchanges for another. Rates of exchange are determined by demand and supply in the foreign exchange market. Demand for the domestic currency consists of all the credit items in the balance of payments account. Supply consists of all the debit items.
4. The exchange rate will depreciate (fall) if the demand for the domestic currency falls and/or the supply increases. These shifts can be caused by increases in domestic prices or incomes relative to foreign ones, reductions in domestic interest rates relative to foreign ones, worsening investment prospects at home compared with abroad, or the belief by speculators that the exchange rate will fall. The opposite in each case would cause an appreciation (rise).

APPENDIX: CALCULATING GDP

As explained in section 15.2, there are three ways of estimating GDP. In this appendix, we discuss each method in more detail. We also look at some alternative measures of national income.

The product method of measuring GDP

This approach simply involves adding up the value of everything produced in the country during the year: the output of cars, timber, lollipops, shirts, etc.; and all the

myriad of services, such as football matches, haircuts, bus rides and insurance services. In the national accounts these figures are grouped together into broad categories such as manufacturing, construction and distribution. The figures for the UK economy for 2015 are shown in Figure 15.19.

When we add up the output of various firms, we must be careful to avoid *double counting*. For example, if a manufacturer sells a television to a retailer for £600 and the retailer sells it to the consumer for £800, how much has this television contributed to GDP? The answer is *not* £1400. We do not add the £600 received by the manufacturer to the £800 received by the retailer: that would be double counting. Instead we either just count the final value (£800) or the *value added* at each stage (£600 by the manufacturer + £200 by the retailer).

The sum of all the values added at each of the stages of production by all the various industries in the economy is known as *gross value added at basic prices (GVA)*.

Figure 15.19 UK GVA by product-based measure, 2015

Agriculture, forestry and fishing	£10 833m	0.7
Mining and Quarrying	£16 947m	1.0
Manufacturing	£162 829m	9.8
Electricity, gas, steam and air conditioning supply	£24 824m	1.5
Water supply, sewerage, waste management and remediation	£16 708m	1.0
Construction	£101 937m	6.1
Total distribution, transport, hotels and restaurants	£309 287m	18.6
Total information and communications	£108 474m	6.5
Financial and insurance	£120 351m	7.2
Real estate activities	£216 115m	13.0
Professional and support services	£205 128m	12.3
Total government, health and education	£307 296m	18.4
Other services	£65 613m	3.9
Gross value added (GVA) at basic prices	£1 666 342m	100.0
plus VAT and other taxes on products	£211 759m	
less Subsidies on products	-£8 541m	
Total GDP (at market prices)	£1 869 560m	

Some qualifications

Stocks (or inventories). We must be careful only to include the values added in the *particular year in question*. A problem here is that some goods start being produced *before* the year begins. Thus when we come to work out GDP, we must ignore the values that had previously been added to stocks of raw materials and goods. Similarly, other goods are only sold to the consumer *after* the end of the year. Nevertheless we must still count the values that have been added during *this year* to these stocks of partially finished goods.

A final problem concerned with stocks is that they may increase in value simply due to increased prices. This is known as *stock (or inventory) appreciation*. Since there has been no real increase in output, stock appreciation must be deducted from value added.

Government services. The output of private industry is sold on the market and can thus be easily valued. This is not the case with most of the services provided by the government. Such services (e.g. health and education) should be valued in terms of what they cost to provide.

Ownership of dwellings. When a landlord rents out a flat, this service is valued as the rent that the tenant pays. But owner-occupiers living in their own property do not pay rent and yet they are 'consuming' a similar 'service'. Here a rental value for owner-occupation is 'imputed'. In other words, a figure corresponding to a rent is included in the GDP statistics under the heading 'letting of property' in the real estate activities category.

Taxes and subsidies on products. Taxes paid on goods and services (such as VAT) and any subsidies on products are *excluded* from gross value added (GVA), since they are not part of the value added in production. Nevertheless the way GDP is measured throughout the EU and most other countries of the world is at *market prices*: i.e. at the prices actually paid at each stage of production. Thus *GDP at market prices* (sometimes referred to simply as GDP) is *GVA plus taxes on products minus subsidies on products*.

Definitions

Gross value added at basic prices (GVA) The sum of all the values added by all industries in the economy over a year. The figures exclude taxes on products (such as VAT) and include subsidies on products

Stock (or inventory) appreciation The increase in monetary value of stocks due to increased prices. Since this does not represent increased output, it is not included in GDP

GDP (at market prices) The value of output (or income or expenditure) in terms of the prices actually paid.

$GDP = GVA + \text{taxes on products} - \text{subsidies on products}$.

The income method of measuring GDP

The second approach focuses on the incomes generated from the production of goods and services. This must be the same as the sum of all values added, since value added is simply the difference between a firm's revenue from sales and the costs of its purchases from other firms. This difference is made up of wages and salaries, rent, interest and profit: the incomes earned by those involved in the production process.

Since GDP is the sum of all values added, it must also be the sum of all incomes generated: the sum of wages and salaries, rent, interest and profit.

If a retailer buys a product from a wholesaler for £80 and sells it to a consumer for £100, then the £20 of value that has been added will go partly in wages, partly in rent and partly in profits. Thus £20 of income has been generated at the retail stage. But the good actually contributes a total of £100 to GDP. Where, then, is the remaining £80 worth of income recorded?

Figure 15.20 shows how these incomes are grouped together in the official statistics. By far the largest category is 'compensation of employees': in other words, wages and salaries. As you can see, the total in Figure 15.20 is the same as in Figure 15.19, although the components are quite different. In other words, GDP is the same whether calculated by the product or the income method.

Some qualifications

Stock (inventory) appreciation. As in the case of the product approach, any gain in profits from inventory appreciation must be deducted, since they do not arise from a real increase in output.

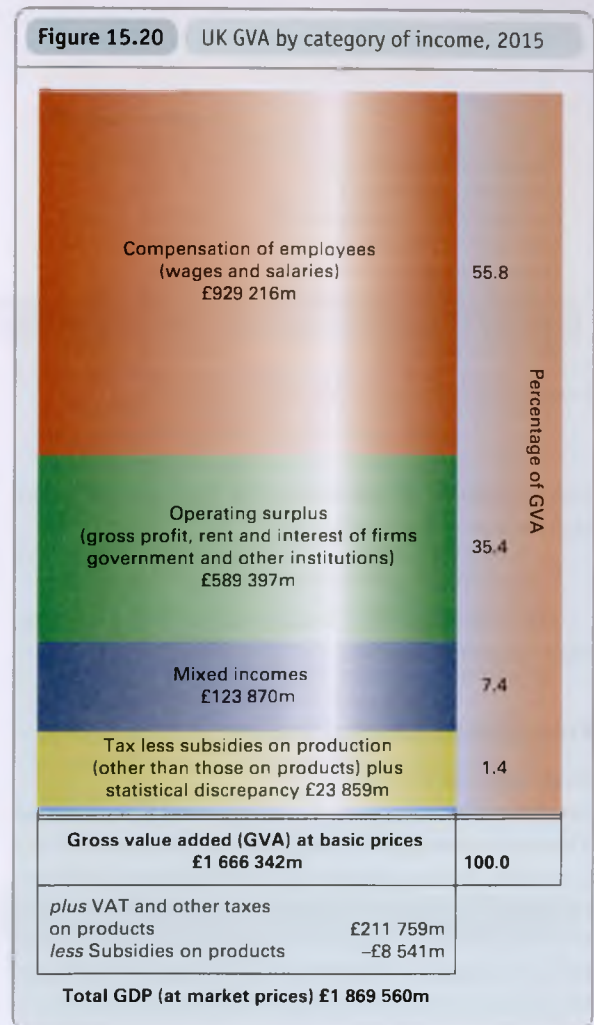

Transfer payments. GDP includes only those incomes that arise from the production of goods and services. We do not, therefore, include *transfer payments* such as social security benefits, pensions and gifts.

Direct taxes. We count people's income *before* the payment of income and corporation taxes, since it is this *gross* (pre-tax) income that arises from the production of goods and services.

Taxes and subsidies on products. As with the product approach, if we are working out GVA, we measure incomes before the payment of taxes on products or the receipt of subsidies on products, since it is these pre-tax-and-subsidy incomes that arise from the value added by production. When working out GDP, however, we add in these taxes and subtract these subsidies to arrive at a *market price* valuation.

The expenditure method of measuring GDP

The final approach to calculating GDP is to add up all expenditure on final output (which will be at market prices). This will include the following:

- **Consumer expenditure (C).** This includes all expenditure on goods and services by households and by non-profit institutions serving households (NPISH) (e.g. clubs and societies).
- **Government expenditure (G).** This includes central and local government expenditure on final goods and services. Note that it includes non-marketed services (such as health and education), but excludes transfer payments, such as pensions and social security payments.
- **Investment expenditure (I).** This includes investment in capital, such as buildings and machinery. It also includes the value of any increase (+) or decrease (-) in inventories, whether of raw materials, semi-finished goods or finished goods.
- **Exports of goods and services (X).**

We then have to *subtract* imports of goods and services (*M*) from the total in order to leave just the expenditure on *domestic* product. In other words, we subtract the part of consumer expenditure, government expenditure and investment that

Table 15.6 UK GDP at market prices by category of expenditure, 2015

	£ million	% of GDP
Consumption expenditure of households and NPISH (C)	1 216 113	65.0
Government final consumption (G)	360 828	19.3
Gross capital formation (I)	327 855	17.5
Exports of goods and services (X)	510 340	27.3
Imports of goods and services (M)	-548 908	-29.4
Statistical discrepancy	3 332	0.2
GDP at market prices	1 869 560	100.0

Source: UK National Accounts, *The Blue Book: 2016* (ONS).

goes on imports. We also subtract the imported component (e.g. raw materials) from exports.

$$\text{GDP (at market prices)} = C + I + G + X - M$$

Table 15.6 shows the calculation of the 2015 UK GDP by the expenditure approach.

From GDP to national income

Gross national income

Some of the incomes earned in this country will go abroad. These include wages, interest, profit and rent earned in this country by foreign residents and remitted abroad, and taxes on production paid to foreign governments and institutions (e.g. the EU). On the other hand, some of the incomes earned by domestic residents will come from abroad. Again, these can be in the form of wages, interest, profit or rent, or in the form of subsidies received from governments or institutions abroad. Gross *domestic* product, however, is concerned only with incomes generated *within* the country, irrespective of ownership. If, then, we are to take 'net income from abroad' into account (i.e. these inflows minus outflows), we need a new measure. This is *gross national income (GNY)*.⁶ It is defined as follows:

$$\begin{aligned} \text{GNY at market prices} &= \text{GDP at market prices} \\ &+ \text{Net income from abroad} \end{aligned}$$

Thus GDP focuses on the value of domestic production, whereas GNY focuses on the value of incomes earned by domestic residents.

Net national income

The measures we have used so far ignore the fact that each year some of the country's capital equipment wears out or becomes obsolete: in other words, they ignore capital depreciation. If we subtract from gross national income an allowance for *depreciation* (or 'capital consumption' as it is called in the official statistics), we get *net national income (NNY)*.

$$\begin{aligned} \text{NNY at market prices} &= \text{GNY at market prices} \\ &- \text{Depreciation} \end{aligned}$$

Table 15.7 UK GDP, GNY and NNY at market prices, 2015

	£ million
Gross domestic product (GDP)	1 869 560
Plus net income from abroad	-37 016
Gross national income (GNY)	1 832 544
Less capital consumption (depreciation)	245 144
Net national income (NNY)	1 587 400

Source: UK National Accounts, *The Blue Book: 2016* Tables (ONS).

Table 15.7 shows the 2015 GDP, GNY and NNY figures for the UK.

Although NNY gives a truer picture of a nation's income than GNY, economists tend to use the gross figures because depreciation is hard to estimate accurately.

Households' disposable income

Finally, we come to a measure that is useful for analysing consumer behaviour. This is called *households' disposable income*. It measures the income that people have available for spending (or saving): i.e. after any deductions for income tax, national insurance, etc. have been made. It is the best measure to use if we want to see how changes in household income affect consumption.

How do we get from GNY at market prices to households' disposable income? As GNY measures the incomes that firms receive from production⁷ (plus net income from abroad), we must deduct that part of their income that is *not* distributed to households. This means that we must deduct taxes that firms pay – taxes on goods and services (such as VAT), taxes on profits (such as corporation tax) and any other taxes – and add in any subsidies they receive. We must then subtract

Definitions

Gross national income (GNY) GDP plus net income from abroad.

Depreciation The decline in value of capital equipment due to age, or wear and tear.

Net national income (NNY) GNY minus depreciation.

Households' disposable income The income available for households to spend: i.e. personal incomes after deducting taxes on incomes and adding benefits.

⁶ In the official statistics, this is referred to as GNI. We use Y to stand for income, however, to avoid confusion with investment.

⁷ We also include income from any public-sector production of goods or services (e.g. health and education) and production by non-profit institutions serving households.

allowances for depreciation and any undistributed profits. This gives us the gross income that households receive from firms in the form of wages, salaries, rent, interest and distributed profits.

To get from this to what is available for households to spend, we must subtract the money that households pay in income taxes and national insurance contributions, but add

all benefits to households, such as pensions and child benefit: in other words, we must *include* transfer payments.

$$\begin{aligned} \text{Households' disposable income} &= \text{GNY at market prices} \\ &- \text{Taxes paid by firms} + \text{Subsidies received by firms} \\ &- \text{Depreciation} - \text{Undistributed profits} - \text{Personal taxes} \\ &+ \text{Benefits} \end{aligned}$$

Section summary

- The product method measures the values added in all parts of the economy. Care must be taken in the evaluation of stocks, government services and the ownership of dwellings.
- The income method measures all the incomes generated from domestic production: wages and salaries, rent, interest and profit. Transfer payments are not included, nor is stock appreciation.
- The expenditure method adds up all the categories of expenditure: consumer expenditure, government expenditure, investment and exports. We then have to deduct the element of each that goes on imports in order to arrive at expenditure on domestic products. Thus $GDP = C + G + I + X - M$.
- GDP at market prices measures what consumers pay for output (including taxes and subsidies on what they buy). Gross value added (GVA) measures what factors of production actually receive. GVA, therefore, is GDP at market prices minus taxes on products plus subsidies on products.
- Gross national income (GNY) takes account of incomes earned from abroad (+) and incomes earned by people abroad from this country (-). Thus $GNY = GDP$ plus net income from abroad.
- Net national income (NNI) takes account of depreciation of capital. Thus $NNI = GNY - \text{depreciation}$.
- Personal disposable income is a measure of household income after the deduction of income taxes and the addition of benefits.

END OF CHAPTER QUESTIONS

- In 1974, the UK economy shrank by 2.5 per cent before shrinking by a further 1.5 per cent in 1975. However, actual GDP rose by 13 per cent in 1974 and by 24 per cent in 1975. What explains these apparently contradictory results?
- Economists sometimes refer to the 'twin characteristics of economic growth'. What are these characteristics?
- (i) What do you understand by the term financialisation?
(ii) How might we assess the financial well-being of households?
- Explain how equilibrium would be restored in the circular flow of income if there were a fall in investment.
- Explain the circumstances under which an increase in pensions and child benefit would (a) increase national income; (b) leave national income unaffected; (c) decrease national income.
- For what reasons might GDP be a poor indicator of (i) the level of development of a country; (ii) its rate of economic development?
- (i) Will the rate of actual growth have any effect on the rate of potential growth? (ii) For what possible reasons may one country experience a persistently faster rate of economic growth than another?
- Why will investment affect both actual (short-term) growth and the long-term growth in potential output? What will be the implications if these two effects differ in magnitude?
- At what phase of the business cycle is the average duration of unemployment likely to be the highest? Explain.
- Consider the most appropriate policy for tackling each of the different types of unemployment.
- Do any groups of people gain from inflation?
- If everyone's incomes rose in line with inflation, would it matter if inflation were 100 per cent or even 1000 per cent per annum?
- Imagine that you had to determine whether a particular period of inflation was demand-pull, or cost-push, or a combination of the two. What information would you require in order to conduct your analysis?
- Explain how the current account of the balance of payments is likely to vary with the course of the business cycle.
- The overall balance of payments must always balance. If this is the case, why might a deficit on one part of the balance of payments be seen as a problem?
- List some factors that could cause an increase in the credit items of the balance of payments and a decrease in the debit items. What would be the effect on the exchange rate (assuming that it is freely floating)? What effect would these exchange rate movements have on the balance of payments?
- Explain how you would derive a figure for households' disposable income if you were starting from a figure for GDP.

Emergence of a new consensus?	514
Areas of general agreement?	514

In this second and final chapter of Part E we provide an overview of how macroeconomics has developed over the past 100 years or so. In reading this chapter you will see how macroeconomic debates and theories have been shaped by real-world events, such as the Great Depression of the 1930s, the rapid inflation of the 1970s or the global economic and financial crisis of the late 2000s. You will also see how the development of economic ideas has affected actual policy, such as the granting of independence to central banks and the pursuit of inflation targets.

The unfolding of the 'macroeconomic story' allows us to see how different theories and approaches have developed. It also helps us to understand where there is greatest agreement among economists and where controversies remain. Although we urge you to read this chapter as it really helps put macroeconomics into historical context, it is not essential and you can, if your lecturer recommends it, move directly to Chapter 17.

16.1 THE MACROECONOMIC ENVIRONMENT AND DEBATES

In the previous chapter we identified some key macroeconomic issues: growth, unemployment, inflation, our interconnectedness with foreign economies, the financial well-being of economic agents and the stability of the financial system. While these issues are interconnected, we tend to find that the focus of macroeconomic debates at any moment in time reflects the macroeconomic environment of the time.

The 2010s nicely illustrates how the focus of macroeconomics can change. It has seen, for example, considerable attention paid to the relationship between the financial system and the macroeconomy. A decade earlier there was much less focus on this. This does not mean that economists were not researching in this field. This is far from the case. But, the amount of work being undertaken by economists in this area was to grow considerably. It would also affect the curriculum of students of economics as, understandably, their curiosity was aroused by the financial crisis of the late 2000s.

Many of the debates and advancement of ideas, therefore, arise because existing theories appear unable to explain fully the prevailing macroeconomic conditions. Sometimes this has resulted in relatively small incremental changes to theory and to policy, but on other occasions very different views of how economies work have come to the fore and consequently policy has been radically reshaped.

Figure 16.1 plots the path of a selection of macroeconomic indicators since 1900. It helps to set the scene for

some of the key macroeconomic debates over the past 100 years or so.

Macroeconomics as a separate branch of economics had its birth with the mass unemployment experienced in the 1920s and 1930s. The old 'classical theories' of the time, which essentially said that free markets would provide a healthy economy with full employment, could not provide solutions to the problem. Their analysis seemed totally at odds with the facts.

A new analysis of the economy – one that *did* offer solutions to mass unemployment – was put forward by the economist John Maynard Keynes. His book *The General Theory of Employment, Interest and Money*, published in 1936, saw the dawn of 'Keynesian economics'. Keynes advocated active intervention by governments, in particular through changes to government expenditures and taxation to affect aggregate demand. By carefully managing aggregate demand, the government could prevent mass unemployment on the one hand, or an 'overheated' economy with unsustainable growth and high inflation on the other.

After the Second World War, governments around the world adopted Keynesian demand-management policies; and they seemed to be successful. The 1950s and 1960s were a period of low inflation, low unemployment and relatively high economic growth. Macroeconomists were largely concerned with refining Keynesian economics.

In the 1970s, however, the macroeconomic consensus broke down. As we can see from Figure 16.1, both inflation

Figure 16.1 UK macroeconomic indicators, 1900–2018

Notes: (i) Inflation is the annual rate of consumer price inflation; (ii) Unemployment rate is the standardised unemployment rate as % of UK workforce; (iii) Growth is the annual growth in constant-price GDP; (iv) Balance of trade is the balance on goods and services as % of GDP; and (v) Fiscal deficit is public sector net borrowing as a % of GDP; (v) Figures from 2016 are forecasts.

Source: Based on data from *Three Centuries of Data* (Bank of England), June 2016 and *World Economic Outlook* (IMF), October 2016.

and unemployment rose and growth slowed. Macroeconomics became highly controversial. Different 'schools of thought' had their own explanations of what was going wrong, and each had its own solutions to the problems.

Then, as the macroeconomic environment generally improved in the 1990s, increasingly common ground was found and a *new consensus* emerged. At the heart of the new consensus was a view that markets tend to adjust relatively quickly to the random shocks that frequently hit the economy. Nonetheless, market imperfections do affect adjustment processes and the characteristics of an economy's equilibrium.

While some economists were highly sceptical of the new consensus, it was the financial crisis of the late 2000s and the subsequent global economic downturn that re-energised long-standing debates and differences amongst macroeconomists. These differences were mirrored by the debates amongst politicians and policy makers and were significantly greater than they had been for many years.

In some ways, the debates of the late 2000s and early 2010s were a microcosm of much of the preceding 100 years. Many familiar questions were again being asked, not least concerning the role that governments should play in modern, developed economies. However, other questions emerged concerning the way that macroeconomic analysis and macroeconomic models had developed during the new orthodoxy.

The new consensus had largely sought to model the effect of economic shocks on key macroeconomic variables, such

as the growth of real GDP or the rate of inflation, by building models based on aggregating the behaviour of representative rational, forward-looking economic agents. Elaborately technical models began to characterise macroeconomics. However, in light of the general failure of macroeconomists to foresee the financial crisis, economists began to ask whether the models of the new orthodoxy had taken a wrong turn. New models began to be developed which put more emphasis on the role of the financial sector, debts and speculative behaviour.

Some disagreement between economists is inevitable. Nonetheless, there exist some areas of broad agreement between many macroeconomists over the causes of macroeconomic problems and the appropriate policies to deal with them. Therefore, in this chapter we will be identifying areas not only where disagreement remains, but areas where there is more agreement.

The focus of the remainder of the chapter is to provide an understanding of key developments in macroeconomic thinking. To do so, we introduce some of the principal 'schools of macroeconomic thought'. Essentially, these schools are a means of understanding different views on the determinants of key macroeconomic variables, such as growth, unemployment and inflation. We shall see how these schools have evolved as time has passed. An important reason for this is that the macroeconomic environment that economists try to understand changes and different issues become more or less important.

16.2 CLASSICAL MACROECONOMICS

We begin our story in the earlier twentieth century. Classical economists had over the previous century or so advocated a policy of *laissez-faire* (non-intervention) and free trade. Britain had experienced rapid industrialisation and growth and seen a massive expansion of its overseas trade. This had, if anything, strengthened their advocacy of *laissez-faire*. Consequently, in the early years of the twentieth century, most economists, most politicians and virtually all bankers and businesspeople were relatively confident in the power of the free market to provide growing output and low unemployment.

The main role for the government was to provide 'sound finance' (i.e. not to print too much money), so as to maintain stable prices.

The classical analysis of output and employment

The classical theory predicted that, in the long run, equilibrium in the economy would be at virtually full employment. In the long run, any unemployment would be merely *frictional* unemployment: namely, people in the process of changing jobs.

There were two important elements in the classical theory.

The free-market economy works to equate demand and supply in all markets

This element of classical theory assumes flexible prices: of goods and services, of labour (i.e. wage rates) and of money (i.e. the rate of interest).

The classical economists argued that flexible prices would ensure that saving equalled investment ($S = I$) and that imports equalled exports ($M = X$). From this it follows that, if the government were to 'balance its budget' and make taxation equal to government expenditure ($T = G$), then total withdrawals would equal total injections ($W = J$).¹

But why should flexible prices ensure that $S = I$ and $M = X$? The reasoning of the classical economists was as follows.

¹ The classical economists did not use the terms 'withdrawals' and 'injections': these are modern terms. Nevertheless, their analysis implied an automatic equation of W and J if markets cleared and the government balanced its budget.

$S = I$. This would be brought about by flexible rates of interest in the **market for loanable funds**. When firms want to invest in new plant and equipment, they will require finance. Investment demand, therefore, represents a demand for loanable funds from financial institutions (an outflow). Meanwhile, saving represents a supply of loanable funds (an inflow). The supply of savings represents the deposits by people in financial institutions.

The relevant interest rate for loanable funds is the **real** rate of interest (r). This is the nominal rate (i) minus the rate of inflation (π). The higher the real rate of interest, the more expensive will borrowing be, and hence the less will be the demand for investment. On the other hand, the higher the real rate of interest, the more people will be attracted to save: that is, the more they will deposit in financial institutions.

The equilibrium real interest rate is that where $S = I$. If the rate of interest were above this, financial institutions would be accumulating funds. They would have to lower the rate of interest to attract sufficient borrowers. If the rate of interest were below this, financial institutions would find their funds reducing. They would have to raise the rate of interest to attract sufficient savers.

 *Illustrate equilibrium in the market for loanable funds using a demand and supply diagram.*

$M = X$. This would be brought about by flexible prices and wages. At the start of the twentieth century many countries, including the UK, Russia, Japan and the USA, operated some form of **gold standard**. This was a *fixed* exchange rate system in which each participating country's currency was valued at a certain fixed amount of gold.

If a country had a balance of trade deficit ($M > X$), this had to be paid for in gold from its reserves (unless there was a compensating net inflow of finance on the financial account from, say, deposits in domestic banks or the purchase of domestic shares). A country was then supposed to respond to this outflow of gold by reducing the amount of money in the economy and hence reducing total expenditure. This would create surpluses in the goods and labour markets, which would, in turn, lead to a fall in prices and wages.

Definitions

Market for loanable funds The market for loans from and deposits into the banking system.

Gold standard The system whereby countries' exchange rates were fixed in terms of a certain amount of gold and whereby balance of payments deficits were paid in gold.

Say's law Supply creates its own demand. In other words, the production of goods will generate sufficient demand to ensure that they are sold.

This fall in the prices of domestic goods would increase the sale of exports and reduce the consumption of the now relatively expensive imports. This whole process would continue until the balance of payments trade was eliminated until $M = X$.²

What would have happened if countries in deficit had not responded to an outflow of gold by reducing total expenditure?

Provided governments balanced their budgets ($T = G$), therefore, flexibility in the various markets would ensure that withdrawals equalled injections.

Say's law

J.-B. Say was a French economist of the early nineteenth century. **Say's law** states that *supply creates its own demand*. What this means is that the production of goods and services will generate expenditures sufficient to ensure that they are sold. There will be no deficiency of demand and no need to lay off workers. There will be full employment. The justification for the law is as follows.

When firms produce goods, they pay out money either directly to other firms, or as factor payments to households. The income that households receive is then partly paid back to firms in the form of consumption expenditure (C_d): the inner flow of the circular flow of income.

But any withdrawals by firms or households are also fully paid back to firms in the form of injections, since $S = I$, $M = X$ and $T = G$. Thus, all the incomes generated by firms' supply will be transformed into demand for their products, either directly in the form of consumption, or indirectly via withdrawals and then injections. There will thus be no deficiency of demand.

Of course, although aggregate demand might equal aggregate supply, consumers may shift their demand away from some industries in favour of others. Consequently, structural unemployment may then occur (see section 15.5). But then wages would fall in the declining industries and rise in the expanding industries. This would help to eliminate the structural unemployment.

The reduction in structural unemployment will be quicker (a) the more flexible are wages and (b) the more willing and able are workers to move to industries and towns where jobs are available (labour mobility). In other words, the better markets work, the lower will be the level of structural unemployment (and frictional unemployment too).

² Note that, under a system of freely floating exchange rates, it is the flexibility in exchange rates, rather than the prices of goods and factors, that ensures that the balance of payments balances.

The classical analysis of prices and inflation

The classical economists based their analysis of inflation on the **quantity theory of money**. In its simplest form, it states that the general level of prices (P) in the economy depends on the supply of money (M):³

$$P = f(M)$$

The greater the quantity of money, the higher the level of prices. Under this theory, inflation is simply caused by a rise in money supply. (We examine the role of money in the economy in Chapters 18 and 19.)

To understand the reasoning behind the quantity theory of money, we need to examine the **equation of exchange**. This comes in various versions (see Case Study 16.1 on the student website), but the one most useful for our purposes is the simple identity between national expenditure and national income. This identity may be expressed as follows:

$$MV = PY$$

M , as we have already seen, is the supply of money in the economy. V is the **velocity of circulation**. This is the number of times per year a unit of currency (e.g. £1) is spent on buying goods and services that make up GDP. Suppose that each pound's worth of money is typically spent eight times per year on such goods and services, and that money supply is £250 billion. This would mean that total expenditure on GDP ($M \times V$) is £2 trillion (£2000 billion).

P , again as we have already seen, is the general level of prices. Let us define it more precisely as the price index based on some specific year (e.g. 2010), where the index in the base year is assumed to be 1.00 (not 100) (see pages A:6–7). Y is the real value of national income (i.e. GDP expressed in the prices of the base year). $P \times Y$, therefore, is simply the 'nominal' value of GDP (i.e. GDP expressed in *current* prices, rather than those of the base year). Thus if GDP in real terms (Y) (i.e. measured in base-year prices) were £1 trillion and if the current price index (P) were 2, then nominal GDP ($P \times Y$) would be £2 trillion.

Thus both MV and PY are equal to GDP and must, therefore, by definition be equal to each other.

The classical economists argued that both V and Y were determined independently of the money supply: i.e. a change in the money supply would *not* be expected to lead to a change in V or Y . The velocity of circulation (V), they claimed, was determined by the frequency with which people were paid (e.g. weekly or monthly), the nature of the

³ In the quantity theory of money the letter M is used to refer to money supply, whereas in the circular flow of income it is used to refer to the expenditure on imports. Naturally this is potentially confusing, but unfortunately it is normal practice to use the letter M in both ways. To avoid any such confusion we will always specify which is being referred to. Elsewhere, however, you will just have to judge from the context! (There is the same problem with the letter P , which can refer either to price or to product.)

banking system and other institutional arrangements for holding money. As far as Y was concerned, Say's law would ensure that the real value of output (Y) was maintained at the full-employment level.

With V and Y as 'constants' with respect to M , therefore, the quantity theory must hold:

$$P = f(M)$$

Increases in money supply simply lead to inflation. This is consistent with the principle known as the **neutrality of money**. Classical economists argued that changes in the money supply would not affect real variables such as real output or real consumption. Changes in the money supply would merely affect nominal variables through their impact on prices.

Assuming that Y rises each year as a result of increases in productivity, can money supply rise without causing inflation? Would this destroy the validity of the quantity theory?

The classical response to the Great Depression

As Figure 16.1 (see page 492) helps to show, the period between the First and Second World War (1919–38) saw Britain experience bouts of prolonged recession of unparalleled severity. To help put this period into perspective, the size of the Britain's real GDP in 1934 was roughly that of 1913.

Throughout Britain's prolonged 'Great Depression' unemployment was very much higher than before the war. By 1933 there were 3.4 million people unemployed, equivalent to almost 16 per cent of the working population. However, the depression eliminated inflation. In every year from 1921 to 1934 prices either were constant or fell. During this period the annual rate of inflation averaged -3.2 per cent and the unemployment rate 10 per cent.

The events of the 1920s and early 1930s appeared to contradict the predictions of classical economists. After all, they

Definitions

Quantity theory of money The price level (P) is directly related to the quantity of money in the economy (M).

Equation of exchange $MV = PY$. The total level of spending on GDP (MV) equals the total value of goods and services produced (PY) that go to make up GDP.

Velocity of circulation The average number of times annually that money is spent on goods and services that make up GDP.

Neutrality of money The principle that changes in the money supply affect only nominal variables and have no effect on real variables.

TC 13

K1 34
p453

had predicted that there would be virtually full employment. Any unemployment would simply be the frictional and structural unemployment of people being 'between jobs'.

Part of the cause of the Depression was the decision in 1925 by Winston Churchill, the Chancellor of the Exchequer, to return to the gold standard following the UK's withdrawal from it in 1914 at the outbreak of the First World War. The decision was made to return at the pre-war rate of £1 = \$4.86. But with many export markets lost in the war and a rapid rise in imports for rebuilding the economy, the balance of payments was in severe deficit. The UK's trade deficit had risen to 5 per cent by 1925.

To correct the UK's trade position required severely deflationary policies. The aim was to drive wage rates down, reduce costs and restore the competitiveness of exports. The result, however, was a severe recession: the UK economy contracted by an estimated 3.1 per cent in 1926.

But while in Britain output slumped and unemployment soared, most of the rest of the industrialised world initially experienced a boom. But in 1929, after a decade of rapid growth and a huge rise in share values, Wall Street crashed. This sent the US economy plunging into deep recession, with the rest of the world following suit. As the world economy slumped, so did international trade. With a collapse of its exports, Britain dived even deeper into depression. 1931 saw the UK economy contract by 4.6 per cent.

Eventually, in 1932, Britain was forced to leave the gold standard and allow the pound to depreciate. (Case Study 16.4 on the student website looks at the bitter experience of the return to the gold standard in 1925 and its aftermath.)

The deflationary policies of the 1920s seemed to be directly responsible for increasing unemployment. Many critics argued that the government ought deliberately to *expand* aggregate demand. However, the Treasury and other classical economists rejected the analysis that unemployment was caused by a lack of demand; they also rejected policies of reflation (e.g. increased government expenditure).

The classical Treasury view on unemployment

Would deflation of demand not lead to unemployment? According to the Treasury view, unemployment would occur only if labour markets *failed to clear*: if real wage costs did not fall sufficiently.

The Treasury concluded that people should be encouraged to take wage cuts. This would also help to reduce prices and restore export demand, thus correcting the balance of payments. People should also be encouraged to save. This would, via flexible interest rates, lead to more investment and hence a growth in output and demand for labour.

The classical Treasury view on public works

In the 1920s and 1930s, some politicians and economists argued that unemployment could be reduced if the government pursued a programme of public works: building roads, hospitals, houses, etc. The Treasury view was that this would not work and could have costly side effects.

A programme of public works could be funded in three ways: from extra taxation, from extra government borrowing or by printing extra money. *None* of these three ways would, according to the classical Treasury view, solve the unemployment problem.

- *Extra taxation* would merely have the effect of reducing the money that consumers would spend on private industry. Extra public-sector demand would thus be offset by a fall in private-sector demand.
- If the government *borrowed more*, it would have to offer higher interest rates in order to persuade people to buy the additional government securities. The private sector would

Definition

Crowding out Where increased public expenditure diverts money or resources away from the private sector.

BOX 16.1 BALANCE THE BUDGET AT ALL COSTS

CASE STUDIES AND APPLICATIONS

Fiscal policy in the early 1930s

The budget must be balanced. All government expenditure should be financed from taxation. This was orthodox opinion in the 1920s.

But as unemployment increased during the Great Depression (see Figure 16.1), spending on unemployment benefits (the most rapidly growing item of government expenditure) threatened the balanced budget principle. Other spending had to be cut to restore balance. The result was more unemployment, and hence the payment of more unemployment benefits.

Treasury officials and classical economists called for cuts in unemployment benefits. The May Committee, set up to

investigate the budgetary problem, recommended a 20 per cent reduction. Even the Labour government, elected on a mandate to tackle the unemployment problem, proposed a 10 per cent reduction in 1931. This contributed to its subsequent collapse.

Philip Snowden, Labour's Chancellor of the Exchequer, remarked in 1931 how pensioners had returned their pension books and children sent in their savings to help the nation balance its budget. And yet, as Keynes argued, it was not saving that was necessary to cure the unemployment, but spending. Government deficits were *desirable*. Attempts to balance the budget merely deflated the economy further and deepened the problem of unemployment.

BOX 16.2

THE CROWDING-OUT EFFECT

EXPLORING
ECONOMICS

When public expenditure replaces private

Critics of the use of government expenditure to stimulate output and employment often refer to the problem of *crowding out*. In its starkest form, the argument goes like this.

There is no point in the government embarking on a programme of public works to bring the economy out of recession. If it attempts to spend more, it can do so only by reducing private expenditure. The effect on total spending will be zero. This crowding out can take two main forms.

Resource crowding out

This is when the government uses resources such as labour and raw materials that would otherwise be used by the private sector. If the economy is operating near full capacity, then if resources are used by the government, they cannot at the same time be used by private companies.

The argument is far less convincing, however, if there is slack in the economy. If the government merely mobilises otherwise *idle* resources, there need be no reduction in private-sector output. In fact, if private-sector firms have spare capacity, they will respond to the higher demand by producing more themselves: aggregate demand will stimulate extra production.

Financial crowding out

This occurs when extra government spending diverts *funds* from private-sector firms and thus deprives them of the finance necessary for investment.

If the government spends more (without raising taxes or printing more money), it will have to borrow more and will therefore have to offer higher rates of interest. Private companies will then have to offer higher rates of interest themselves in order to attract funds. Alternatively, if they borrow from banks, and banks have less funds, the banks will charge them higher interest rates. Higher interest rates will discourage firms from borrowing and hence discourage investment.

The weakness with this argument is that it assumes that the supply of money is fixed. If the government spends more but *increases* the amount of money in the economy, it need not deprive the private sector of finance. Interest rates will not be bid up.

But would that not be inflationary? Not if there are idle resources and hence the extra money can be spent on extra output. Only if *resource* crowding out takes place would it be inflationary.

Could resource crowding out take place at less than full employment?

then have to offer higher interest rates, to compete for funds. As interest rates went up, private borrowing would go down. Thus public investment would *crowd out* private investment (see Box 16.2). This debate was to be revisited many years later when, following the financial crisis and subsequent economic downturn of the late 2000s, government borrowing rose sharply (see Figure 16.1).

- According to the quantity theory of money, printing extra money would simply lead to inflation. The argument here is that a rise in aggregate demand would simply lead to a rise in the price level with no increase in national output and, hence, employment. A re-emergence of inflation, which had been eliminated in the early 1920s, would further erode the competitiveness of British goods,

jeopardising the return to the gold standard at the pre-war exchange rate.

Treasury orthodoxy insisted, therefore, that government should attempt to balance its budget, even if this meant cutting welfare benefits to the rising numbers of unemployed (see Box 16.1). The governments of the 1920s and early 1930s followed these classical recommendations. They attempted to balance their budgets and rejected policies of deflation. Yet mass unemployment persisted.

It is interesting to note that the policy of reducing deficits through cuts in government expenditure, even at a time of recession, was a central part of the UK Coalition government's policy in the early 2010s.

Section summary

1. The classical analysis of output and employment is based on the assumption that markets clear. More specifically, it assumes that there are flexible wages, flexible prices and flexible rates of interest. The result will be that demand and supply are equated in the labour market, in the goods market and in the market for loanable funds.
2. Given that markets will clear, Say's law will operate. This law states that supply creates its own demand. In other words, the production of goods and services will generate incomes for households, which in turn will generate consumption expenditure, ensuring that the goods are sold. If any incomes are not directly spent on domestic goods, flexible prices will help to ensure that any money withdrawn is reinjected. Flexible interest rates will ensure that investment equals saving, and flexible prices and wages will ensure that exports equal imports. Provided the government balances its budget, withdrawals will equal injections and Say's law will hold.
3. The classical economists based their analysis of prices on the quantity theory of money. This states that the level of prices is directly related to the quantity of money (M) in the economy. Their position can be demonstrated using the equation of exchange:

$$MV = PY$$

where V is the velocity of circulation, P is the price index and Y is real national income expressed in the prices of the base year. The classical economists assumed that V and Y were not affected by changes in the money supply and could thus be regarded as 'constants'. From this it follows that

$$P = f(M)$$

Increases in the money supply simply lead to inflation.

4. In 1925, Britain returned to the gold standard system of fixed exchange rates at the pre-war rate. But given the massive balance of payments deficit at this rate, it had to pursue tough deflationary policies. The result was mass unemployment.
5. The classical economists saw the remedy to the problem as lying in reductions in wages and prices. According to the classical theory, this would allow Say's law to operate and full employment to be restored. They rejected public works as the solution, arguing that it would lead to crowding out if financed by borrowing, and to inflation if financed by printing money.

16.3 THE KEYNESIAN REVOLUTION

Keynes' rejection of classical macroeconomics

The main critic of classical macroeconomics was John Maynard Keynes. In his major work, *The General Theory of Employment, Interest and Money* (1936), he rejected the classical assumption that markets would clear. Disequilibrium could persist and mass unemployment could continue. There are two crucial markets in which disequilibrium could persist.

The labour market

Workers would resist wage cuts. Wages were thus 'sticky' downwards. In a recession, when the demand for labour is low, wages might not fall far or fast enough to clear the labour market. Consequently, there would exist demand-deficient unemployment (see section 15.5).

But even if wage cuts could be introduced, as advocated by classical economists, Keynes rejected that as the solution to demand deficiency. Workers are also consumers. A cut in workers' wages would mean less consumer spending. Firms would respond to this by further reducing their demand for labour, which would more than offset the reduction in wages. Wage rates would not fall fast enough to clear the market. Disequilibrium would worsen. The recession would deepen.

Employers might well find that labour was cheaper to employ, but if demand for their product were falling, they would hardly be likely to take on more labour.

The market for loanable funds

Keynes also rejected the classical solution of increased saving as a means of stimulating investment and growth. Again the problem was one of market disequilibrium.

An increase in saving will cause a disequilibrium in the market for loanable funds. An increase in the supply of loanable funds will lead to the real rate of interest for loanable funds falling. But an increase in saving also means a fall in consumption. Consequently, firms will sell less and will thus be discouraged from investing. This results in a fall in the demand for loanable funds. The rate of interest would have to fall further to clear the market, perhaps considerably so.

The demand for investment, according to Keynes, depends very much on business confidence in the future. A slide into recession could shatter such confidence. The resulting fall in investment would deepen the recession.

The problem of disequilibrium in the market for loanable funds is made worse, according to Keynes, because neither saving nor investment is very responsive to changes in interest rates, and thus very large changes in interest rates would be necessary if equilibrium were ever to be restored after any

BOX 16.3

WILL WAGE CUTS CURE UNEMPLOYMENT?

EXPLORING
ECONOMICS

Keynes' dismissal of the classical remedy

In *The General Theory of Employment, Interest and Money*, Keynes rejects the classical argument that unemployment is due to excessive wages. In Chapter 2 he argues:

[T]he contention that the unemployment which characterises a depression is due to a refusal by labour to accept a reduction of money wages is not clearly supported by the facts. It is not very plausible to assert that unemployment in the United States in 1932 was due either to labour obstinately refusing to accept a reduction of money wages or to its obstinately demanding a real wage beyond what the productivity of the economic

machine was capable of furnishing. Wide variations are experienced in the volume of employment without any apparent change either in the minimum real demands of labour or in its productivity. Labour is not more truculent in the depression than in the boom – far from it. Nor is its physical productivity less. These facts from experience are a *prima facie* ground for questioning the classical analysis.¹

1 J. M. Keynes, *The General Theory of Employment, Interest and Money* (Macmillan, 1967), p. 9.

change in the supply of loanable funds (saving) or demand for loanable funds (investment).

Keynes also rejected the simple quantity theory of money. Increases in money supply will not necessarily lead merely to rises in prices. If there is a lot of slack in the economy, with high unemployment, idle machines and idle resources, an increased spending of money may lead to substantial increases in real income (Y) and leave prices (P) little affected.

If the government were to cut money supply in an attempt to reduce prices, the major effect might be to reduce output and employment instead. In terms of the quantity equation, a reduction in M may lead to a reduction in output and hence real income Y rather than a reduction in P .

All these arguments meant a rejection of Say's law. Far from supply creating demand and thus ensuring full employment, Keynes argued that it was *demand that created supply*. If aggregate demand rose, firms would respond to the extra demand by producing more and employing more people. But a fall in demand would lead to less output and rising unemployment.

Keynes' central point was that an unregulated market economy *could not ensure sufficient demand*. Governments should therefore abandon *laissez-faire*, and should intervene to *control* aggregate demand.

Keynes' analysis of employment and inflation

Keynes' analysis of unemployment can be explained most simply in terms of the circular flow of income (see Figure 16.2). Keynes himself did not use this exact model, but it clearly explains the essence of his argument.

If injections (J) do not equal withdrawals (W), a state of disequilibrium exists. What will bring them back into equilibrium, however, is not a change in prices (of labour or of loanable funds), but rather a change in *national income* and *employment*.

Start with a state of equilibrium, where injections equal withdrawals, but with substantial unemployed resources (as was the case in the Great Depression). If there is now a

rise in injections – for example, a rise in government expenditure – aggregate demand ($C_d + J$) will be higher. Firms will respond to this increased demand by using more labour and other resources and thus paying out more incomes (Y) to households. Household consumption will rise and so firms will sell more.

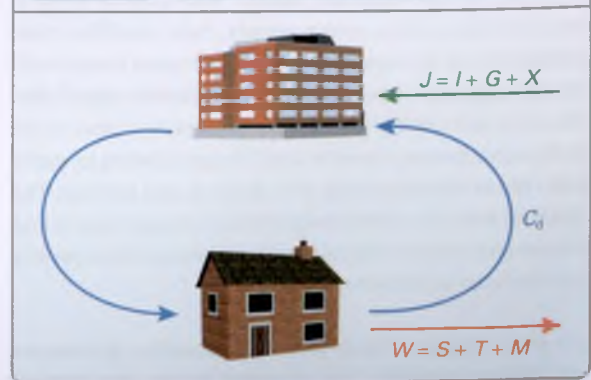

Firms will respond by producing more, and thus using more labour and other resources. Household incomes will rise again. Consumption and hence production will rise again, and so on. There will thus be a multiplied rise in incomes and employment. This is known as the *multiplier effect* and is an example of the 'principle of cumulative causation'. Cumulative causation refers to where an initial event can cause an ultimate effect that is much larger. It is our final threshold concept and we examine it in detail in Chapter 17 (see page 535).

TC 15
p535

Definition

Multiplier effect An initial increase in aggregate demand of $\text{£}x_m$ leads to an eventual rise in national income that is greater than $\text{£}x_m$.

Figure 16.2 The circular flow of income

The process, however, does not go on for ever. Each time household incomes rise, households save more, pay more taxes and buy more imports. In other words, withdrawals rise. When withdrawals have risen to match the increased injections, equilibrium will be restored and national income and employment will stop rising. The process can be summarised as follows:

$$J > W \rightarrow Y \uparrow \rightarrow W \uparrow \text{ until } J = W$$

Similarly, an initial fall in injections (or rise in withdrawals) will lead to a multiplied fall in national income and employment:

$$J < W \rightarrow Y \downarrow \rightarrow W \downarrow \text{ until } J = W$$

Thus equilibrium in the circular flow of income can be at *any* level of output and employment.

If aggregate demand is too low, there will be a recession and high unemployment. The equilibrium output level would be considerably below that consistent with the full employment of the economy's resources. In this case, argued Keynes, governments should intervene to boost aggregate demand. There are two policy instruments that they can use.

Fiscal policy

Fiscal policy is where the government alters the balance between government expenditure (G) and taxation (T). By engaging in fiscal policy, government can alter the balance between injections and withdrawals. In this way, it controls aggregate demand. Faced with a recession, it should raise G and/or lower T . In other words, the government should run a budget deficit rather than a balanced budget. There will then be a multiplier effect:

$$G \uparrow \text{ or } T \downarrow \rightarrow J > W \rightarrow Y \uparrow \rightarrow W \uparrow \text{ until } J = W$$

The larger the multiplier effect the larger the eventual increase in output following the initial increase in aggregate demand.

Monetary policy

Monetary policy is where the central bank alters the supply of money in the economy and/or manipulates interest rates. If it were to raise money supply, there would be more available in the economy for spending, interest rates would fall and aggregate demand would rise. Keynes argued that this was a less reliable policy than fiscal policy, since some of the extra money could be used for speculating in paper assets rather than spending on real goods and services. The details of how the central bank controls money supply and interest rates and the effects of such actions on the economy are examined in later chapters.

It is most effective if both fiscal and monetary policies are used simultaneously. For example, if the government

undertook a programme of public works (fiscal policy) and financed it through increases in money supply (monetary policy), there would be no crowding out. There would be a significant rise in output and employment.

What would be the classical economists' criticisms of this argument?

If aggregate demand rises too much, however, inflation becomes a problem. (This was the case during the Second World War, with the high expenditure on the war effort.) As the economy's full-capacity output is approached, with more and more firms reaching their full capacity and with fewer and fewer idle resources, so additional increases in aggregate demand lead more and more to higher prices rather than higher output. The aggregate level of employment therefore becomes unresponsive to an increase in the effective demand for output. Thus, the level of output when this situation arises is sometimes referred as to the 'full-employment output level'.

If a rise in aggregate demand were to encourage firms to invest more, how would this influence the size of the rise in real GDP?

Governments faced with the resulting demand-pull inflation should, according to Keynes, use *contractionary* fiscal and monetary policies to reduce demand. Contractionary fiscal policy would involve reducing government expenditure and/or raising taxes. Contractionary monetary policy would involve reducing the rate of growth of money supply and/or raising interest rates. Keynes argued that here too fiscal policy was the more reliable, but again that the best solution was to combine both policies.

The Keynesian policies of the 1950s and 1960s

By the end of the Second World War, the economic consensus had changed and this was to have a direct impact on economic policy making in many countries. The dominance of classical economics was to be replaced by Keynesian ideas. From 1945 up to the mid-1970s, many governments around the world, including Conservative and Labour governments in the UK, pursued Keynesian **demand-management policies** in an attempt to stabilise the economy and avoid excess or deficient demand.

Definitions

Monetary policy Where the central bank alters the supply of money in the economy and/or manipulates interest rates.

Demand-management policies Demand-side policies (fiscal and/or monetary) designed to smooth out the fluctuations in the business cycle.

When the economy began to grow too fast, with rising inflation and balance of trade deficits, the government adopted *deflationary* (contractionary) fiscal and monetary policies. When inflation and the balance of payments were sufficiently improved, but probably with recession looming, threatening rising unemployment and little or no growth, governments adopted *reflationary* (expansionary) fiscal and monetary policies. This succession of deflationary and reflationary policies to counteract the effect of the business cycle became known as *stop-go policies* (see Case Study 16.7 on the student website for an account of 'fine-tuning' in the UK).

As Figure 16.1 shows (see page 492), during the 1950s and 1960s, inflation in the UK averaged 4 per cent and unemployment a mere 1.7 per cent (see also Case Study 16.8 on the student website). Low rates of inflation and unemployment were experienced in other industrialised countries too.

Nevertheless, from the mid-1960s onwards there was increasing criticism of short-term demand-management policies. Criticisms included the following:

- *Economic fluctuations still existed.* The policies had mixed success in stabilising economies. The business cycle remained. Some economists even claimed that demand-management policies made fluctuations worse. The main reason given was the time it took for policies to be adopted and to work. If time lags are long enough, a deflationary policy may begin to work only when the economy has already turned down into recession. Likewise, a reflationary policy may begin to work only when the economy is already booming, thus further fuelling inflation.
- *Neglect of structural problems.* Some economists argued that an over-concentration on short-term policies of

stabilisation meant that underlying structural problems in economies were neglected. This was particularly significant in the UK since its post-war growth rate of around 2¾ per cent per annum was appreciably lower than that of other industrialised countries.

- *Balance of payments problems.* Countries like the UK and the USA had persistent balance of trade deficits. At the time, with virtually fixed rates of exchange (something we shall examine in Chapter 25), a *depreciation* of the exchange rate was not an option for correcting balance of payments deficits. This meant that Keynesian reflationary policies were not always possible in recessions. The reason was that *deflationary* policies had to be pursued instead to bring prices down to boost exports and dampen demand to reduce imports.
- *Breakdown of the simple Phillips curve.* The simple Phillips curve relationship between inflation and unemployment was breaking down (see Box 15.6). If reflationary policies were the cure for unemployment and deflationary policies were the cure for inflation, what policies should be pursued when both inflation *and* unemployment were rising?
- *Focus on aggregate demand.* Perhaps the most fundamental criticism of all came from a group of economists called 'monetarists'. They rejected Keynesianism as a whole, with its concentration on demand. They returned to the earlier classical analysis, with its concentration on supply, and extended it to take account of the increasingly important role of *price expectations* in explaining 'stagflation' – the problem of slow growth and rising unemployment (i.e. stagnation) combined with rising inflation (see the next section).

From the mid-1970s onwards, the Keynesian/monetarist split between economists was often reflected in countries' political systems. For example, in the UK the Conservative leadership embraced monetarism, whereas the other political parties continued to embrace variants of Keynesianism.

Stop-go policies Alternate deflationary and reflationary policies to tackle the currently most pressing of the four problems that fluctuate with the business cycle.

Section summary

1. Keynes rejected the classical assumption that all markets would clear. Disequilibrium could persist in the labour market. A fall in aggregate demand would not simply lead to a fall in wages and prices and a restoration of the full-employment equilibrium. Instead there would be demand-deficient unemployment: as demand fell, there would be less demand for labour.
2. Disequilibrium could also persist in the market for loanable funds. As aggregate demand fell, and with it business confidence, so the demand for loanable funds for investment would shrink. Reductions in interest rates would be insufficient to clear the market for loanable funds.
3. Keynes also rejected the simple quantity theory. If there is slack in the economy, an expansion of the money supply can lead to an increase in *output* rather than an increase in prices.
4. Keynes argued that there would be a multiplier effect from changes in injections or withdrawals. A rise in investment, for example, would cause a multiplied rise in national income, as additional expenditures flowed round and round the circular flow, stimulating more and more production and thus generating more and more real income.
5. If the economy is operating below full employment, the government can use fiscal and/or monetary policies to boost aggregate demand and thereby take up the slack in the economy. Excessive aggregate demand, however, causes inflation. Deflationary fiscal and monetary policies can be used to remove this excess demand.
6. Keynesianism became the orthodoxy of the 1950s and 1960s. Governments used fiscal (and to a lesser extent monetary) policies to manage the level of aggregate demand.
7. After the mid-1960s, however, there was growing criticism of Keynesian demand management. Economies still fluctuated and the various macroeconomic problems seemed to be getting worse.

16.4 THE RISE OF THE MONETARIST AND NEW CLASSICAL SCHOOLS

Sowing the seeds of a new orthodoxy

As we saw in section 16.3, the Keynesian orthodoxy began to break down during the 1960s. This breakdown can be seen in the context of a more volatile macroeconomic environment (see Figure 16.3). The high inflation and low growth of the 1970s stimulated macroeconomic debates. As we shall see, some of the resulting developments were to

have a significant impact on macroeconomics, helping to shape a new orthodoxy.

In charting the path to a new orthodoxy, we begin by considering the rise of the monetarist and new classical schools. A feature that distinguished both schools from the Keynesian orthodoxy was the belief that the market economy can deliver macroeconomic stability. Government

intervention, they argued, can be a contributory factor to macroeconomic *instability*.

The monetarist counter-revolution

The chief advocate of monetarism was Milton Friedman, Professor of Economics at Chicago University and recipient of the Nobel Memorial Prize in Economics in 1976 (see Case Study 16.9 on the student website). Monetarists returned to the old classical theory as the basis for their analysis, and extended it to take account of the growing problem of *stagflation* – low growth accompanied by high inflation.

At the heart of monetarism is the *quantity theory of money*, which, as we saw earlier, was central to the classical analysis of inflation (see section 16.2). Friedman examined the historical relationship between money supply and prices, and concluded that inflation was ‘always and everywhere a monetary phenomenon’. If money supply over the long run rises faster than the potential output of the economy, inflation will be the inevitable result.

Monetarists argued that over the long run, in the equation $MV = PY$, both V and Y are independently determined and are not, therefore, affected by changes in M . Any change in money supply (M), therefore, will only affect prices (P). In other words, the *neutrality of money* (see section 16.2) holds in the long run.

Monetarists drew two important conclusions from their analysis.

- The rising inflation from the mid 1960s onwards was entirely due to the growth in money supply increasingly outstripping the growth in output. If money supply rises, they argued, then the resulting rise in aggregate demand will lead to higher output and employment only in the short run. But soon people’s expectations will adjust. Workers and firms come to expect higher wages and prices. Their actions then ensure that wages and prices *are* higher. Thus after a short period, perhaps one or two years, the extra demand is fully taken up in inflation, and so output and employment fall back again. Then governments are tempted to raise money supply and aggregate demand again in a further attempt to get unemployment down. The effect of this over several years is for the inflation rate to get higher and higher.
- Reducing the rate of growth of money supply will reduce inflation without leading to long-run increases in unemployment. It *will* lead to temporary increases in unemployment, they argued, as the demand for goods and labour fall. But as price and wage inflation adjust down to this new level of demand, unemployment will fall. This process will be hindered and high unemployment is likely to persist if workers continue demanding excessive wage increases, or if firms and workers continue to expect high inflation rates.

Monetarists argued that inflation is damaging to the economy. Inflation creates uncertainty for businesspeople and so reduces investment while also reducing a country’s

competitiveness in international trade. They saw it as essential, therefore, for governments to keep a tight control over money supply and advocated the setting of money supply *targets*. Modest and well-publicised targets should help to reduce the *expected* rate of inflation. Targets for the growth of the money supply were central to the ‘medium-term financial strategy’ from the late 1970s to the mid-1980s of the UK governments of Margaret Thatcher.

A vertical long-run Phillips curve

Monetarist analysis implied that the long-run Phillips curve is vertical at the equilibrium rate of unemployment. The equilibrium rate is frequently referred to as the *natural rate of unemployment* by monetarists. This is illustrated in Figure 16.4. It is the rate consistent with the economy being at its potential or ‘long-run’ level. It is therefore argued to be determined principally by structural factors. Though not directly measurable, it can be thought of as capturing structural and frictional unemployment (see section 15.5).

In the *short run*, higher aggregate demand will reduce the unemployment rate below the natural rate. This is because there is a *real* increase in aggregate demand. But in the long run an increase in aggregate demand is fully absorbed by higher inflation. Therefore, a monetary expansion will

Stagflation A term used to refer to the combination of stagnation (low growth and high unemployment) and high inflation.

Natural rate of unemployment The rate of unemployment consistent with market clearing in the labour market. It is the rate of unemployment at which the vertical long-run Phillips curve cuts the horizontal axis.

increase output and employment in the short run, but not so in the long run, when money neutrality holds. The key to understanding why is the role of expectations.

Friedman argued that, in forming expectations of inflation, people learn from experience. If, for example, in the previous period, they under-predicted the rate of inflation, then this period they will adapt: they will revise their expectations of inflation upwards. This type of behaviour is thus known as **adaptive expectations**.

Assume that the economy is in equilibrium with unemployment at its natural rate (U_n) and that the authorities engage in a monetary expansion. This increases aggregate demand, resulting in an excess demand for goods and labour. The effect of this is to cause prices and nominal wages to rise. Even though *real* wages have not risen, workers could be 'fooled' into supplying more labour, believing that the rise in nominal wages represented a real rise. In fact, prices typically rise more quickly than nominal wages, resulting in a *fall* in real wages. Consequently, firms increase their demand for labour; output expands and the unemployment rate falls below its natural rate.

Gradually workers recognise that their real wages have fallen following the monetary expansion. This puts further upward pressure on money wages. In the long run, as expectations of inflation converge on actual inflation, all the extra demand is absorbed in higher inflation. Output falls to its potential level and unemployment rises back to the natural rate.

If unemployment is to be reduced in the long run, therefore, this vertical Phillips curve must be shifted to the left. This will be achieved by a reduction in the natural (equilibrium) rate of unemployment (U_n), *not* by an increase in demand. To reduce the natural rate, argued the monetarists, **supply-side policies** would be needed. These are policies that focus on increasing *potential* output by increasing the quantity and/or productivity of factors of production.

 Give some examples of supply-side policies that would help to reduce the natural rate of unemployment.

The new classical school

The **new classical school** took on increasing significance during the 1970s and 1980s. The monetarist view was that markets adjust relatively quickly, but that there may be disequilibrium in the short run.

In contrast, new classical economists believed that markets clear continuously. The implication of **continuous market clearing** for the labour market is that there is no demand-deficient unemployment: wage flexibility equates the demand and supply of labour. The only unemployment is 'voluntary' unemployment, where unemployed people choose not to take jobs on offer, preferring, perhaps, to spend time looking for better-paid employment. The assumption of continuous market clearing has another important implication: the distinction between the short run and long run breaks down.

Is voluntary unemployment the same as frictional unemployment?

Another key assumption of the new classical school is **rational expectations**. This means that economic agents use all available information and predict inflation, or any other macroeconomic variable, as well as they can. The important point here is that, unlike with adaptive expectations, economic agents avoid making the same error repeatedly. Therefore, errors are random. This means that, on average, economic agents' expectations of inflation are correct.

The implication of continuous market clearing combined with rational expectations is that a change in aggregate demand will simply cause a change in prices, not a change in output and employment, even in the short run. This applies equally to both a rise and a fall in aggregate demand.

But, with continuous market clearing and rational expectations, how did new classical models explain the fluctuations in output and unemployment associated with the business cycle?

Monetary surprises

The first strand of new classical models focused on how imperfect information could generate unexpected inflation. The work was led by Professor Robert Lucas, who, like Friedman, spent much of his career at the University of Chicago. Lucas was a recipient of the Nobel Memorial Prize in Economics in 1995 (see Box 21.3).

Monetary surprise models show how **unexpected** changes in monetary policy can result in both firms and workers changing their supply decisions such that the economy temporarily deviates from equilibrium. Consider an unexpected monetary expansion that causes aggregate demand to grow more than expected and, in turn, results in the inflation rate

Definitions

Adaptive expectations hypothesis The theory that people base their expectations of inflation on past inflation rates.

Supply-side policies Policies to increase *potential* output. Such policies focus on increasing the quantity and/or productivity of resources.

New classical school A body of economists who believe that markets are highly competitive and clear very rapidly; any expansion of demand will feed through virtually instantaneously into higher prices, giving a vertical short-run as well as a vertical long-run Phillips curve.

Continuous market clearing The assumption that all markets in the economy continuously clear so that the economy is permanently in equilibrium.

Rational expectations Expectations based on the *current* situation. These expectations are based on the information people have to hand. While this information may be imperfect and therefore people will make errors, these errors will be random.

being higher than expected. If, as wages and prices rise, workers and firms wrongly believe that the *real* price of their labour and output has increased, they will supply more.

Conversely, an unexpected monetary contraction would see labour supply and output fall. This time, workers and firms wrongly believe that a fall in wages and prices represents a real fall in the price of labour and output.

Why are monetary surprises less likely with independent central banks pursuing an inflation target? Would monetary surprises still be possible in such circumstances?

The key to economic fluctuations in monetary surprise models is the errors in expected inflation that arise from imperfect information. Once economic agents recognise these errors, output and employment return to their equilibrium levels. In the presence of continuous market clearing and rational expectations, *anticipated* changes in economic policy have no effect on output and employment, which remain at their equilibrium levels. This prediction is known as the **policy ineffectiveness proposition**.

The monetary surprise models and the policy ineffectiveness proposition are highly contentious. Two principal objections have been raised.

The first objection is the assumption of *continuous market clearing*. As we shall see in the next section, a key Keynesian response has been to explore why instead prices might adjust only *slowly* in clearing product and labour markets. If prices do adjust slowly then economic policy can have real effects on output and employment, even in the presence of rational expectations.

The second objection is the conclusion of *money neutrality*, whereby expected changes in monetary policy do not affect output. Could the business cycle be explained only by monetary *surprises*? It was this second concern that some new classical economists attempted to address with the development of real business cycle models.

Real business cycles

Like the monetary surprise models, *real business cycle theories* also assume continuous market clearing and rational expectations. However, real business cycle theories challenge the traditional understanding of the business cycle as

fluctuations in real GDP around potential (natural) output (see section 15.3). Instead, it is argued, the business cycle is created by movements in potential output itself: in other words, shifts in aggregate supply, not aggregate demand. These movements come from frequent 'shocks' that hit the economy which permanently affect the path of the economy's output over time.

Real business cycle (RBC) theories typically focus on supply-side shocks. These shocks are also known as 'impulses' and frequently take the form of technology shocks. Technology shocks can, in theory, refer to anything that affects production processes and levels of productivity. For example, a technological breakthrough in telecommunications could positively affect potential output while a decline in energy sources could negatively affect potential output.

Would an intensification of government regulation constitute a positive or negative economic shock in RBC models?

Real business cycle theory challenges the traditional view that technology is important largely when explaining the *long-term* rate of economic growth and development. Instead, frequent technology shocks are also seen as an important explanation of business cycles. Therefore, real business cycle theories dispense with the distinction between the business cycle and long-term economic growth; supply-side shocks are important both in the short run and in the long run.

The economic effects of shocks to the economy, such as those from technological change, are assumed to reflect the optimal decisions of economic agents (firms, households, government, etc.). In making consumption and production choices, economic agents take into account the impact of their choices not only in the current period, but in all future periods too.

This means that an expansion in the economy's output (e.g. from a technological breakthrough) reflects purposeful decisions by firms to increase output and workers to increase their labour supply. On the other hand, declining output (e.g. from a less business-friendly regulatory climate) reflects decisions by firms to reduce output and workers to reduce labour supply.

The role of representative agents. Real business cycle models use representative agents (i.e. a typical person or firm) to analyse and illustrate the impact of economic shocks. They are assumed to allocate their time between work and leisure so as to maximise their lifetime satisfaction.

Consider the effect of a positive technology shock. Again, this could be a technological breakthrough. This enables the representative agent to produce and earn more now. If they believe that the benefits of this positive shock will be relatively short-lived, the incentive to work and earn more now is especially strong. Therefore, following positive economic shocks economic agents actively choose to work more. In doing so, output rises. Some of the increased income from

Definitions

Policy ineffectiveness proposition The conclusion drawn from new classical models that when economic agents anticipate changes in economic policy, output and employment remain at their equilibrium (or natural) levels

Real business cycle theories The new classical theory which explains fluctuations in real GDP in terms of economic shocks, especially technology shocks, and which have persistent effects on potential output.

the additional production is invested, increasing levels of investment. This further increases the economy's potential output, so raising possible future output levels.

When economic shocks are negative, such as from a decline in energy sources, economic agents choose to work less. Such shocks reduce current output levels and reduce levels of investment. The effect is to reduce possible future output levels.

 Assume that there is a positive economic shock and the economy expands. Why may it continue to expand for some time? Why may the expansion eventually cease and be followed by a recession?

Government policies

Governments up to the late 1970s responded to rising unemployment by boosting aggregate demand (the balance of payments permitting). This, however, as monetarists and new classical economists predicted, led only to more inflation, fuelled by rising expectations of inflation (see Figure 16.3 on page 502). When governments eventually did curb the growth in aggregate demand, it took time for expectations to adjust downwards.

As we saw earlier, to help bring inflationary expectations down, the UK government from the late 1970s to the

mid-1980s set targets for the growth of money supply. This was largely consistent with monetarist principles. In the short term, however, the effect was a rise in unemployment. As can be seen in Figure 16.3, the standardised UK unemployment rate rose to as high as 12 per cent by 1984.

Nevertheless, the pursuit of these policies did, according to monetarists, lead to a dramatic fall in the rate of inflation. Inflationary expectations fell and wage rises moderated. In 1980, the inflation rate was 15 per cent; by 1986, it had fallen to 3 per cent. Eventually the rise in unemployment was to be reversed too.

The rise of monetarist and new classical macroeconomics was to be reflected in economic policy during the 1980s in many countries, though particularly so in the USA and the UK. The result was that governments were again to place a greater reliance on the market. The UK saw policies of privatisation and deregulation pursued; union power curbed; and tax rates cut. Controls over the financial system were reduced, with banks given much more freedom to expand their activities (we examine this in Chapter 18). This 'supply-side' revolution was designed to increase incentives to work, to invest and to innovate. We explore these market-orientated supply-side policies in section 23.5.

Section summary

1. Monetarists argued that there is a close correlation between the rate of growth of the money supply and the rate of inflation. Increases in money supply cause increases in aggregate demand, which in turn cause inflation. Along with the classical economists, they argued that output and employment are determined independently of money supply (at least in the long run). This means that a deflationary policy to cure inflation will *not* in the long run cause a fall in output or a rise in unemployment.
2. Monetarists thus argued that the long-run Phillips curve is vertical. Its position along the horizontal axis will depend on the level of equilibrium or 'natural' unemployment.
3. Building on monetarist ideas, early new classical macroeconomic models focused on how monetary surprises induce short-term deviations in unemployment from its natural rate. However, under the assumptions of continuous market clearing and rational expectations, unemployment does not deviate from its natural rate if monetary policy is anticipated.
4. Real business cycle theorists argue that the business cycle is the result of frequent economic shocks, such as technology shocks, which affect the path of potential output. Economic outcomes, including the path of real GDP, are the result of optimal choices made by rational economic agents under continuous market clearing.

16.5 THE KEYNESIAN RESPONSE

Market imperfections

Monetarist and new classical ideas reshaped macroeconomics radically during the 1970s and 1980s. These ideas affected policy making with increasing emphasis placed on

the supply side of the economy. Governments began to place less emphasis on using its discretion over monetary and fiscal policy to fine-tune the economy.

Many Keynesians could agree with monetarists and new classical economists on one point. If demand is expanded

too fast and for too long, inflation will result – and there will be a certain amount of unemployment of labour (and other resources too) that cannot be eliminated simply by expanding aggregate demand. However, they rejected the notion that the policy ineffectiveness proposition always holds. Because of the behaviour of markets, they argued, governments could intervene through policies designed to affect aggregate demand and make a positive difference.

A large number of academic Keynesians began a research agenda focused on gaining a better understanding of *aggregate supply*. The motivation was to develop stronger theoretical explanations of why markets may be slow to adjust. Consequently, a large amount of work was undertaken into market imperfections and the frictions which cause prices to be ‘sticky’. Much of the focus was to establish stronger *microeconomic* foundations. The group of Keynesians who have taken this approach have been subsequently labelled *new Keynesians*.

Menu costs and nominal price rigidity

The assumption of continuous market clearing is seen by many Keynesian as the most controversial of the new classical assumptions. New Keynesians have focused on the *frictions* that may cause prices to adjust only slowly following economic shocks, especially to aggregate demand.

New Keynesians argue that firms are often operating in imperfectly competitive markets (see Chapter 8). Therefore, firms are price-makers rather than price-takers as portrayed in the perfectly competitive model (see Chapter 7). In other words, firms set not just quantity but also price.

However, a firm's product price may exhibit *stickiness* in the presence of demand shocks because of the *menu costs* of price changes (see Box 15.5, page 475). Menu costs include both the physical costs to firms in updating price lists and the costs incurred in determining and negotiating prices with customers and suppliers.

If the menu costs to an individual firm are larger than the profit lost from not adjusting prices, then the rational firm will not change its prices. When price rigidity is commonplace throughout the economy, any change in aggregate demand can have a significant effect on national output.

Consider a decrease in demand for a representative profit-maximising firm with power to affect both price and output. Intuitively, we would expect the firm to reduce both output and prices. The extent of both would be ordinarily determined by the rule for the profit-maximising level of output: marginal revenue (*MR*) equals marginal cost (*MC*) (see Chapter 6). However, if frictions, such as those arising from menu costs, result in price stickiness, then output will fall further. The stickiness in prices causes the quantity demanded to fall more than it otherwise would do following the initial decline in demand. Box 16.4 analyses menu costs more formally.

Illustrate the effect of a fall in demand for an imperfectly competitive firm (a) in the presence of menu costs and (b) in the absence of menu costs.

The significance of price rigidities is that changes in aggregate demand can have significant effects on an economy's actual output. Therefore, in the presence of such frictions to market adjustment, governments may need to intervene to affect the level of aggregate demand.

Such frictions are also important because they mean that changes in the money supply can affect the economy's output. In other words, money ceases to be neutral as predicted by real business cycle theory: it can have real effects on the economy.

What technological developments are likely to have reduced menu costs in recent years?

Sources of other frictions and imperfections

The extensive new Keynesian literature that has developed since the 1980s has identified a series of other market imperfections. These imperfections can help to reinforce the nominal rigidity in product prices arising from menu costs and so increase fluctuations in real GDP. Imperfections include the following:

- **Price inelasticity of demand.** Where competition is limited, demand will be less elastic. Under such circumstances a firm will be under less pressure to reduce prices if demand falls. In an economic downturn, therefore, firms may prefer to reduce output than cut prices.
- **Anticipating other firms' pricing strategy.** If firms' products are close substitutes for one another, they are likely to be very wary of cutting prices for fear of retaliation from their rivals. They may prefer to reduce output during a downturn rather than risk a price war.
- **Sticky nominal wages.** Wage rates are largely determined through negotiation between workers and employers. The presence of contracts allows both sides to avoid the costs incurred in frequent wage negotiations and provide both with a degree of certainty. Even in the absence of contracts, workers are likely to be resistant to cuts in their money wages. They may prefer a reduction in hours, or the non-replacement of workers who leave, rather than take a cut in wages. Indeed, the flexibility of hours, often with 'zero hours contracts', where workers have no

Definitions

New Keynesians Economists who seek to explain how market imperfections and frictions can result in fluctuations in real GDP and the persistence of unemployment.

guaranteed hours, but simply are allocated hours on a weekly or monthly basis, means that employers are more likely to adjust hours than wage rates.

- **Real wage rigidity.** New Keynesians argue that equilibrium real wage rates may be above market clearing levels. The result can be involuntary unemployment. As we saw in section 10.2 (page 291), the **efficiency wage hypothesis** maintains that firms may pay wage rates above market levels in order to provide an incentive for workers. The implication that new Keynesians draw is that, in a downturn, a firm may be reluctant to cut real wages for fear of lowering morale and thereby reducing productivity.

Insider–outsider theories emphasise the power of employees in resisting real wage cuts. Those currently employed (the **insiders**, see page 290) may, through their unions or close relationships with their employers, or because of the possession of specific skills, be able to prevent the unemployed (the **outsiders**) from competing wages down.

Definitions

Efficiency wage hypothesis The hypothesis that the productivity of workers is affected by the wage rate that they receive.

Insiders Those in employment who can use their privileged position (either as members of unions or because of specific skills) to secure pay rises, or resist wage cuts, despite an excess supply of labour (unemployment).

Outsiders Those out of work or employed on a casual, part-time or short-term basis, who have little or no power to influence wages or employment.

- **Sources of finance.** During a downturn, both internal and external sources of finance for investment may diminish. The decline in demand will reduce profit and hence internal sources. What is more, banks may be less willing to lend, seeing risks rising in a downturn. The result is a decline in investment. During a boom, by contrast, sources

BOX 16.4 MENU COSTS

EXPLORING ECONOMICS

How sticky prices amplify fluctuations in output

Menu costs are any costs incurred by firms when changing prices. These include not only costs to firms of updating price lists, such as the costs of printing new menus in restaurants from which the name of the concept is derived, but also costs in developing new price strategies, in negotiating new contracts and in the very processing of the information around the new price structure that customers will need to undertake.

Menu costs, it is argued, may create a stickiness or rigidity in firms' prices because they are reluctant to change prices even when faced with a change in demand. In other words, menu costs create a friction to the adjustment of nominal (actual) product prices to economic shocks. The more widespread is such price rigidity the more significant can be the effect of a change in aggregate demand on national output.

To illustrate the effect of price rigidity on output, consider the diagram of a monopolistically competitive firm. The firm's demand curve (D_1) is downward sloping, the elasticity depending on how close its competitors' products are as substitutes to its own. The marginal revenue (MR_1) curve lies below the demand curve (average revenue curve) because, in reducing price to sell more units, all units attract the lower price (see Chapter 7 pages 218–20). For simplicity, we assume that marginal cost (MC) is constant across all output levels.

The firm experiences a decrease in demand for its product because of a decrease in aggregate demand in the economy. Before the decrease in aggregate demand, the firm is producing at output level Q_1 , where marginal cost (MC) equals marginal revenue (MR_1), and selling its output at price P_1 . Its profit is represented by the area CP_1DE .

The decrease in demand results in a leftward movement in both the demand curve (D_1 to D_2) and the marginal revenue

Price frictions and the monopolistically competitive firm

curve (MR_1 to MR_2). In the absence of frictions, our price-setting firm will reduce price from P_1 to P_2 and output from Q_1 to Q_2 . Profit falls to CP_2FG .

However, if frictions, such as those arising from menu costs, result in price stickiness, then output will fall further. If price remains at P_1 then output falls to Q_3 . Hence, output has fallen by the additional amount equivalent to $Q_2 - Q_3$. Profits fall to CP_1JK . But, the key point is that firms will be willing to incur this forsaken profit, $CP_2FG - CP_1JK$, if the menu costs incurred in reducing prices are greater.

Illustrate the effect of nominal price rigidities on output if the firm's demand increases because of a rise in aggregate demand.

of funds for investment are likely to increase. These 'pro-cyclical' changes in the availability of finance are thus likely to exacerbate existing fluctuations in real GDP.

- **Attitudes towards debt.** In a boom, consumer and business confidence is likely to encourage borrowing. Debts are likely to rise. In a recession, however, with people more anxious about the future, consumers and firms may seek to reduce their debts by curbing spending. These effects could be reinforced by risk-averse financial institutions which reduce lending, seeing it as riskier when firms are more likely to go out of business or individuals more likely to lose their jobs. Again, this means that bank lending tends to be pro-cyclical and exacerbates existing fluctuations in real GDP.

Hysteresis

In the early 1980s there was a recession, or slowdown, throughout the industrialised world. Unemployment rose to unprecedented levels. But as the world began to recover, unemployment remained stubbornly high. This focused minds on the extent to which current rates of unemployment affect the future path of unemployment. Could there be a persistence or inertia in unemployment rates? And, if so why?

Keynesians argued that the rise in unemployment, though largely caused by a lack of demand, could not simply be reversed by a *rise* in demand. The recession had itself *caused* higher rates of unemployment to become embedded in the economy. The reason is that during a recession, many people become deskilled and/or demoralised and firms become more cautious about taking on workers, preferring to manage with a smaller, more efficient workforce. What is more, as we saw above, people who remain employed (the *insiders*) are often able to secure wage increases for themselves, and prevent the unemployed (the *outsiders*) from competing wages down. Many of the unemployed thus remain unemployed.

This persistence of high unemployment that characterised many developed economies through the 1980s and into the 1990s and once more in the late 2000s and into the 2010s is known as ***hysteresis***. This term, used in physics, refers to the lagging or persistence of an effect, even when the initial cause has been removed. In our context, it refers to the persistence of unemployment even when the initial demand deficiency no longer exists.

Past rates of aggregate demand and unemployment were thus affecting the *natural rate of unemployment*, or what some

Keynesians refer to as the ***non-accelerating-inflation rate of unemployment (NAIRU)***.

Strictly speaking, the natural rate and the NAIRU are theoretically different, though the concepts are often used interchangeably. The natural rate of unemployment is the unemployment rate consistent with market clearing in the labour market. It depends on structural factors affecting labour demand and supply. On the other hand, the NAIRU is the rate of unemployment in a world characterised by market imperfections and frictions at which the inflation rate is steady in the short term, say the next 12 months or so.

Why has UK unemployment been less persistent following the recession of 2008–10 than following that in the early 1980s? In other words, why has hysteresis been less of a problem in the UK in recent times?

Government intervention

Targeted government intervention may be needed to help smooth the path of aggregate demand. A substantial increase in demand may be necessary if the economy is in danger of falling into deep recession, as was the case in 2008–9. The debate then concerns the form that this intervention should take.

One approach is for the government to increase its expenditure on public works such as roads, school building and housing. The advantages of such infrastructural projects is that they can directly impact on the economy's potential output and, because they have a relatively low import content, increased expenditure on such projects does not lead to balance of payments problems.

Thereafter, the government should maintain a high and stable demand by appropriate demand-management policies. This should keep unemployment down and set the environment for long-term investment and growth.

Definitions

Hysteresis The persistence of an effect even when the initial cause has ceased to operate. In economics, it refers to the persistence of unemployment even when the demand deficiency that caused it no longer exists.

Non-accelerating-inflation rate of unemployment (NAIRU) The rate of unemployment consistent with steady inflation in the near term, say, over the next 12 months.

Section summary

1. A group of Keynesian economists sometimes referred to as 'new Keynesians' responded to the monetarist/new classical challenge by building models highlighting market imperfections, including frictions that affect the adjustment of markets to shocks. These imperfections were argued to provide a rationale for government intervention.
2. Keynesians argued that unemployment caused initially by a recession (a deficiency of demand) may persist even when the economy is recovering. This 'hysteresis' may be due to the deskilling of labour, a decline in firms' capacity, insiders preventing outsiders from bidding down the wage rate, or firms being cautious about taking on extra labour when the recovery does come.
3. Whereas monetarist and new classical macroeconomists generally favoured policies of freeing up markets, Keynesians generally favoured a rather more interventionist approach by the government. Through appropriately targeted fiscal measures, governments can help to smooth the business cycle and limit the adverse effects on the economy's future potential output.

16.6 AN EMERGING CONSENSUS UP TO THE CRISIS OF 2008

The Great Moderation and a new mainstream consensus

The period from the early 1990s up to the financial crisis of the late 2000s was to be known as the 'Great Moderation'. The period was characterised in many developed countries by low and stable inflation and continuous economic growth. As Figure 16.3 shows (see page 502), the UK was no exception. From 1994 to 2007 annual UK growth averaged 2.9 per cent while the annual rate of consumer price inflation averaged 1.75 per cent.

The period of the Great Moderation also saw the emergence of a new mainstream macroeconomic consensus. The new consensus built on elements from the new classical and new Keynesian schools of thought. In particular, it combined the idea from real business cycle theory of the economy being hit by frequent random shocks, particularly supply shocks, with the new Keynesian idea of market imperfections that then affect the adjustment process of the economy to the shocks.

The new consensus macroeconomics argued that there is no long-run trade-off between inflation and unemployment, with the natural rate of unemployment and the economy's potential output being determined by supply-side or structural factors. The new Keynesian market imperfections, therefore, explain the deviations of output from its potential or long-run level.

DSGE models – the new consensus macro model

The new consensus has been identified with the development of elaborately technical models of the economy. One particularly well-known group of models are known as *dynamic stochastic general equilibrium models* or *DSGE models* for short.

The dynamic nature of DSGE models. DSGE models of the economy are a fusion of new Keynesian and new classical ideas. In these models, forward-looking rational economic agents (individuals and firms) make choices to maximise their welfare. They attempt to achieve the best outcome outcomes in any given set of circumstances. These choices are affected by future uncertain outcomes and so evolve as events unfold and changes occur in agents' rational expectations. Hence, the models are *dynamic*.

The stochastic element in DSGE models. The economy is hit by frequent random (stochastic) 'shocks'. These *stochastic shocks* generate uncertainty for economic agents. Crucially, it is these shocks and hence the uncertainty that they generate that result in the economy's output deviating from what would otherwise be a predictable growth path. These deviations or disturbances also affect the economy's future growth path. In other words, the effects persist. This means that new consensus models combine an analysis of both short-term and long-term economic growth.

Give some examples of stochastic shocks.

Definitions

Dynamic stochastic general equilibrium (DSGE) models Models that seek to explain macroeconomic phenomena by examining the microeconomic behaviour of rational forward-looking individual economic agents acting in a variety of market conditions. The microeconomic equilibria are subject to random shocks, such as technological change, political events or changes in the supply of natural resources.

Stochastic shocks Shocks that are random and hence unpredictable, or predictable only as occurring within a range of values.

TC 8
p109

TC 9
p129

The types of shock considered by new consensus economists are quite broad. On the supply side, shocks included, for instance, changes in the price mark-up (over marginal cost) of imperfectly competitive firms, changes in the cost to firms of external finance relative to internal finance, or productivity shocks. On the demand side, shocks include changes to the 'impatience' of economic agents and therefore their preference for spending now relative to the future, and changes in expected future consumption, in government spending or in interest rates.

General equilibrium. DSGE models seek to understand macroeconomic aggregates, such as real GDP, by analysing the interaction of economic agents in markets. They take a 'bottom-up approach' by analysing the macroeconomy through the interaction of representative agents in different markets which all tend to equilibrium. This explains why DSGE models are *general equilibrium* models.

Market imperfections and frictions. DSGE models typically assume monopolistically competitive firms and monopolistically competitive labour markets. Furthermore, they incorporate a number of frictions to price adjustment drawn from new Keynesian developments (see page 510). The exact nature of competition in product and labour markets and the frictions applied in the models can vary. This allows economists and policy makers to analyse how these imperfections affect the way in which economic shocks impact on the economy.

Constrained policy discretion

In the UK, as in many other industrialised countries, the Great Moderation was a period when policy makers frequently spoke about the importance of policies that help to foster a stable economic environment and that are conducive to long-term economic growth and prosperity. This led to the birth of what economists call **constrained discretion**: a set of rules or principles providing a framework for economic policy.

Constrained discretion typically involves the use of targets, such as an inflation target or a public-sector deficit or debt ceiling. The key is to affect the *expectations* of the public, for example in relation to inflation.

? *Does the use of public-sector deficit targets rule out the use of fiscal policy to reduce economic fluctuations associated with the business cycle?*

In many countries, governments handed over the operation of monetary policy to central banks. In the UK, in 1997 the Bank of England was granted independence to determine interest rates to meet an inflation rate target.

The new classical models of the late 1970s and early 1980s played an important role in developing the theoretical foundations for central bank independence. If a short-term trade-off between inflation and unemployment only arises because of *unanticipated* changes in monetary policy then, new classical economists argued, it makes sense to remove the temptation for governments to use expansionary monetary policy unexpectedly.

In the longer term, in the absence of central bank independence or transparent inflation rate targeting, the result is likely to be higher inflationary expectations and higher actual inflation. Output and unemployment will be at their natural levels. This is because the general public is only too aware of governments' incentive to want to induce faster growth by loosening monetary policy and creating 'surprise' inflation. Economic agents therefore push up the inflation rate by revising their inflationary expectation upwards, so choking off any increase in output and employment. This excessive inflation is known as **inflation bias**.

The elimination of inflation bias is commonly identified as a key economic benefit of central bank independence. By sticking to an inflation target, a central bank can create the stable environment necessary for the market to flourish: expectations will adjust to the target rate of inflation (assuming central banks are successful in achieving the target) and firms will be able to plan with more confidence. Investment is thereby encouraged and this, in turn, encourages a growth in potential output. In other words, sticking to the targets creates the best environment for the expansion of aggregate *supply*.

From the mid-1990s to 2007/8, these policies seemed to be successful. But then things went horribly wrong!

Definitions

Constrained discretion A set of principles or rules within which economic policy operates. These can be informal or enshrined in law.

Inflation bias Excessive inflation that results from people raising their expectations of the inflation rate following expansionary demand management policy, encouraging government to loosen policy even further.

Section summary

1. During the 1990s a new mainstream consensus began to develop. It drew ideas principally from the new classical and new Keynesian schools. Central to most new consensus models are representative forward-looking economic agents who form rational expectations.
2. Dynamic Stochastic General Equilibrium (DSGE) models became the standard model of the economy. These allowed economists to model the impact of frequent economic shocks under certain assumptions about competition in product and labour markets and the speed with which these markets adjust to equilibrium.
3. Government policy moved to one of constrained discretion, with fiscal and monetary targets. This, it was argued, would provide the stable environment for the mixed market system to flourish and for firms and consumers to take a longer-term perspective.

16.7 THE FINANCIAL CRISIS AND THE SEARCH FOR A NEW CONSENSUS

The financial crisis and its aftermath

Throughout the late 1990s/early 2000s, many banks had massively increased their lending. Also many mortgages were granted, especially in the USA, to people unlikely to be able to repay them, especially if house prices stopped rising. This 'sub-prime debt' made banks very vulnerable to an economic downturn or to worries by depositors about banks' viability.

In 2007, several smaller banks were in difficulties and some had to be bailed out. Then, in 2008, Lehman Brothers in the USA collapsed and was liquidated. With many of the world's major banks being seen as having too little capital, there was a real danger that many more would collapse. Lending between banks dried up and several banks had to be bailed out by their governments. There was a sharp reduction in banks' lending to customers.

The financial crisis led to a deep recession in many developed countries. In the USA, for example, the economy shrank by 2.8 per cent in 2009, while in the UK it shrank by 4.3 per cent (see Figure 16.3 on page 502).

The impact of the banking crisis on the economy was on such a scale that important debates followed. These debates challenged the new macroeconomic consensus; after all, why had so few economists predicted the global financial crisis? Indeed, Queen Elizabeth II, on a visit to the London School of Economics in November 2008, asked why economists had got it so wrong. But economists were not slow in providing explanations.

Economists' explanations. Economists on the right tended to argue that the banking crisis was the result of too much government intervention. Such intervention, it was argued, had distorted incentives such that banks believed that they would not be allowed to fail (a moral hazard: see page 135). Consequently, financial institutions took excessive risks, expanding their balance sheets aggressively with too little loss-absorbing capital.

Economists on the left tended to argue that the banking crisis was the result of too *little* intervention. Financial institutions had been too lightly regulated and it was this that had resulted in excessive risk-taking. Some on the left argue that the banking sector is prone to excessive lending during times of prosperity, which ultimately lays the seeds for financial crises (see Box 9.4 on page 262). Therefore, the financial system is an important contributory factor to the business cycle (see section 15.3). Banks should be required to build their capital base in times of rapid growth so that they have sufficient reserves in times of recession.

There are some who argue that tighter regulation should not simply involve increasing the loss-absorbing capital that banks are required hold, which has been the mainstream response since the crisis. Rather, they would advocate a return to controls on the flows of credit, a policy which many countries began abandoning from the late 1970s.

Fiscal expansion to fiscal austerity

Despite disagreement about the causes of the financial crisis, the immediate priorities of policy makers were to ensure the stability of the financial system and to mitigate the effects on aggregate demand of the limited levels of credit now available for households and firms. There was initially a general consensus on the medicine to be applied.

The initial expansionary policies. First, vast amounts of liquidity were supplied to the banking sector. Second, fiscal stimulus packages were used to boost aggregate demand. In other words, the consensus was that central banks and governments needed to act.

This was not a time for passive economic policy. Rules and frameworks were loosened or applied more flexibly and in some cases even abandoned completely. We discuss this in more detail in Chapter 22.

Followed by austerity policies. This consensus was to be relatively short-lived, however, as many countries saw a marked deterioration in the state of their public finances. Governments began running relatively large fiscal deficits which needed financing. These deficits were worsened by governments having to bail out banks and by the recession which saw tax revenues fall and the number claiming benefits rising.

Cutting the deficit became the new priority of many governments, including the UK's Coalition government formed in 2010. In the UK, as illustrated in Figure 16.3 on page 502, the government's deficit had now reached in excess of 10 per cent of GDP. Consequently, in a short space of time the UK witnessed a fiscal policy yo-yo with fiscal austerity (spending cuts and tax rises) replacing fiscal loosening.

This was not confined to the UK. In the eurozone the **sovereign debt crisis** became so serious that Greece, Portugal, Ireland and later Cyprus had to receive bailouts from European funds and the IMF. In return they were obliged to agree to severe fiscal austerity measures.

Debates over policy. In the light of this turmoil, debates re-emerged amongst academics and policy makers over the economic costs of fiscal deficits and of public expenditure crowding out private expenditure. In effect, we were witnessing a re-run of some the debates of the 1920s and 1930s between classical and Keynesian economists (see pages 496–7).

Those on the political left took a more Keynesian line, believing that cutting the deficit too quickly would endanger the economic recovery, with private-sector demand unable to offset the cuts to public expenditure.

Those on the political right argued in favour of rapid deficit reduction. Without this, they claimed, there would be upward pressure on interest rates as the confidence in the government's finances was undermined and as the public sector competed with the private sector for scarce resources. This was the line taken in the UK by the Coalition government.

Debates about the state of macroeconomics

While the financial crisis raised debates amongst academics and policy makers about its causes and its remedies, it also fuelled a debate about the state of macroeconomics. The new mainstream consensus came under scrutiny. We have

seen how this consensus brought together ideas from different schools of thought and, in particular, from new classical and new Keynesian economists.

However, it is important to recognise that the views of macroeconomists in relation to key issues, particularly the flexibility of prices, the role of expectations, the impact of changes in aggregate demand on economic activity and the role of government policy (see section 16.2), tend to fall along a spectrum, rather than being in some very specific camp.

At one end of the *spectrum of views* are those who see the free market as working well and who generally blame macro-economic problems on excessive government intervention. At the other are those who see the free market as fundamentally flawed.

Then there are economists who were never party to the consensus. In particular, objections were raised by a group of Keynesians who have become known as **post-Keynesians**. They highlight some of the key features of Keynes' *General Theory* to explain why economies are not self-correcting. In particular, they stress the importance of what Keynes called 'animal spirits', or what is today known as sentiment or confidence. Changes in confidence can have fundamental effects on the behaviour of economic agents. For instance, the mood of the country's business community can be crucial in determining firms' investment and output decisions. Without appropriate demand-management policy, this mood can remain depressed into the long term.

Post-Keynesians and other **heterodox economists** also challenge most of the microeconomic assumptions on which other more 'mainstream' macroeconomic theories are based. Firms, for example, are not cold, rational profit maximisers, making calm calculations based on marginal analysis. Instead, firms make output decisions largely in response to anticipated demand, again based on their *confidence* in their market. The result is that anticipated demand changes are likely to lead to *output* and *employment* changes, not price changes.

Post-Keynesians tend to focus on a country's *institutions* and *culture* to explain how firms and consumers respond to economic stimuli. In other words, they try to base their explanations and policies on real-world institutional and behavioural information rather than on abstract models.

Definitions

Sovereign debt crisis The financial and economic problems caused by excessive public-sector debt and by the fear that governments will be unable to raise sufficient finance to repay maturing debt.

Post-Keynesians Economists who stress the importance of institutional and behavioural factors, and the role of confidence in explaining the state of the economy. They

argue that firms are more likely to respond to changes in demand by changing output rather than prices.

Heterodox economists Economists who reject the assumptions of neoclassical economics, in particular the assumptions of rational optimising behaviour. They highlight the importance of institutional behaviour and factors influencing human behaviour.

Two economists disagree over what would have been the best way of tackling the problem of unemployment arising from the credit crunch and recession. For what reasons might they disagree? Are these reasons positive or normative?

Emergence of a new consensus?

While some groups, including post-Keynesians, have consistently voiced their concerns about the new consensus, a more broad-based debate began to develop in the aftermath of the financial crisis. The debate extended to the macroeconomics curriculum being taught in universities. Conferences and working parties have considered both what should be taught and how it should be taught.

Problems with relying on micro foundations

One concern is the extent to which the new consensus had focused too heavily on developing microeconomic foundations and thereby applying a 'bottom-up' approach to analysing macroeconomic aggregates. In the process, often very technical and mathematical models emerged. These were based on the assumption that people typically behave rationally – known as representative agents with rational expectations. Some economists note that the acronym spelt out by 'representative agents with rational expectations' is RARE! This is a reminder of the importance of the behavioural assumptions we attach to economic agents in our economic models.

Another issue with a purely 'bottom-up' approach to macroeconomic analysis is the fallacy of composition. We first came across this in Chapter 3 (see page 97) in the context of poor harvests. When one farmer alone has a poor harvest their own revenue falls, but if all farmers have poor harvests total revenue may well rise. More generally, what applies in one case does not necessarily apply when repeated in all cases. This is important in macroeconomics because we are analysing aggregates. For this reason the fallacy of composition is also known as the *paradox of aggregates*.

The paradox of thrift. The most commonly cited paradox of aggregates is the paradox of thrift (see Box 16.5). If just a few individuals increase their propensity to save, their saving increases and they can consume more in the future. However, if this is repeated across all individuals, it can lead to a fall in aggregate saving because the fall in consumption causes firms to produce less, which reduces national income.

The example of the paradox of thrift illustrates the importance, when building macroeconomic models, of taking into account not only how individuals behave but how they *interact*. Consequently, it also illustrates how aggregate or group behaviour impacts on individual behaviour and well-being.

A contemporary example of the paradox of thrift is the attempt by economic agents to improve their financial well-being following the financial crisis. To reduce their debts many people cut back on their spending. The general effect

Definitions

Paradox of debt (or paradox of deleveraging) The paradox that one individual can increase their net worth by selling assets, but if this is undertaken by a large number of people aggregate net worth declines because asset prices fall.

Downward causation The name given to the impact on individual behaviour or well-being of aggregate or group effects. This is an example of cumulative causation (Threshold Concept 15, page 535).

of this was a decline in sales, output and jobs. Additionally, people sought to sell assets, such as property and shares. However, because large numbers of people looked to do likewise, the value of property, shares and other assets fell. Therefore, rather than individuals seeing their net worth increase as they sold assets, group behaviour resulted in the aggregate net worth of economic agents actually falling. For this reason it is known as the *paradox of debt*.

The paradox of thrift and the paradox of debt are illustrations of what, in this context, is known as *downward causation*: group behaviour affects individual behaviour and well-being.

The importance of the financial sector

Unsurprisingly, given the financial crisis, there has been a keen debate around the assumptions made about the financial system in economic models. Financial frictions and imperfections had been incorporated in new consensus models, albeit to varying degrees. However, the financial crisis illustrates the importance of the *behavioural assumptions* we make about financial institutions and the way in which we model their *interaction* with other economic agents. Financial institutions need to be both fully and appropriately incorporated in macroeconomic models. As the financial crisis showed, the behaviour of financial institutions can be acutely destabilising.

Areas of general agreement?

As we have seen, the financial crisis and its aftermath have re-energised long-standing macroeconomic debates, while also fuelling important debates about the state of macroeconomics in the 2010s. Nonetheless, we can attempt to identify some general points of agreement that have emerged in recent years, at least among the majority of economists.

- In the short run, changes in aggregate demand can have a significant effect on output and employment. If there is a collapse in demand, as in 2008, governments and/or central banks should intervene through expansionary fiscal and/or monetary policies. Only a few extreme new classical economists would disagree with this proposition.

BOX 16.5 THE PARADOX OF THRIFT

EXPLORING
ECONOMICS

When prudence is folly

The classical economists argued that saving was a national virtue. More saving would lead via lower interest rates to more investment and faster growth. Keynes was at pains to show the opposite. Saving, far from being a national virtue, could be a national vice.

Remember the fallacy of composition (see Box 3.5 on page 97). Just because something is good for an individual, it does not follow that it is good for society as a whole. This fallacy applies to saving. If individuals save more, they will increase their consumption possibilities in the future. If society saves more, however, this may *reduce* its future income and consumption. As people save more, they will spend less. Firms will thus produce less. There will thus be a multiplied *fall* in income. The phenomenon of higher saving leading to *lower* national income is known as 'the paradox of thrift'.

But this is not all. Far from the extra saving encouraging more investment, the lower consumption will *discourage* firms from investing. There will then be a further multiplied fall in national income.

The paradox of thrift had in fact been recognised before Keynes, and Keynes himself referred to various complaints

about 'underconsumption' that had been made back in the sixteenth and seventeenth centuries:

In 1598 Laffemas . . . denounced the objectors to the use of French silks on the grounds that all purchasers of French luxury goods created a livelihood for the poor, whereas the miser caused them to die in distress. In 1662 Petty justified 'entertainments, magnificent shews, triumphal arches, etc.', on the ground that their costs flowed back into the pockets of brewers, bakers, tailors, shoemakers and so forth . . . In 1695 Cary argued that if everybody spent more, all would obtain larger incomes 'and might then live more plentifully'.¹

But despite these early recognitions of the danger of underconsumption, the belief that saving would increase the prosperity of the nation was central to classical economic thought.

When is an increase in saving desirable?

1 J. M. Keynes, *The General Theory of Employment, Interest and Money* (Macmillan, 1967), pp. 358–9.

- In the long run, changes in aggregate demand will have much less effect on output and employment and much more effect on prices. In fact, many economists say that there will be no effect at all on output and employment, and that the whole effect will be on prices. There is still a substantial body of Keynesians, however, especially post-Keynesians, who argue that changes in aggregate demand will have substantial effects on long-term output and employment via changes in investment and hence in potential output.
- There is no simple long-run trade-off between inflation and unemployment. There is still disagreement, however, as to whether there is no relationship between them at all (i.e. the long-run Phillips curve is vertical), or whether they are connected indirectly via the long-term effects of changes in aggregate demand, for example, on investment or the overall skillset of a country's workforce.
- Expectations have an important effect on the economy. There is still disagreement, however, as to whether it is people's expectations of price changes or of output changes that are more important. Also, it is difficult to model people's expectations when these can so easily be affected by random shocks; and where optimism can sometimes build in a burst of 'irrational exuberance' or pessimism descend in a cloud of despondency, while at other times optimism or pessimism can quickly fade.
- Excessive growth in the money supply will lead to inflation. Some economists argue that the quantity theory of money holds in the long run (i.e. that inflation is entirely due to increases in the money supply). Others argue that the relationship is more general. Nevertheless, the consensus is that governments should avoid allowing the money supply to grow too rapidly.
- Controlling inflation through control of the money supply, however, is difficult, since money supply itself is not easy to control. Even if it were possible to control money supply accurately, there is a time lag between changes in money supply and the resulting changes in inflation. This makes a precise control of inflation by this means very difficult. Most economists, therefore, argue that it is easier to control inflation by controlling interest rates, since this directly affects aggregate demand. Most central banks around the world today therefore use interest rate changes to achieve a target rate of inflation.
- If the economy is in deep recession, most economists agree that it may be necessary to expand the money supply, rather than relying on cuts in interest rates. However, monetary expansion (known as 'quantitative easing') does not directly affect spending. Banks have to be willing to lend the extra money and individuals and firms have to be willing to borrow and spend it.
- Macroeconomic policy should not focus exclusively on the demand side. Long-term growth depends primarily

on changes in supply (i.e. in potential output). It is important, therefore, for governments to develop an effective supply-side policy if they want to achieve faster economic growth. There is still disagreement, however, over the forms that supply-side policy should take: should it focus on freeing up the market, or should it focus on various forms of government intervention to compensate for market deficiencies?

- Governments' ability to control their country's macroeconomic destiny is being increasingly eroded by the process of globalisation. As countries become more and more interdependent, and as capital moves more and more freely around the globe, so there is a growing need for co-ordinated policies between governments to tackle problems of global recessions or excessive exchange rate fluctuations. This lesson was brought home in 2008, when it became obvious that most countries were experiencing a collapse in aggregate demand following the

banking crisis and the credit crunch. Leaders discussed common policy approaches at several international summits, including both bank rescue packages and expansionary fiscal and monetary policies.

It is perhaps too soon to say, particularly in the aftermath of the economic and financial crisis of 2007–9 and in the more recent rise in populism and the questioning of 'establishment' ideas, what the future holds for the mainstream macroeconomic consensus. Nevertheless, economists are actively debating developments in the subject and what should be in the university macroeconomic curriculum.

As the book progresses, we will be looking at the various areas of agreement and disagreement in more detail. One thing is certain: these are incredibly fascinating times to be studying macroeconomics.

Section summary

1. During the 1990s a new mainstream consensus began to develop. It drew ideas principally from the new classical and new Keynesian schools. Central to most new consensus models are representative forward-looking economic agents who form rational expectations.
2. Dynamic stochastic general equilibrium (DSGE) models became the standard models of the economy. These allowed economists to examine the impact of frequent economic shocks under certain assumptions about competition in product and labour markets and the speed with which these markets adjust to equilibrium.
3. There are many shades of opinion among economists, from extreme new classical economists who advocate almost complete laissez-faire to post-Keynesian and heterodox economists who focus much more on individual and institutional behaviour and who see markets as having many failings. In between comes a whole spectrum of opinions and theories about the relative effectiveness of markets and the government in achieving the various macroeconomic goals.
4. The financial crisis and its aftermath reignited long-standing debates about policy, while also fuelling debates about the state of macroeconomics. Key concerns included the importance that had been placed on developing models with microeconomic foundations, the appropriateness of the behavioural assumptions of economic agents and assumptions made around the role of the financial system.
5. Despite these disagreements, most economists would agree on the following points: changes in aggregate demand have a direct effect on output and employment in the short run, but either no effect or a far less certain effect in the long run; there is no simple long-run trade-off between inflation and unemployment; expectations have an important effect on the economy, but can be affected in ways that are not easy to predict; excessive growth in the money supply causes inflation; it is easier to achieve inflation targets by controlling interest rates than by controlling money supply; monetary expansion is an important policy tool in tackling recession; changes on the supply side of the economy are the major determinant of long-term growth; globalisation reduces individual countries' ability to control their economies.

END OF CHAPTER QUESTIONS

1. In a given economy, the supply of money is £10 billion; the velocity of circulation of money (spent on final goods and services) is 3; and the price index is 2.00.
 - (a) What is the level of real national income?
 - (b) How much have prices risen (in percentage terms) since the base year?
 - (c) Assume that money supply increases by 10 per cent and that the velocity of circulation remains constant. By what percentage will prices rise if
 - (i) there is no increase in real national income;
 - (ii) real national income increases by 10 per cent;
 - (iii) real national income increases by 5 per cent?
2. In what way will the nature of aggregate supply influence the effect of a change in aggregate demand on prices and real national income?
3. Criticise the classical theory that higher government spending will necessarily crowd out private spending.
4. Criticise the use of increasing government expenditure as a means of reducing unemployment.
5. In what way may short-term demand-management policies help to stabilise the economy? What problems occur in the use of such policies?
6. What explanations can you give for the increase in *both* unemployment and inflation in the 1970s?
7. What do you understand by the policy ineffectiveness proposition? On what assumptions is the proposition based?
8. Identify a series of possible frictions which could affect the speed with which markets adjust or which affect the nature of market equilibria.
9. What is meant by *hysteresis* when applied to unemployment? How do you account for this phenomenon in the 1980s?
10. What will cause people to expect higher rates of inflation? How will expectations of inflation affect the actual rate of inflation?
11. Explain how pro-cyclical lending criteria applied by financial institutions could amplify fluctuations in real GDP.
12. What is meant by the paradox of aggregates? Of what importance might they be for how we analyse macroeconomic problems?

We now build on the foundations of Part E. We will see why economies grow over the longer term but fluctuate in the short term and what governments can do to prevent these fluctuations.

In the following three chapters, we look at what determines the level of national income and the role that money plays in the process. Then, in Chapters 20 and 21 we look at the relationship between inflation and unemployment. In Chapter 22, we look at government policy to stabilise the economy. Finally, in Chapter 23, we turn to the long run and ask how economies can sustain faster growth.

In this chapter we look at the determination of national income, employment and inflation in the short run: i.e. over a period of up to around two years. The analysis is based on the model developed by Keynesians. Although many economists argue that this is not appropriate for analysing the performance of the macroeconomy over the longer term, most agree that the analysis is essentially true over the short term.

The model assumes that aggregate demand determines the level of economic activity in the economy. In other words, the nation's production and employment depend on the amount of spending. Too little spending will lead to unemployment. More spending will stimulate firms to produce more and employ more people. Too much spending, however, will cause inflation. This chapter examines this relationship between aggregate demand and national income (GDP), employment and inflation.

One important simplifying assumption is made: the rate of interest is fixed. This allows us for the time being to ignore what is happening to the amount of money in the economy. A fixed interest rate effectively means that the supply of money will passively rise or fall as aggregate demand rises or falls. In other words, if spending rises and hence the demand for money from the banking system also rises, there will be a corresponding increase in the amount of money made available and hence no need for interest rates to rise. In subsequent chapters, we will drop this assumption and take specific account of the role of money in the economy.

17.1 BACKGROUND TO THE THEORY

The relationship between aggregate demand and national income

This chapter explains what determines the level of national income (GDP) in the short run. It is based on the model developed by John Maynard Keynes, back in the 1930s (see Case Study 16.6 on the student website).

The basic explanation is quite simple: the level of production in the economy depends on the level of aggregate demand. If people buy more, firms will produce more in response to this, providing they have spare capacity. If people buy less, firms will cut down their production and lay off workers. But just *how much* will national income rise or fall as aggregate demand changes? We will answer this as the chapter progresses.

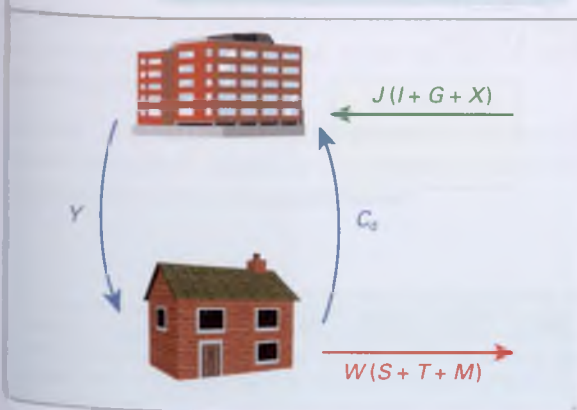

First, let us return to the circular flow of income that we looked at in Chapter 15. This is illustrated in Figure 17.1. Looking at the bottom of the diagram, the consumption of domestically produced goods (C_d) and the three withdrawals (W) – net saving (S), net taxes (T) and spending on imports (M) – all depend on the level of national income (Y). In fact, in the model, national income must always equal consumption of domestic goods plus withdrawals: there is nothing else people can do with their incomes!

$$Y \equiv C_d + W$$

Moving now to the top part of Figure 17.1, total spending in the economy on the goods and services of domestic firms is what we have already defined as aggregate demand (AD). In the Keynesian model that we are examining in this chapter, it is normally referred to as *aggregate expenditure* (E). Aggregate expenditure consists of C_d plus the three injections (J): investment in the domestic economy (I), government purchases in the domestic economy (G) and expenditure from abroad on the country's exports (X).

$$AD \equiv E \equiv C_d + J$$

Figure 17.1 A simplified circular flow of income model

In equilibrium, withdrawals equal injections. (We demonstrated this in Chapter 15.) Since national income (Y) is simply withdrawals plus C_d , and aggregate expenditure (E) is simply injections plus C_d , it follows that in equilibrium national income must equal aggregate expenditure. To summarise:

$$\begin{aligned} W &= J \\ \therefore C_d + W &= C_d + J \\ \therefore Y &= E (= AD) \end{aligned}$$

Whenever aggregate expenditure ($C_d + J$) exceeds national income ($C_d + W$), injections will exceed withdrawals. Firms will respond to the extra demand by producing more and hence employing more factors of production. National income will thus rise. But as national income rises, so too will saving, imports and the amount paid in taxes: in other words, withdrawals will rise. Withdrawals will go on rising until they equal injections: until a new equilibrium has been reached. To summarise:

$$J > W \rightarrow Y \uparrow \rightarrow W \uparrow \text{ until } W = J$$

But *how much* will national income rise when aggregate demand (expenditure) rises? What will the new equilibrium level of national income be? To answer this question we must examine the relationship between national income and the component parts of the circular flow of income: consumption, withdrawals and injections. This relationship is shown in the Keynesian '45° line diagram'.

Introducing the Keynesian 45° line diagram

In this model, it is assumed that the levels of consumption and withdrawals are determined by the level of national income. Since national income is part of the model, we say that consumption and withdrawals are *endogenous*. This means that they vary with one of the other components of the model (i.e. income). Injections, however, are assumed to be *exogenous*: they are determined independently of what is going on in the model; they *do not* depend on the level of national income.

We will justify these assumptions later. First we must look at how the diagram is constructed, and at the

Definitions

Aggregate expenditure (E) Aggregate demand in the Keynesian model: i.e. $C_d + J$.

Endogenous variable A variable whose value is determined by the model of which it is part.

Exogenous variable A variable whose value is determined independently of the model of which it is part.

significance of the 45° line, which is shown in Figure 17.2. We plot real national income (i.e. national income matched by output) on the horizontal axis, and the various component parts of the circular flow (C_d , W and J) on the vertical axis. If the two axes are plotted to the same scale, then at every point on the 45° line the items on each axis are equal.

But what items on the vertical axis will always equal national income (Y), which is plotted on the horizontal axis? The answer is $C_d + W$, since, by definition, $Y = C_d + W$. For example, if Y were £100 billion, then $C_d + W$ must also be £100 billion (see Figure 17.2).

We turn now to look at each of the components of the circular flow and see how they fit into the 45° line diagram.

Consumption

We will need to distinguish total consumption (C) from that part of consumption that goes purely on the output of domestically produced goods (C_d). C_d excludes expenditure taxes (e.g. VAT) and expenditure on imports.

We start by looking at *total* consumption.

The consumption function

As national income increases, so does consumption. The reason is simple: if people earn more, they can afford to spend more. The relationship between consumption and income is expressed by the **consumption function**:

$$C = f(Y)$$

It can be shown graphically on the 45° line diagram (see Figure 17.3 which is based on Table 17.1). The consumption function slopes upwards. This illustrates that, as national income rises, so does consumption. To keep the analysis simple, the consumption function is drawn as a straight line.

At very low levels of income, the consumption function will lie above the 45° line. When a nation is very poor, most people may be forced to spend more than they earn merely to survive. They usually do this by borrowing or drawing on savings. Above a certain level of income, however (£500 billion in Figure 17.3), the consumption function will lie

Figure 17.2 The 45° line

800	740
900	820
1000	900
1100	980

below the 45° line. People will spend less than they earn. The remainder will go on saving and taxes.

The higher the level of national income, the smaller the proportion that will be consumed: people can afford to save proportionately more, and will have to pay proportionately more in taxes. It follows that the slope of the consumption function is less than that of the 45° line.

The marginal propensity to consume. The slope of the consumption function is given by the **marginal propensity to consume**. This is the proportion of any increase in national income that goes on consumption.¹ In Table 17.1, for each £100 billion rise in national income there is an £80 billion rise in consumption. Thus the marginal propensity to consume is £80 billion/£100 billion = 80/100 or 4/5 or 0.8. The formula is

$$mpc = \Delta C / \Delta Y$$

In Figure 17.3, the consumption function is a straight line: it has a *constant* slope, and hence the *mpc* is also constant.

? *It is possible that as people get richer they will spend a smaller and smaller fraction of each rise in income (and save a larger fraction). Why might this be so? What effect will it have on the shape of the consumption function?*

The other determinants of consumption

Of course, people's incomes are not the only determinants of the amount they consume. There are several other determinants.

Taxation. The higher the level of income taxes, the less will people have left to spend out of their gross income: consumption depends on **disposable income**.

¹ The *mpc* is normally defined as the proportion of a rise in *disposable* national income that goes on consumption, where disposable income is income *after* taxes. By defining it the way we have done (i.e. as the proportion of *gross* income that goes in consumption), the analysis is simpler. The conclusions remain the same.

Expected future incomes. Many people take into account both current and expected future incomes when planning their current and future consumption. You might have a relatively low income when you graduate, but can expect (you hope!) to earn much more in the future.

You are thus willing to take on more debts now in order to support your consumption, not only as a student but shortly afterwards as well, anticipating that you will be able to pay back these loans later. It is similar with people taking out a mortgage to buy a house. They might struggle to pay the interest at first, but hope that this will become easier over time.

In fact, the financial system (such as banks and building societies) plays an important part in facilitating this **smoothing of consumption** by households. You can look to borrow or draw on accumulated savings from the past when your current income is low. The hope is that you can then pay back the loans or replenish your savings later on when your income is higher. Therefore, the financial system can provide households with greater flexibility over when to spend their expected future incomes.

The financial system and attitudes of lenders. The financial sector provides households not only with longer-term loans but also short-term credit. This short-term credit enables transactions to take place by bridging short-term gaps between income and expenditure. This helps to explain why short-term rates of change in household spending, say from one quarter of the year to the next, are often less variable than those in disposable income.

But financial institutions can affect the growth in consumption if their ability and willingness to provide credit changes. The global financial crises of the second half of the 2000s saw credit criteria tighten dramatically. A tightening of credit practices, such as reducing overdraft facilities or reducing income multiples (the size of loans made available relative to household incomes), tends to weaken consumption growth. This is because the growth of consumption becomes more dependent on the growth of current incomes. Consequently, there is a growth in the number of **credit-constrained households**.

Definitions

Marginal propensity to consume The proportion of a rise in national income that goes on consumption:

$$mpc = \Delta C / \Delta Y.$$

Disposable income Household income after the deduction of taxes and the addition of benefits.

Consumption smoothing The act by households of smoothing their levels of consumption over time despite facing volatile incomes.

Credit-constrained households Households which are limited in their ability to borrow against expected future incomes.

In contrast, a relaxation of lending practices, as seen in many countries during the 1980s, can strengthen consumption growth. This allows households more readily to borrow against future incomes: there are fewer credit-constrained households.

Changes in interest rates can affect household spending by affecting how expensive loans are to 'service'. **Debt-servicing costs** are the costs incurred in repaying the loans and the interest payments on the loan. Where the rate of interest on debt is variable, any changes in interest rates affect the cost of servicing the debt. This can be especially important for mortgages. In the UK, where a large proportion of mortgage-payers are on a variable mortgage rate, changes in mortgage rates can have a sizeable impact on their debt-servicing costs. This then has significant implications for the proportion of income that a household needs to set aside to pay the mortgage.

Wealth and household sector balance sheets. By borrowing and saving, households accumulate financial liabilities (debts), financial assets (savings) and physical assets (mainly property). The household sector's *financial* balance sheet details the sector's holding of financial assets and liabilities, while its *capital* balance sheet details its physical assets. Its balance of financial assets over liabilities is the household sector's net *financial wealth*. The household sector's *net worth*, as recorded in the capital balance sheet, is the sum of its net financial wealth and its physical wealth.

Changes on the household sector's balance sheets affect the sector's financial health – sometimes referred to as its level of *financial distress*. Such changes can significantly affect short-term prospects for household spending. For instance, a declining net worth to income ratio is an indicator of greater financial distress. This could be induced by falling house prices or falling share prices. In response to this, we might see the sector engage in *precautionary* or *buffer-stock* saving. Such saving is a means by which households build up a buffer stock of wealth which acts as a form of insurance or protection. Alternatively, households may look to repay some of their outstanding debt.

Therefore, the impact of worsening household balance sheets may be to weaken spending, while improvements on the balance sheets may strengthen the growth of consumption. Household balance sheets are discussed in Box 17.2.

Consumer sentiment. If people are uncertain about their future income prospects, or fear unemployment, they are likely to be cautious in their spending. Surveys of consumer confidence are closely followed by policy makers (see Box 17.3) as an indicator of the level of future spending.

Expectations of future prices. If people expect prices to rise, they tend to buy durable goods such as furniture and cars before this happens.

The distribution of income. The poor have a higher *mpc* than the rich, with very little left over to save. A redistribution of national income from the poor to the rich will therefore tend to reduce the total level of consumption in the economy.

Tastes and attitudes. If people have a 'buy now, pay later' mentality, or a craving for consumer goods, they are likely to have a higher level of consumption than if their tastes are more frugal. The more 'consumerist' and materialistic a nation becomes, facilitated by the financial system, the higher will its consumption be for any given level of income.

The age of durables. If people's cars, carpets, clothes, etc., are getting old, they will tend to have a high level of 'replacement' consumption, particularly after a recession when they had cut back on their consumption of durables. Conversely, as the economy reaches the peak of the boom, people are likely to spend less on durables as they have probably already bought the items they want.

Movements along and shifts in the consumption function

The effect on consumption of a change in national income is shown by a movement *along* the consumption function. A change in any of the other determinants is shown by a *shift* in the consumption function.

What effect will the following have on the *mpc*: (a) the rate of income tax rises; (b) the economy begins to recover from recession; (c) people anticipate that the rate of inflation is about to rise; (d) the government redistributes income from the rich to the poor? In each case sketch what would happen to the consumption function.

Long-run and short-run consumption functions

The long-run consumption function is likely to be steeper than the short-run one (see Figure 17.4).

In the short run, people may be slow to respond to a rise in income. Perhaps they are cautious about whether their higher income will last, or are slow to change their consumption habits. In the short run, then, people may have a relatively low *mpc*. In the long run, however, people have time to adjust their consumption patterns.

Assuming that national income rises over time, the long-run consumption function will be intersected by a series of short-run ones. Each year's short-run function will be above the previous year's.

Which is likely to show the greater variation from one person to another at any given level of income: the short-run *mpc* or the long-run *mpc*?

Definition

Debt-servicing costs The costs incurred when repaying debt, including debt interest payments.

Figure 17.4 Long-run and short-run consumption functions

Consumption of domestically produced goods (C_d)

The parts of consumption that go on imports and indirect taxes constitute withdrawals from the circular flow of income and thus do not contribute to aggregate demand. We shall concentrate on the part of consumption that *does*: namely, the consumption of domestic product (C_d). The C_d function lies below the C function, as in Figure 17.5. The gap between them constitutes imports of consumer goods and indirect taxes.

Withdrawals

All three withdrawals – net saving, net taxes and import expenditure – depend on the level of national income. They are thus all *endogenously* determined within the model.

Net saving

As with consumption, the major determinant of net saving (i.e. saving minus consumer borrowing and drawing on past savings) is income. As income increases, and a decreasing fraction of it goes on consumption, so an increasing fraction of it will be saved. The rich can afford to save a larger proportion of their income than the poor.

The proportion of an increase in national income that is saved is given by the *marginal propensity to save* (mps).

$$mps = \Delta S / \Delta Y$$

Other determinants of saving. To a large extent these are the same as the other determinants of consumption, since most things that encourage people to spend more will thereby encourage them to save less.

Definition

Marginal propensity to save The proportion of an increase in national income saved: $= \Delta S / \Delta Y$.

Figure 17.5 The consumption of domestic product

*LOOKING AT THE MATHS

Let us examine the relationship between C and C_d a bit more closely. When people make consumption decisions, this is largely based on their *disposable* income (Y_{dis}), where disposable income is income after the payment of income taxes and the receipt of benefits. We use the term 'net income taxes (T_Y)' to refer to income taxes minus benefits. Thus

$$Y_{dis} = Y - T_Y$$

Also, people tend not to distinguish between domestic goods and imports when they make consumption decisions. Let us then focus on total consumption (C), not just the consumption of domestic products (C_d).

To get a better understanding of people's consumption behaviour, we could express the marginal propensity to consume *all products* (domestic and imported) relative to *disposable* income. Let us call this term mpc' (rather than mpc or mpc_d) where

$$mpc' = \frac{\Delta C}{\Delta Y_{dis}} = \frac{\Delta C}{\Delta Y - \Delta T_Y} \quad (1)$$

To get from C to C_d , we would have to subtract the amount spent on imports (M) and the part of consumer expenditure paid in indirect taxes, such as VAT and excise duties, (T_E). Thus

$$C_d = C - M - T_E \text{ or } C = C_d + M + T_E$$

Thus

$$\Delta C = \Delta C_d + \Delta M + \Delta T_E \quad (2)$$

Substituting equation (2) in equation (1) gives

$$mpc' = \frac{\Delta C_d + \Delta T_E + \Delta M}{\Delta Y - \Delta T_Y} \quad (3)$$

Contrast this with the mpc_d , where

$$mpc_d = \frac{\Delta C_d}{\Delta Y} \quad (4)$$

It might be easy to get the impression that saving is merely what is left over after consumption has taken place. In fact, for many people the decision to save is a purposeful one. For example, they might be saving up for something they are eager to buy but cannot afford at the moment, or they may be saving for retirement. Or, as we saw above (page 524), they may undertake precautionary or buffer stock saving to insure themselves against the possibility of future income loss, such as from unemployment or theft. Indeed, people may be encouraged to save *more* by various factors, such as changes in pension provisions, new government-sponsored saving schemes or uncertainty about the macroeconomic environment.

Go through each of the determinants of consumption that were listed in the previous section and consider how they will affect saving. Are there any determinants of consumption that will not cause saving to rise if consumption is caused to fall?

Net taxes

As national income increases, so the amount paid in tax will also increase. The **marginal tax propensity** (*mpt*) is the proportion of an increase in national income paid in taxes:²

$$mpt = \Delta T / \Delta Y$$

The *mpt* depends on tax rates. In a simple world where there was only one type of tax, which was charged at a constant rate – for example, an income tax of 20 per cent – the *mpt* would be given directly by the tax rate. In this example,

for each extra pound earned, 20p would be paid in income tax. The $mpt = \Delta T / \Delta Y = 20/100 = 0.20$. In practice, of course, there are many types of tax charged at many different rates, and thus working out the *mpt* is more complicated.

In most countries, the *mpt* rises as national income rises. This is because income tax is progressive. At higher incomes, people pay a higher marginal rate of income tax. In the UK and many other countries, however, income tax became much less progressive in the 1980s and 1990s, but the *mpt* remained roughly the same because of rises in indirect taxes.

Imports

The higher the level of national income, the higher will be the amount spent on imports. The **marginal propensity to import** (*mpm*) is the proportion of a rise in national income that goes on imports:

$$mpm = \Delta M / \Delta Y$$

²We have defined net taxes as taxes minus benefits (i.e. the net flow from the household sector to the government). For our purposes, then, the *mpt* is the proportion of any rise in income going in taxes and reduced benefits.

Definitions

Marginal tax propensity The proportion of an increase in national income paid in tax: $= \Delta T / \Delta Y$.

Marginal propensity to import The proportion of an increase in national income that is spent on imports:

$$mpm = \Delta M / \Delta Y.$$

*BOX 17.1 USING CALCULUS TO DERIVE THE MPC

EXPLORING ECONOMICS

The consumption function can be expressed as an equation. For example, the consumption function of Table 17.1 and Figure 17.3 is given by the equation:

$$C = 100 + 0.8Y \quad (1)$$

Try using this equation to derive the figures in Table 17.1.

From this equation we can derive an equation for *mpc*. It is found by differentiating the consumption function. Remember from previous calculus boxes what it is we are doing when we differentiate an equation. We are finding its rate of change. Thus by differentiating the consumption function, we are finding the rate of change of consumption with respect to income. But this is what we mean by the *mpc*.

The difference between using differentiation and the formula $\Delta C / \Delta Y$ is that with the former we are looking at the *mpc* at a single point on the consumption function. With the $\Delta C / \Delta Y$ formula we were looking at the *mpc* between two points.

Differentiating equation (1) gives

$$mpc = dC/dY = 0.8 \quad (2)$$

Note that, since the consumption function is a straight line in this case, the *mpc* (which measures the slope of the consumption function) is constant.

What would we do to find the *mpc* of a non-linear (curved) consumption function? The procedure is the same.

Assume that the consumption function is given by the following equation:

$$C = 250 + 0.9Y - 0.0001Y^2 \quad (3)$$

The *mpc* is given by dC/dY :

$$mpc = 0.9 - 0.0002Y$$

1. First of all, try constructing a table like Table 17.1 and then graph the consumption function that it gives. What is it about equation (3) that gives the graph its particular shape?
2. What are the values of *mpc* at incomes of (a) 200; (b) 1000?
3. What happens to the value of *mpc* as national income increases? Is this what you would expect by examining the shape of the consumption function?

Note that we only count that part of the expenditure on imports that actually goes abroad. Amounts retained by the retailer, the wholesaler and the importer, and amounts paid in indirect taxes, are excluded.

Whether the *mpm* rises or falls as national income rises depends on the nature of a country's imports. If a country imports predominantly basic goods, which have a relatively low income elasticity of demand, the rate of increase in their consumption would tail off rapidly as incomes increase. The *mpm* for such a country would thus also rapidly decrease.

If, however, a country's imports were mainly of luxury goods, they would account for an increasing proportion of any rise in national income: the *mpm* would rise.

? *If a country imports a whole range of goods whose average income elasticity of demand is the same as for home-produced goods, will the mpm rise or fall as national income rises?*

The determinants of the level of imports. Apart from national income, there are a number of other determinants of the level of imports:

- **Relative prices.** If the prices of home-produced goods go up relative to the prices of imports, the level of imports will rise. The rate of exchange is a major influence here. The higher the rate of exchange, the cheaper will imports be and hence the more will be spent on them.
- **Tastes.** If consumer tastes shift towards foreign goods and services, imports will rise. For example, it might become more popular to go abroad for your holidays.
- **Relative quality.** If the quality of foreign goods and services increases relative to that of domestic goods and services, imports will rise.
- **The determinants of consumption.** Since imports of goods and services are part of *total* consumption (as opposed to C_d), the various determinants of consumption that we looked at on pages 522–4 will also be determinants of imports.

The total withdrawals function

Remember that withdrawals consist of the three elements: net saving, net taxes and imports, all of which rise as national income rises. A withdrawals function along with the corresponding consumption of domestic goods function is shown in Figure 17.6.

Note the relationship between the C_d and W curves. The steeper the slope of the one, the flatter the slope of the other. The reason for this is that C_d and W add up to total national income (Y):

$$Y = C_d + W$$

Since the 45° line measures $C_d + W$, the distance between the C_d function and the 45° line must equal withdrawals. Thus at point x , where national income is £100 billion and

Figure 17.6 The W and C_d functions

C_d is £70 billion, W must be £30 billion – the gap between C_d and the 45° line.

The marginal propensity to withdraw

The formula for the *marginal propensity to withdraw* (*mpw*) is as we would expect:

$$mpw = \Delta W / \Delta Y$$

The *mpw* is the slope of the withdrawals function. Note that, since $W = S + T + M$, *mpw* must equal $mps + mpt + mpm$. For example, if for any rise in national income, 1/10 were saved, 2/10 paid in net taxes, and 2/10 spent on imports, then 5/10 must be withdrawn.

Note also that, since $C_d + W = Y$, $mpc_d + mpw$ must add up to 1. For example, if the country spends, say, 3/5 of any rise in income on domestically produced goods, the remaining 2/5 must go on withdrawals.

? *If the slope of the C_d function is 3/4, what is the slope of the W function?*

Injections

In simple Keynesian theory, injections are assumed not to depend on the level of national income: they are *exogenously* determined. This means that the injections function is drawn as a horizontal straight line. Injections will be at a given level irrespective of the level of national income.

Definition

Marginal propensity to withdraw The proportion of an increase in national income that is withdrawn from the circular flow: $mpw = \Delta W / \Delta Y$, where $mpw = mps + mpt + mpm$.

BOX 17.2 THE HOUSEHOLD SECTOR BALANCE SHEETS

Net worth and consumption

Net worth

The national balance sheet details a country's net worth (i.e. wealth). This aggregates the net worth of the household, corporate and public sectors. We consider here the net worth of the household sector and the extent to which this may influence consumption (C).¹ The sector's net worth is the sum of its *net financial wealth* and *non-financial assets*.

- The household sector's net financial wealth is the stock of financial assets minus the stock of financial liabilities. Financial assets include wealth held in savings accounts, shares and pension funds. Financial liabilities include debts secured against property, largely residential mortgages, and unsecured debts, such as overdrafts and unpaid balances on credit cards.
- The stock of non-financial assets largely comprises the sector's residential housing wealth. Therefore, this is affected by changes in house prices.

The table summarises the net worth of the UK household sector. By the end of 2015 the sector had a stock of net worth estimated at £10.20 trillion compared with £2.84 trillion at

the end of 1995 – an increase of 258 per cent. This, of course, is a nominal increase, not a real increase, as part of it merely reflects the rise in asset prices.

To put the size of net worth and its components into context, we can express them relative to annual disposable income or GDP. This shows that the household sector's net worth in 2015 was equivalent to 8.2 times the flow of household disposable income in that year, or 5.4 times GDP. In 1995 it was 5.0 times and 3.4 times respectively.

The ratio of the sector's net worth to disposable income has typically increased year on year. An important factor behind this long-term rise has been the rise of non-financial assets (mainly housing). This increased from £1.26 trillion (219 per cent of disposable income) in 1995 to £4.38 trillion (446 per cent of disposable income) in 2007. It then fell in 2008, the year of the financial crisis, but then rose again each year up to 2015, reaching £5.64 trillion (452 per cent of disposable income).

In contrast, net financial wealth to disposable income has been more volatile, without the marked upward trend seen in non-financial assets. The ratio of net financial wealth to

Summary of household-sector balance sheets, 31 December 1995 and 2015

	1995			2015		
	£ billions	% of disposable income	% of GDP	£ billions	% of disposable income	% of GDP
Financial assets	2 143.8	373.1	256.2	6 310.9	506.2	337.0
Financial liabilities	556.4	96.8	66.5	1 750.9	143.4	93.5
Net financial wealth	1 587.4	276.3	189.7	4 560.0	365.8	243.5
Non-financial assets	1 257.6	218.9	150.3	5 636.7	452.2	301.0
Net worth	2 844.9	495.2	340.0	10 196.7	817.9	544.5

Source: Based on data from *National Balance Sheet* and *Quarterly National Accounts* (National Statistics).

disposable income in 2015, for example, was almost the same as that in 1999. However, this does not mean that the absolute value of financial wealth of the household sector has not risen. In fact, it increased by 188 per cent from 1995 to 2015, though considerably less than the 348 per cent by which net non-financial assets rose. Net worth rose by 258 per cent.

Financial balance sheet

The household sector has experienced significant growth in the size of its financial balance sheet. This is captured by the chart, which shows the components of net financial wealth: financial assets and liabilities.

The ratio of financial liabilities to disposable income rose from 97 per cent in 1995 to 160 per cent in 2007; people were taking on more and more debt relative to their incomes, fuelled by the ease of accessing credit – both consumer credit (loans and credit card debt) and mortgages. Then, in the aftermath of the credit crunch, the ratio began to fall. By 2015 the ratio had fallen to 140 per cent.

The longer-term increase in the sector's debt-to-income ratio up to 2007 meant that interest payments involved increasingly significant demands on household budgets and hence on the discretionary income households had for spending. This is likely to have made the sector's spending more sensitive to changes in interest rates. For example, increases in interest rates can place a substantially larger burden on households, adversely affecting aggregate demand as households curb their expenditures.

Higher debt-to-income levels can also fuel people's concerns about the potential risks arising from debt. If the prospects for income growth are revised down or become more uncertain, people may decide to cut their spending in order to pay off some of their debts.

Non-financial assets

In absolute terms, the financial liabilities of the household sector more than tripled between 1995 and 2015 (see the table). But the long-term accumulation of household debt needs to be seen in the context of the growth in the value of non-financial assets, particularly property. However, while UK house price values have risen by around 10 per cent per annum over the past 50 years, they are very volatile in the short term.

House price volatility is important because it makes the net worth of the household sector volatile too. Furthermore, the impact of house price volatility on net worth has grown. This is because high long-term average rates of growth in house prices have meant that a larger proportion of household sector net worth is now held in property. In 1995, 38 per cent of the household sector's net worth came from the value of dwellings; by 2015 it had risen to 51 per cent.

Volatility in house prices may have the following effects on the spending and saving choices of households:

A precautionary effect. The volatility in net worth from volatile house prices (and potentially the prices of other assets, such as shares) can induce volatility in consumption. If asset prices are falling, households may respond by cutting their spending and increasing saving. This, as we saw on page 524, is a *precautionary or buffer-stock effect*. Conversely, higher asset prices enable households to reduce saving and spend more.

A collateral effect. As house prices rise households' *housing equity* rises, while falling house prices reduce housing equity. Housing equity is the difference between the value of a property and the value of any outstanding loan secured against it. House price movements affect the collateral that households have to secure *additional* lending. They affect the extent to which households are credit constrained.

When house prices are rising it may enable households to borrow resources which can then be used to fund consumption, to purchase other assets (e.g. shares) or to repay other debts. On the other hand, when house prices fall households have less collateral to secure additional resources. They become more credit constrained.

Case Study 17.5 on the student website details the patterns in housing equity withdrawal and consumer spending in the UK.

Draw up a list of the various factors that could affect the household sector's net worth and then consider how these could impact on consumer spending.

¹ The household sector in the official statistics also includes 'non-profit institutions serving households (NPISH)' such as charities, clubs and societies, trade unions, political parties and universities.

BOX 17.3 SENTIMENT AND SPENDING

Does sentiment help forecast spending?

Keynesian economists have frequently pointed to the importance of confidence or sentiment in influencing expenditure decisions. Each month, consumers and firms across the European Union are asked a series of questions, the answers to which are used to compile indicators of consumer and business confidence. For instance, consumers are asked about how they expect both their own financial position and the general economic situation to change over the coming 12 months. For each question, they are offered various options, such as 'get a lot better', 'get a lot worse', and balances are then calculated based on the number of positive and negative replies.¹

Chart (a) plots economic sentiment in the EU across industry as a whole, consumers and the construction industry

since 1990. The chart shows the volatility of economic sentiment. This volatility is more marked amongst businesses than consumers and, in particular, in the construction sector.

Now compare the volatility of economic sentiment in Chart (a) with the annual rates of growth in household consumption and gross capital formation (investment), shown in Chart (b). Capital spending in the EU is significantly more volatile than household spending. Therefore, the extent of the volatility in economic sentiment is reflected in patterns of expenditure.

What is less clear is the extent to which changes in sentiment *lead* to changes in spending. In fact, a likely scenario is that spending and sentiment interact. High rates of spending growth may result in high confidence through

(a) Economic sentiment in the EU

Source: Based on data from *Business and Consumer Surveys* (European Commission, DGECFIN).

The injections function is the vertical addition of the investment, government expenditure and export functions, each of which is a horizontal straight line.

The assumption that injections are independent of national income makes the theory simpler. (It is possible to drop this assumption, however, without destroying the theory.) But is the assumption sufficiently realistic? Let us examine each of the injections in turn.

Investment

There are five major determinants of investment.

Increased consumer demand. Investment is to provide extra capacity. This will only be necessary, therefore, if consumer demand increases. The bigger the increase in consumer demand, the more investment will be needed.

You might think that, since consumer demand depends on the level of national income, investment must too, and

that therefore our assumption that investment is independent of national income is wrong. But we are not saying that investment depends on the *level* of consumer demand; rather it depends on *how much it has risen*. If income and consumer demand are high but *constant*, there will be no point in firms expanding their capacity: no point in investing.

The relationship between investment and *increased* consumer demand is examined by the 'accelerator theory'. We will look at this theory in section 17.4.

Expectations. Since investment is made in order to produce output for the future, investment must depend on firms' expectations about future market conditions.

The cost and efficiency of capital equipment. If the cost of capital equipment goes down or machines become more efficient, the return on investment will increase. Firms will invest more. Technological progress is an important determinant here.

Notes: Figures from 2017 based on forecasts.

Source: Based on data in AMECO Database (European Commission, DGECFIN).

economic growth, which in turn leads to more spending. The reverse is the case when economic growth is subdued: low spending growth leads to a lack of confidence, which results in low spending growth and so low rates of economic growth.

What makes measures of confidence particularly useful is that they are published monthly. By contrast, measures of GDP and spending are published annually or quarterly and with a considerable time delay. Therefore, measures of confidence are extremely timely for policy makers and provide

them with very useful information about the likely path of spending and output growth.

What factors are likely to influence the economic sentiment of (i) consumers; and (ii) businesses? Could the trends in the economic sentiment indicators for consumers and businesses diverge?

1 More information on the EU programme of business and consumer surveys can be found at http://ec.europa.eu/economy_finance/db_indicators/surveys/index_en.htm

The rate of interest. The higher the rate of interest, the more expensive it will be for firms to finance investment, and hence the less profitable will the investment be. Just how responsive total investment in the economy is to changes in interest rates is a highly controversial issue and we will return to it later.

Availability of finance. Investment requires financing. Retained earnings provide one possible source. Alternatively, they could seek finance from banks, or perhaps issue debt instruments, such as bonds, or issue new shares. Therefore, difficulties in raising finance, such as seen in the late 2000s and early 2010s, can limit investment.

So if these are the main determinants of investment, does it mean that investment is totally independent of the level of national income? Not quite. Replacement of worn-out or outdated equipment will depend on the level of national

income. The higher the current level of national income, the greater will be the stock of capital and therefore the more will need replacing each year. It is also possible that, if the level of national income is high and firms' profits are high, they will be able to afford more investment. However, it is not a gross distortion of reality to assume that investment and the level of national income are independent, at least in the short run.

Government purchases

Government spending on goods and services in any year is independent of the level of national income. In the months preceding the Budget each year, spending departments make submissions about their needs in the coming year. These are discussed with the Treasury and a sum is allocated to each department. That then (excepting any unforeseen events) fixes government expenditure on goods and services for the following financial year.

Thus, again, for our purposes we can take government purchases as independent of national income in the short term. Even if tax revenues turn out to be more or less than expected, this will not influence that year's government spending. The government can end up running either a budget surplus ($T = G$) or a budget deficit ($G = T$).

Over the longer term, however, government purchases *will* depend on national income. The higher the level of national income, the higher is the amount of tax revenue that the government receives, and hence the more it can afford to spend. The governments of richer nations clearly spend much more than those of developing countries.

Exports

Exports are sold to people abroad, and thus depend largely on *their* incomes, not on incomes at home. Nevertheless, there are two indirect links between a country's national income and its exports:

- Via other countries' circular flows of income. If domestic incomes rise, more will be spent on imports. But this will

cause a rise in other countries' incomes and lead them to buy more imports, part of which will be this country's exports.

- Via the exchange rate. A rise in domestic incomes will lead to a rise in imports. Other things being equal, this will lead to a depreciation in the exchange rate. This will make it cheaper for people in other countries to buy this country's exports. Export sales will rise.

However, it is useful in simple Keynesian models to assume that exports are determined independently of domestic national income.

Note that, although the injections function is assumed to be constant with respect to income and is drawn as a horizontal straight line, this does not mean that it will be constant *over time*. Investment can suddenly rise or virtually collapse as the confidence of businesspeople changes. Exports can change too with shifts in the exchange rate or with speculation. The injections line, then, is constantly shifting up and down.

Section summary

1. In the simple Keynesian model, equilibrium national income is where withdrawals equal injections, and where national income equals the total expenditure on domestic products: where $W = J$ and where $Y = E$.
2. The relationships between national income and the various components of the circular flow of income can be shown on a 45° line diagram. In such a diagram, C , C_d and W are endogenous variables. Each one rises as income rises. The relationships can also be expressed in terms of marginal propensities. The marginal propensity is given by $\Delta V / \Delta Y$ (where V is the variable in question).
3. Apart from being determined by national income, consumption is determined by wealth, taxation, the availability and cost of credit, expectations about future prices and incomes, the distribution of income, tastes and attitudes, and the average age of durables. Consumption of domestic product (C_d) is total consumption minus imports of goods and services and minus indirect taxes and plus subsidies on goods and services.
4. Like consumption, withdrawals (S , T and M) vary with national income. Net saving is also determined by the various factors that determine consumption: if these factors cause consumption to rise, then, except in the case of a cut in income taxes, they will cause saving to fall and vice versa. Net tax revenues, apart from being dependent on incomes, depend on the rates of tax and benefits that the government sets and how progressive or regressive they are. Imports depend on the relative prices and quality of domestic and foreign goods, total consumption and tastes.
5. In the simple Keynesian model, injections are assumed to be exogenous variables. They are therefore drawn as a horizontal straight line in the 45° line diagram. In practice, there will be *some* relationship between injections and national income. Replacement investment depends to some extent on the level of output; government purchases depend to some extent on the level of tax revenues; and exports depend on exchange rates and foreign incomes, both of which will depend on the level of imports. Nevertheless, in the short run it is reasonable to assume that injections are independent of national income.
6. The determinants of investment include the rate of interest, the size of increases in consumer demand, the cost and efficiency of capital equipment, and expectations about prices, consumer demand, interest rates and other costs.

17.2 THE DETERMINATION OF NATIONAL INCOME

Equilibrium national income

We can now put the various functions together on one diagram. This is done in Figure 17.7. Note that there is a new line on the diagram that we have not looked at so far. This is the aggregate expenditure (i.e. the aggregate demand) function. We defined aggregate expenditure as $C_d + J$. Graphically, then, the E function is simply the C_d function shifted upwards by the amount of J .

Equilibrium national income can be found in either of two ways.

$W = J$

Withdrawals equal injections at point x in Figure 17.7. Equilibrium national income is thus Y_e . If national income were below this level, say at Y_1 , injections would exceed withdrawals (by an amount $a - b$). This additional net expenditure injected into the economy would encourage firms to produce more and hence cause national income to rise. But as people's incomes rose, so they would save more, pay more taxes and buy more imports. In other words, withdrawals would rise. There would be a movement up along the W function. This process would continue until $W = J$ at point x .

If, on the other hand, national income were at Y_2 , withdrawals would exceed injections (by an amount $c - d$). This deficiency of demand would cause production and hence national income to fall. As it did so, there would be a movement down along the W function until again point x was reached.

$Y = E$

If $W = J$, then $C_d + W = C_d + J$. In other words, another way of describing equilibrium is where national income ($Y \equiv C_d + W$) equals aggregate expenditure ($E \equiv C_d + J$).

This is shown at point z in Figure 17.7. This is where the expenditure function ($C_d + J$) crosses the 45° line ($C_d + W$).

If aggregate expenditure exceeded national income, say at Y_1 , there would be excess demand in the economy (of $e - f$). In other words, people would be buying more than was currently being produced. Firms would find their stocks dwindling and would therefore increase their level of production. In doing so, they would employ more factors of production. National income would thus rise. As it did so, consumption and hence aggregate expenditure would rise. There would be a movement up along the expenditure function. But because not all the extra income would be consumed (i.e. some would be withdrawn), expenditure would rise less quickly than income (the E line is flatter than the Y line). As income rises towards Y_e , the gap between Y and E gets smaller. Once point z is reached, $Y = E$. There is then no further tendency for income to rise.

If national income exceeded national expenditure, at say Y_2 , there would be insufficient demand for the goods and services currently being produced. Firms would find their stocks of unsold goods building up. They would thus respond by producing less and employing fewer factors of production. National income would thus fall and go on falling until Y_e was reached.

Why is it the case that $a - b = e - f$, and $c - d = g - h$?

The multiplier: the withdrawals and injections approach

When injections rise (and continue at the higher level), this will cause national income to rise. But by how much?

In fact, national income will rise by *more* than injections: Y rises by a *multiple* of the rise in J .

$$\Delta Y > \Delta J$$

The number of times that the increase in income (ΔY) is greater than the increase in injections (ΔJ) is known as the **multiplier** (k).

$$k = \Delta Y / \Delta J$$

Thus if a £10 billion rise in injections caused a £30 billion rise in national income, the multiplier would be 3.

What causes the multiplier effect? The answer is that, when extra spending is injected into the economy, it will

Definition

(Injections) multiplier The number of times by which a rise in income exceeds the rise in injections that caused it: $K = \Delta Y / \Delta J$.

Figure 17.7 Equilibrium national income

then stimulate further spending, which in turn will stimulate yet more spending and so on. For example, if firms decide to invest more, this will lead to more people being employed and hence more incomes being paid to households. Households will then spend part of this increased income on domestically produced goods (the remainder will be withdrawn). This increased consumption will encourage firms to produce more goods to meet the demand. Firms will thus employ more people and other factors of production. This leads to even more incomes being paid out to households. Consumption will thus increase yet again. And so the process continues.

The multiplier is an example of an important principle in economics: that of **cumulative causation**. This is the last of our 15 threshold concepts.

Note that in this simple Keynesian theory we are assuming that prices are constant (i.e. that there is no inflation) and hence that any increase in income is a *real* increase in income matched by extra production. So when we talk about extra injections into the economy causing extra spending, it is the extra *output* that this spending generates that we are concerned with. If the multiplier were 3, for example, this would mean that an injection of £1 of expenditure into the economy would lead to an increase in *output* of £3.

But even if there were limitless resources, an increase in injections would not cause national income to go on rising for ever: the multiplier is not infinite. Each time people receive extra income, they will save some of it, pay some of it in taxes and spend some of it on imports: in other words, withdrawals will rise. Eventually, as income goes on rising, all the extra injections will have leaked away into the three withdrawals. At that point, the multiplier process will have ceased; a new equilibrium will have been reached.

What determines the size of the multiplier? This can be shown graphically using either withdrawals and injections or income and expenditure. The income/expenditure approach will be examined shortly. For now we will use the withdrawals/injections approach. This is illustrated in Figure 17.8.

Assume that injections rise from J_1 to J_2 . Equilibrium will move from point a to point b . Income will thus rise from Y_{e1} to Y_{e2} . The multiplier is therefore

$$\frac{Y_{e2} - Y_{e1}}{J_2 - J_1} \left(\text{i.e. } \frac{\Delta Y}{\Delta J} \right)$$

It can be seen that the size of the multiplier depends on the slope of the W function. Remember that the slope of the W function is given by the marginal propensity to withdraw ($\Delta W/\Delta Y$). The less steep the line (and hence the lower the mpw), the bigger will be the rise in national income: the bigger will be the multiplier.

? Try this simple test of the above argument. Draw a series of W lines of different slopes, all crossing the J line at the same point. Now draw a second J line above the first. Mark the original equilibrium and all the new ones corresponding

Figure 17.8 The multiplier: a shift in injections

to each of the W lines. It should be quite obvious that the flatter the W line is, the more Y will have increased.

The point here is that the less is withdrawn each time extra income is generated, the more will be recirculated and hence the bigger will be the rise in national income. The size of the multiplier thus varies inversely with the size of the mpw . The bigger the mpw , the smaller the multiplier; the smaller the mpw , the bigger the multiplier. In fact, the **multiplier formula** simply gives the multiplier as the inverse of the mpw :

$$k = 1/mpw$$

or alternatively, since $mpw + mpc_d = 1$ and thus $mpw = 1 - mpc_d$,

$$k = 1/(1 - mpc_d)$$

Thus if the mpw were $1/4$ (and hence the mpc_d were $3/4$), the multiplier would be 4. So if J increased by £10 billion, Y would increase by £40 billion.

But why is the multiplier given by the formula $1/mpw$? This can be illustrated by referring to Figure 17.8. The mpw is the slope of the W line. In the diagram, this is given by the amount $(b - c)/(c - a)$. The multiplier is defined as $\Delta Y/\Delta J$. In the diagram, this is the amount $(c - a)/(b - c)$. But this is merely the inverse of the mpw . Thus the multiplier equals $1/mpw$.³

Definitions

Principle of cumulative causation An initial event can cause an ultimate effect that is much larger.

(Injections) multiplier formula The formula for the multiplier: $K = 1/mpw$ or $1/(1 - mpc_d)$.

³In some elementary textbooks, the formula for the multiplier is given as $1/mps$. The reason for this is that it is assumed (for simplicity) that there is only one withdrawal, namely saving, and only one injection, namely investment. As soon as this assumption is dropped, $1/mps$ becomes the wrong formula.

THRESHOLD CONCEPT 15

CUMULATIVE CAUSATION

THINKING LIKE AN
ECONOMIST

Economic effects can snowball

Once an economy starts to expand, growth is likely to gather pace. Once it starts slowing down, this can gather pace too and end up in a recession. There are many other examples in economics of things getting 'onto a roll'. A rising stock market is likely to breed confidence in investors and encourage them to buy. This 'destabilising speculation' (see pages 72–3) will then lead to further rises in share prices. A fall in stock market prices can lead to panic selling of shares. The booming stock market of the late 1990s and 2003–8, and the falls in the early 2000s and 2008–9 are good examples of this (see chart in Box 2.3 on page 54).

This phenomenon of things building on themselves is known as 'cumulative causation' and occurs throughout market economies. It is a *threshold concept* because it helps us to understand the built-in instability in many parts of the economy and in many economic situations.

Central to explaining cumulative causation is people's psychology. Good news creates confidence and this optimism causes people to behave in ways that build on the good news. Bad news creates pessimism and this leads to people behaving cautiously, which tends to reinforce the bad news.

Take two regions of an economy: an expanding region and a declining region. The expansion of the first region encourages workers to move there in search of jobs. The optimism in the

area causes long-term investment as firms have confidence in an expanding market. This encourages house building and other forms of investment in infrastructure and services. And so the region thrives. Meanwhile, the declining region suffers from deprivation as unemployment rises. This encourages people to move away and businesses to close. There is a further decline in jobs and further migration from the region.

Cumulative causation does not just occur at a macro level. If a company is successful, it is likely to find raising extra finance easier; it may be able to use its power more effectively to out-compete rivals. Giant companies, such as Microsoft, can gain all sorts of economies of scale, including network economies (see Case Study 7.4 on the student website), all of which help the process of building their power base. Success breeds success.

1. How might cumulative causation work at the level of an individual firm that is losing market share?
2. Are there any market forces that work against cumulative causation? For instance, how might markets help to arrest the decline of a depressed region of the economy and slow down the expansion of a booming region?

*LOOKING AT THE MATHS

The multiplier can be expressed as the first derivative of national income with respect to injections.

$$k = \frac{dY}{dJ}$$

Since in equilibrium $J = W$, it is also the first derivative of income with respect to withdrawals. Thus

$$k = \frac{dY}{dW}$$

The marginal propensity to withdraw (i.e. the slope of the withdrawals curve) is found by differentiating the withdrawals function:

$$mpw = \frac{dW}{dY} = \frac{1}{k}$$

Thus

$$k = \frac{1}{mpw}$$

The algebra of the multiplier is explored in Maths Case 17.1 on the student website, which does not use calculus, and Maths Case 17.2, which does.

A shift in withdrawals

A multiplied rise in income can also be caused by a fall in withdrawals. This is illustrated in Figure 17.9.

The withdrawals function shifts from W_1 to W_2 . This means that, at the old equilibrium of Y_{e1} , injections now exceed withdrawals by an amount $a - b$. This will cause national income to rise until a new equilibrium is reached at Y_{e2} where $J = W_2$. Thus a downward shift of the withdrawals function of $a - b$ (ΔW) causes a rise in national income of $c - a$ (ΔY). The multiplier in this case is given by $\Delta Y / \Delta W$:

Figure 17.9 The multiplier: a shift in withdrawals

other words, $(c - a)/(a - b)$. Note that the multiplier is based on the *initial* fall in withdrawals. Once the multiplier effect has worked through, withdrawals will have risen back to equal injections at point *c*.

? Why is the 'withdrawals multiplier' strictly speaking a negative figure?

The multiplier: the income and expenditure approach

The multiplier can also be demonstrated using the income/expenditure approach. Assume in Figure 17.10 that the aggregate expenditure function shifts to E_2 . This could be due either to a rise in one or more of the three injections, or to a rise in the consumption of domestically produced goods (and hence a fall in withdrawals). Equilibrium national income will rise from Y_{e1} to Y_{e2} .

What is the size of the multiplier? The initial rise in expenditure was $b - a$. The resulting rise in income is $c - a$. The multiplier is thus $(c - a)/(b - a)$.

The effect is illustrated in Table 17.2. Consumption of domestic product (C_d) is shown in column 2 for various levels of national income (Y). For every £100 billion rise in Y , C_d

rises by £80 billion. Thus the $mpc_d = 0.8$. Assume initially that injections equal £100 billion at all levels of national income. Aggregate expenditure (column 4) equals $C_d + J$. Equilibrium national income is £700 billion. This is where $Y = E$.

Now assume that injections rise by £20 billion to £120 billion. Aggregate expenditure is now shown in the final column and is £20 billion higher than before at each level of national income (Y). At the original equilibrium national income (£700 billion), aggregate expenditure is now £720 billion. This excess of E over Y of £20 billion will generate extra incomes and continue doing so as long as E remains above Y . Equilibrium is reached at £800 billion, where once more $Y = E$. The initial rise in aggregate expenditure of £20 billion (from £700bn to £720bn) has led to an eventual rise in both national income and aggregate expenditure of £100 billion. The multiplier is thus 5 (i.e. £100bn/£20bn). But this is equal to $1/(1 - 0.8)$ or $1/(1 - mpc_d)$.

- ?**
1. What determines the slope of the E function?
 2. How does the slope of the E function affect the size of the multiplier? (Try drawing diagrams with E functions of different slopes and see what happens when they shift.)

The multiplier: a numerical illustration

The multiplier effect does not work instantaneously. When there is an increase in injections, whether investment, government expenditure or exports, it takes time before this brings about the full multiplied rise in national income.

Consider the following example. Let us assume for simplicity that the mpw is $1/2$. This will give an mpc_d of $1/2$ also. Let us also assume that investment (an injection) rises by £160 million and stays at the new higher level. Table 17.3 shows what will happen.

As firms purchase more machines and construct more factories, the incomes of those who produce machines and those who work in the construction industry will increase by £160 million. When this extra income is received by households, whether as wages or profits, half will be withdrawn ($mpw = 1/2$) and half will be spent on the goods and services of domestic firms. This increase in consumption thus generates additional incomes for firms of £80 million over and above the initial £160 million (which is still being generated

Figure 17.10 The multiplier: a shift in the expenditure function

BOX 17.4 DERIVING THE MULTIPLIER FORMULA

ECONOMICS

An algebraic proof

The formula for the multiplier can be derived using simple algebra. First of all, remember how we defined the multiplier:

$$k = \Delta Y / \Delta J \quad (1)$$

and the marginal propensity to withdraw:

$$mpw = \Delta W / \Delta Y \quad (2)$$

If we now take the inverse of equation (2), we get

$$1/mpw = \Delta Y / \Delta W \quad (3)$$

But in equilibrium we know that $W = J$. Hence any change in injections must be matched by a change in withdrawals and vice versa, to ensure that withdrawals and injections remain equal. Thus

$$\Delta W = \Delta J \quad (4)$$

Substituting equation (4) in equation (3) gives

$$1/mpw = \Delta Y / \Delta J (= k)$$

i.e. the multiplier equals $1/mpw$.

in each time period). When this additional £80 million of incomes is received by households (round 2), again half will be withdrawn and half will go on consumption of domestic product. This increases national income by a further £40 million (round 3). And so each time we go around the circular flow of income, national income increases, but by only half as much as the previous time ($mpc_d = 1/2$).

If we add up the additional income generated in each round (assuming the process goes on indefinitely), the total will be £320 million: twice the rise in injections. The multiplier is 2.

The bigger the mpc_d (and hence the smaller the mpw), the more will expenditure rise each time national income rises, and hence the bigger will be the multiplier.

*The multiplier: some qualifications

(This section examines the multiplier formula in more detail. You may omit it without affecting the flow of the argument.)

Some possible errors can easily be made in calculating the value of the multiplier. These often arise from a confusion over the meaning of terms.

The marginal propensity to consume domestic product

Remember the formula for the multiplier:

$$k = 1/(1 - mpc_d)$$

It is important to realise just what is meant by the mpc_d . It is the proportion of a rise in households' gross (i.e. pre-tax-and-benefit) income that actually accrues to domestic firms. It thus excludes that part of consumption that is spent on imports and that part which is paid to the government in VAT and other indirect taxes.

Up to now we have also been basing the mpc on gross income. As Case Study 17.2 on the student website shows, however, the mpc is often based on *disposable* (i.e. post-tax-and-benefit) income. After all, when consumers decide how much to spend, it is their disposable income rather than their gross income that they will consider. So how do we derive

the mpc_d (based on gross income) from the mpc based on disposable income (mpc')? To do this, we must use the following formula:

$$mpc_d = mpc'(1 - t_E)(1 - t_Y) - mpm$$

where t_Y is the marginal rate of income tax, and t_E is the marginal rate of expenditure tax.

To illustrate this formula consider the following effects of an increase in national income of £100 million. It is assumed that $t_Y = 20$ per cent, $t_E = 10$ per cent and $mpc = 7/8$. It is also assumed that the mps (from gross income) = $1/10$ and the mpm (from gross income) = $13/100$. Table 17.4 sets out the figures.

Gross income rises by £100 million. Of this, £20 million is taken in income tax ($t_Y = 20$ per cent). This leaves a rise in disposable income of £80 million. Of this, £10 million is saved ($mps = 1/10$) and £70 million is spent. Of this, £7 million goes in expenditure taxes ($t_E = 10$ per cent) and £13 million leaks abroad ($mpm = 13/100$). This leaves £50 million that goes on the consumption of domestic product ($mpc_d = 50/100 = 1/2$). Substituting these figures in the above formula gives:

$$\begin{aligned} mpc_d &= mpc(1 - t_E)(1 - t_Y) - mpm \\ &= \frac{7}{8} \left(1 - \frac{1}{10}\right) \left(1 - \frac{2}{10}\right) - \frac{13}{100} \\ &= \left(\frac{7}{8} \times \frac{9}{10} \times \frac{8}{10}\right) - \frac{13}{100} \\ &= \frac{63}{100} - \frac{13}{100} = \frac{50}{100} = \frac{1}{2} \end{aligned}$$

Table 17.4 Calculating the mpc_d

	ΔY	–	ΔT_Y	=	ΔY_{dis}		
(£m)	100		20		80		
	ΔY_{dis}	–	ΔS	=	ΔC		
(£m)	80		10		70		
	ΔC	–	ΔT_E	–	ΔM	=	ΔC_d
(£m)	70		7		13		50

Note that the mpc_d , mps , mpm and mpt are all based on the rise in *gross* income, not *disposable* income. They are 50/100, 10/100, 13/100 and 27/100 respectively.

Maths Case 17.3 on the student website derives the multiplier formula when the propensities to consume, save and import are all based on *disposable* as opposed to *gross* income.

Assume that the rate of income tax is 15 per cent, the rate of expenditure tax is 12.5 per cent, the mps is $\frac{1}{20}$, the mpm is $\frac{1}{8}$ and the mpc (from disposable income) is $\frac{16}{17}$. What is the mpc_d ? Construct a table like Table 17.4, assuming again that national income rises by £100 million.

The effects of changes in injections and withdrawals on other injections and withdrawals

In order to work out the size of a multiplied rise or fall in income, it is necessary to know first the size of the initial *total* change in injections and/or withdrawals. The trouble is that a change in one injection or withdrawal can affect others. For example, a rise in income taxes will reduce not only consumption, but also saving, imports and the revenue from indirect taxes. Thus the total rise in withdrawals will be *less* than the rise in income taxes.

Give some other examples of changes in one injection or withdrawal that can affect others.

Section summary

1. Equilibrium national income can be shown on the 45° line diagram at the point where $W = J$ and $Y = E$.
2. If there is an increase in injections (or a reduction in withdrawals), there will be a multiplied rise in national income. The multiplier is defined as $\Delta Y / \Delta J$.
3. The size of the multiplier depends on the marginal propensity to withdraw (mpw). The smaller the mpw , the less will be withdrawn each time incomes are generated round the circular flow, and thus the more will go round again as *additional* demand for domestic product. The

multiplier formula is $k = 1/mpw$ or $1/(1 - mpc_d)$.

- *4. When working out the size of the multiplier, you must be careful to identify clearly the mpc_d (which is based on *gross* income and only includes expenditure that actually accrues to domestic firms) and not to confuse it with the mpc based on *disposable* income (which includes consumption of imports and the payment of indirect taxes). It is also necessary to identify the *full* changes in injections and withdrawals on which any multiplier effect is based.

17.3 THE SIMPLE KEYNESIAN ANALYSIS OF UNEMPLOYMENT AND INFLATION

'Full-employment' national income

The simple Keynesian theory assumes that there is a maximum level of national output, and hence real income, which can be obtained at any one time. If the equilibrium level of income is at this level, there will be no deficiency of aggregate demand. This level of income is referred to as the **full-employment level of national income**. In practice, there would still be some unemployment at this level because of structural, frictional and seasonal unemployment (see section 15.5).

Governments of the 1950s, 1960s and early 1970s aimed to achieve this full-employment income (Y_f), if inflation and the balance of payments permitted. To do this, they attempted to manipulate the level of aggregate demand.

Many countries around the world in the late 2000s used fiscal and monetary policies to stimulate aggregate demand in an attempt to combat a deepening recession (see Chapter 16 page 512).

The deflationary gap

If the equilibrium level of national income (Y_e) is *below* the full-employment level (Y_f), there will be excess capacity in the economy and hence demand-deficient unemployment.

There will be what is known as a **deflationary** or **recessionary gap**. This is illustrated in Figure 17.11.

Definitions

Full-employment level of national income The level of national income at which there is no deficiency of demand.

Deflationary or recessionary gap The shortfall of national expenditure below national income (and injections).

Figure 17.11 The deflationary (recessionary) gap

The full-employment level of national income (Y_f) is represented by the vertical line. The equilibrium level of national income is Y_e , where $W = J$ and $Y = E$. The deflationary gap is $a - b$: namely, the amount that the E line is below the 45° line at the full-employment level of income (Y_f). It is also $c - d$: the amount that injections fall short of withdrawals at the full-employment level of income.

Note that the size of the deflationary gap is *less* than the amount by which Y_e falls short of Y_f . This provides another illustration of the multiplier. If injections were raised by $c - d$, income would rise by $Y_f - Y_e$. The multiplier is thus given by

$$\frac{Y_f - Y_e}{c - d}$$

In this simple Keynesian model, then, the cure for demand-deficient unemployment is to close the deflationary gap. An increase in aggregate expenditure is needed. This could be achieved by an expansionary *fiscal* policy of increasing government expenditure and/or lowering taxes, or by an expansionary *monetary* policy of reducing interest rates and increasing the amount of money in the economy, thereby encouraging extra consumption and investment. Either way, if the deflationary gap is successfully closed, there will be a multiplied rise in income of $Y_f - Y_e$. Equilibrium national income will be restored to the full-employment level.

The inflationary gap

If, at the full-employment level of (real) income, aggregate expenditure exceeds national income, there will be a problem of *excess demand*. Y_e will be above Y_f . The problem is that Y_f represents a real ceiling to output. In the short run, real national income *cannot* expand beyond this point.⁴ Y_e

Figure 17.12 The inflationary gap

cannot be reached. The result will therefore be demand-pull inflation.⁵

This situation involves an *inflationary gap*. This is the amount by which aggregate expenditure exceeds national income or injections exceed withdrawals at the full-employment level of national income. This is illustrated by the gaps $e - f$ and $g - h$ in Figure 17.12.

To eliminate this inflation, the inflationary gap must be closed by either raising withdrawals or lowering injections, or some combination of the two, until Y_e equals Y_f . A reduction in aggregate expenditure could be achieved through a deliberate government policy of deflation. This could be either a contractionary *fiscal* policy of lowering government expenditure and/or raising taxes, or a contractionary *monetary* policy of raising interest rates and reducing the amount of money in the economy.

Even if the government does not actively pursue a deflationary policy, the inflationary gap may still close *automatically*, though this may take some time. The mechanisms by which this could occur would move the E line down and the J line up and/or the W line up. These include the following:

- Higher domestic prices will lead to fewer exports being sold and more imports being bought in preference to the now dearer home-produced goods. The precise effect will depend on what happens to exchange rates – a subject we explore in Chapter 26.

Definition

Inflationary gap The excess of national expenditure over income (and injections over withdrawals) at the full-employment level of national income.

⁴Note that the horizontal axis in the 45° line diagram represents *real* national income. If incomes were to rise by, say, 10 per cent but prices also rose by 10 per cent, real income would not have risen at all. People could not buy any more than before. In such a case, there will have been no rightward movement along the horizontal axis.

⁵Except with increased overtime working. In this simple model, we assume that this is not possible.

- Higher prices increase the demand for money. The average amount of money that people and firms would need to hold for spending purposes is greater. In the absence of an increase in the money supply, the shortage of money drives up interest rates. This reduces investment and encourages saving.
- Higher prices reduce the real value of people's savings. They may therefore save more to compensate for this.
- As money (nominal) incomes go up, people will tend to find themselves paying higher rates of tax (unless the government increases tax bands and allowances in line with inflation). Hence, higher money incomes lead to increased taxes.
- If the rich are better able than the poor to defend themselves against inflation, there will be a redistribution from the poor to the rich. But the rich tend to have a higher marginal propensity to save (*m_{ps}*) than the poor. Thus saving will rise and consumption will fall.

? The present level of a country's exports is £12 billion; investment is £2 billion; government expenditure is £4 billion; total consumer spending (not C_d) is £36 billion; imports are £12 billion; and expenditure taxes are £2 billion. The economy is currently in equilibrium. It is estimated that an income of £50 billion is necessary to generate full employment. The *m_{ps}* is 0.1, the *m_{pt}* is 0.05 and the *mpm* is 0.1.

- Is there an inflationary or deflationary gap in this situation?
- What is the size of the gap? (Don't confuse this with the difference between Y_e and Y_f .)
- What would be the appropriate government policies to close this gap?

The multiplier and the full-employment level of national income

The simple analysis of the preceding pages implies that up to the full-employment level of national income (Y_f), output and employment can increase with no rise in prices at all. There is no inflation because the economy's deflationary gap is being closed. Hence, increases in aggregate expenditure set in motion the multiplier process resulting in a multiplied increase in real national income.

At Y_f no further rises in output are possible. Any further rise in aggregate demand is entirely reflected in higher prices. An inflationary gap opens. Hence, the additional demand no longer generates an increase in output. There is no increase in real national income because the real value of expenditure has not increased. Additional sums of spending on domestically produced goods and service are purely *nominal* reflecting only higher prices. The volume of purchases and, hence, the level of output is unchanged.

In this simple model, therefore, resource constraints become effective at the full-employment national income

Figure 17.13 Allowing for inflation in the 45° line

level. Up to this point, additional demand generates increases in output without inflation. At the full-employment national income level any further increases in aggregate demand generate only inflation. The multiplier process ceases to operate. We can use the 45° line diagram to illustrate these ideas as shown in Figure 17.13.

Assume that the economy is initially at Y_{e1} where E_1 crosses the 45° line. Now let us assume that there is a rise in aggregate demand. The E line shifts to E_2 resulting in a full multiplied rise in real income. Therefore, equilibrium national income rises to Y_f .

Consider now a further rise in aggregate demand which causes the E line to shift to E_3 . An inflationary gap opens up, illustrated by the gap $e - f$. This time the increase in demand will be reflected only in higher prices with no increase in output. Equilibrium real income will be unchanged. If there is no compensating increase in money supply, the E line will fall back to E_2 . The means by which this happens are those we identified above as the automatic mechanisms that tend to close an inflationary gap.

Unemployment and inflation at the same time

Our simple model implies that either inflation or unemployment can occur, but not both simultaneously. Two important qualifications need to be made to this analysis to explain the occurrence of both unemployment and inflation at the same time.

First, there are *other* types of inflation and unemployment not caused by an excess or deficiency of aggregate demand: for example, cost-push and expectations-generated inflation; frictional and structural unemployment.

Thus, even if a government could manipulate national income so that the equilibrium income level, Y_e , and

full-employment income level, Y_F , coincided, this would not eliminate all inflation and unemployment – only demand-pull inflation and demand-deficient unemployment. Keynesians argue, therefore, that governments should use a whole package of policies, each tailored to the specific type of problem. But certainly one of the most important of these policies will be the management of aggregate demand.

Second, not all firms operate with the same degree of slack. Thus a rise in aggregate demand can lead to *both* a reduction in unemployment *and* a rise in prices: some firms responding to the rise in demand by taking up slack and hence increasing output; other firms, having little or no slack, responding by raising prices; others doing both. Similarly, labour markets have different degrees of slack and therefore the rise in demand will lead to various mixes of higher wages and lower unemployment.

How does the above argument about firms' responses to a rise in demand relate to the shape of their marginal cost curves?

These types of argument were used to justify a belief in a downward-sloping Phillips curve (see Box 15.6) by the majority of economists and politicians in the 1960s and into the 1970s. A modified version of these arguments is still used

today by Keynesian economists. This is examined in more detail in Chapter 21.

The problem is that if there is a trade-off between unemployment and inflation, demand management policies used to make one of the objectives better will succeed only in making the other one worse. It then becomes a matter of political judgement which of the objectives is the right one to direct demand management policies towards. Is *inflation* public enemy number one, or is it *unemployment*?

The multiplier and inflation

We saw earlier how the multiplier process is affected by the constraint posed by the full-employment national income level. We have now introduced the argument that inflation can begin to occur *before* the full-employment level of income is reached. This means that increases in aggregate demand no longer increase real national income by the full extent of the multiplier even before the full-employment output level is reached.

We might expect inflationary pressures to become more significant, and the size of the multiplier to become smaller, the closer the economy is to the full-employment national income level. This is because an increasingly large part of the increase in demand is being reflected in higher prices and a smaller part in higher output.

Section summary

1. If equilibrium national income (Y_e) is below the full-employment level of national income (Y_F), there will be a deflationary (recessionary) gap. This gap is equal to $Y - E$ or $W - J$ at Y_F . This gap can be closed by expansionary fiscal or monetary policy, which will then cause a multiplied rise in national income (up to a level of Y_F) and will eliminate demand-deficient unemployment.
2. If equilibrium national income exceeds the full-employment level of income, the inability of output to expand to meet this excess demand will lead to demand-pull inflation. This excess demand gives an inflationary gap, which is equal to $E - Y$ or $J - W$ at Y_F . This gap can be closed by deflationary policies.
3. This simple analysis tends to imply that aggregate demand can expand up to Y_F without generating inflation. In practice, inflationary pressures are likely to emerge at lower levels of national income, but become more significant as national income approaches its full-employment level. As it does so, resource constraints and bottlenecks are increasingly likely to occur.
4. An initial rise in aggregate demand (and an upward shift in the E curve) will be eroded to the extent that inflation reduces the real value of this demand: the E curve will shift back downwards again somewhat, unless there is a further boost to demand.

17.4 THE KEYNESIAN ANALYSIS OF THE BUSINESS CYCLE

Volatility of aggregate demand

In the previous sections of the chapter we developed the simple Keynesian model. The model shows how fluctuations in aggregate demand can have multiplied effects on output and employment. This is an important insight because we know that economies are inherently volatile. Therefore, Keynesian analysis of the business cycle focuses on fluctuations in aggregate demand.

The instability of aggregate demand, Keynesians argue, is central to explaining the business cycle. In the upturn (phase 1), aggregate demand starts to rise. It rises rapidly in the expansionary phase (phase 2). It then slows down and may start to fall in the peaking-out phase (phase 3). It then falls or remains relatively stagnant in the recession (phase 4) (see Figure 15.5 on page 460).

Keynesians also argue that market imperfections or frictions can magnify the impact of the instability on aggregate

BOX 17.5 ALLOWING FOR INFLATION IN THE 45° LINE DIAGRAM
The relationship between the AD/AS framework and the Keynesian cross

In this box we consider more formally how we can extend the simple Keynesian model to allow for inflation. In other words, the price level is no longer assumed to be constant. Here we introduce a new model: the aggregate demand (AD) and aggregate supply (AS) model. This is a model we develop later (in Chapter 20) and just the bare bones of the model are considered here.

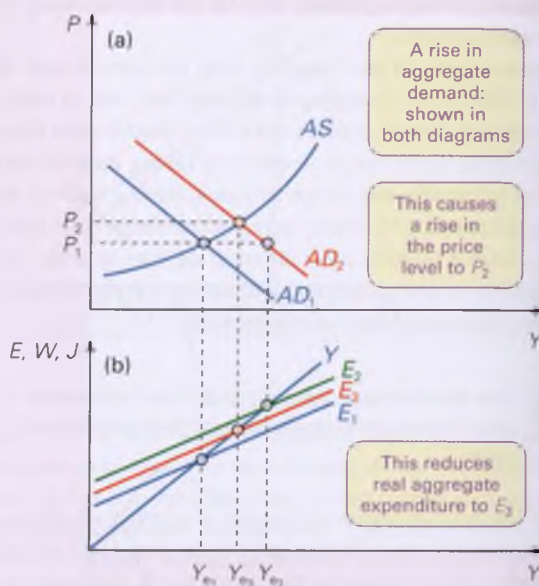

The AD/AS framework enables us to incorporate prices within the context of aggregate demand and aggregate supply. In this box we show the relationship between this framework and the 45° line diagram, known as the 'Keynesian Cross'.

The AD/AS model

Consider the top half of the diagram, part (a). AD_1 and AS are representative aggregate demand and aggregate supply curves. They show how aggregate demand and supply vary with the overall level of prices in the economy (P). The AD curve is downward sloping while the AS curve is upward sloping. But what is the economics behind these curves?

The aggregate demand curve (AD). The downward-sloping AD curve captures the idea that economic agents will demand fewer domestically produced goods and services as the economy's general price level rises (a movement upwards along the curve). Reasons for this include:

- people switching from domestic products to now relatively cheaper imported products;
- an increase in the demand for money (to pay the higher prices), which pushes up interest rates and reduces spending;

Allowing for inflation in the 45° line and AD/AS diagrams

- a decrease in the real value of people's savings, which increases the incentive to save;
- people perhaps finding that they are paying a larger proportion of their incomes in taxes as money incomes rise.

A shift in the AD curve will occur if, for any given price level, there is a change in any of the components of aggregate

demand. For instance, the reluctance of firms to change prices because of menu costs (the costs incurred in adjusting prices) could see them change output levels substantially in response to fluctuations in demand (see section 16.5). When there are frictions to prices adjusting then changes in aggregate demand will tend to have larger effects on output and employment levels: the multiplier effect is larger.

The volatility of aggregate demand must reflect the volatility of the expenditure components: C , I , G , X and M . However, Keynesians argue that central to the volatility of aggregate demand is the volatility of private-sector spending. Hence, this volatility will often require the authorities to devise appropriate stabilisation policies to iron out the fluctuations in economic activity that result. A more stable economy, they argue, provides a better climate for investment. With more investment, potential output grows more rapidly. This, given appropriate demand management policy, then allows a faster growth in actual output to be maintained. We examine demand management policies (fiscal and monetary) in Chapter 22.

Instability of investment: the accelerator

Of the expenditure components that comprise aggregate demand the most volatile is investment (I). To illustrate this volatility consider Figure 17.14, which shows the annual rate of growth in investment for a sample of industrialised countries.

When an economy begins to recover from a recession, investment can rise very rapidly. When the growth of the economy slows down, however, investment can fall dramatically, and during a recession it can all but disappear. Since investment is an injection into the circular flow of income, these changes in investment will cause multiplied changes in income and thus heighten a boom or deepen a recession.

The theory that relates investment to changes in national income is called the **accelerator theory**. The term 'accelerator' is used because a relatively modest rise in national income can cause a much larger percentage rise in investment.

When there is no change in income and hence no change in consumption, the only investment needed is a relatively

demand. For an example, an increase in consumer confidence may encourage increased consumer spending (C) and so the AD curve shifts to the right.

The aggregate supply curve (AS). The upward-sloping AS curve shows firms supplying more as the economy's general price level rises. The curve is drawn on the assumption that various things remain constant. These include wage rates and other input prices, technology and the total supply of factors of production. Because we are holding wages and other input prices constant, as the prices of firms' products rise it becomes profitable for them to expand their output.

The aggregate supply curve will shift if any of the variables that are held constant when we draw the curve now change. For example, a rise in wage rates throughout the economy reduces the amount that firms wish to produce at any level of prices. The AS curve shifts to the left.

The Keynesian cross model

The bottom half of the diagram, part (b), is the 45° line diagram – the Keynesian cross model. Alongside the 45° line ($Y = C_d + W$) are three aggregate expenditure lines (E_1 , E_2 and E_3), which show aggregate demand (E) dependent on the level of national income.

Combining AD/AS and the 45° line models

We are now in a position to combine our two models. Assume initially that the economy is in equilibrium at national income level Y_{e1} , where aggregate demand (AD_1) equals aggregate supply (AS) and where the aggregate expenditure line (E_1) crosses the 45° line.

Now assume that there is a rise in aggregate demand caused, say, by an increase in consumer confidence that results in a rise in consumption. In part (a) of the diagram the AD curve shifts rightwards from AD_1 to AD_2 . Meanwhile in part (b), the E line shifts to E_2 .

If this rise in demand were to lead to a full multiplied rise in real income, equilibrium income would rise to Y_{e2} . For this to happen we would require the AS curve in part (a) to be a flat horizontal line, with no general price rises resulting from the increase in the aggregate demand. If, as is more likely, prices do rise, giving an upward-sloping AS curve, the increase in aggregate demand from AD_1 to AD_2 results in the price level rising to P_2 .

Hence, part of the increase in demand is reflected in higher prices and only *part* is reflected in higher output. Equilibrium real income therefore rises only to Y_{e3} and not Y_{e2} . In other words, it does not rise by the full extent of the multiplier.

In part (b) of the diagram, the effect of the higher prices is to reduce the real value of expenditure (E). In other words, a given amount of money buys fewer goods. If there is no compensating increase in money supply (which would shift the AD curve further to the right in diagram (a)), the E line must fall to the point where it intersects the 45° line at a real income of Y_{e3} ; the E line must fall to E_3 .

Assume that the AS curve is flat up to the full-employment national income level, Y_f , after which it becomes vertical. Combining the AD/AS and 45° line models, illustrate the effect on the multiplier of an increase in AD at output levels below Y_f and at Y_f .

Figure 17.14 Annual growth in investment

Notes: Investment growth is the growth in gross capital formation (gross fixed capital formation plus net change in inventories plus net acquisitions less disposal of valuables).

Source: Based on data in AMECO Database, European Commission, DGEFCIN.

small amount of replacement investment for machines that are wearing out or have become obsolete. When income and consumption increase, however, there will have to be *new* investment in order to increase production capacity. This is called **induced investment** (I_i). Once this has taken place, investment will fall back to mere replacement investment (I_r) unless there is a further rise in income and consumption.

Thus induced investment depends on *changes* in national income (ΔY):

$$I_i = \alpha \Delta Y$$

where α is the amount by which induced investment depends on changes in national income, and is known as the **accelerator coefficient**. Thus if a £1 million *rise* in national income caused the *level* of induced investment to be £2 million, the accelerator coefficient would be 2.

The size of α depends on the economy's **marginal capital/output ratio** ($\Delta K/\Delta Y$). If an increase in the country's capital stock of £2 million (i.e. an investment of £2 million) is required to produce £1 million extra national output, the marginal capital/output ratio would be 2. Other things being equal, the accelerator coefficient and the marginal capital/output ratio will therefore be the same.

? How is it that the cost of an investment to a firm will exceed the value of the output that the investment will yield? Surely that would make the investment unprofitable? (Clue: the increase in output refers to output over a specific time period, usually a year.)

Definitions

Accelerator theory The level of investment depends on the rate of change of national income, and as a result tends to be subject to substantial fluctuations.

Induced investment Investment that firms make to enable them to meet extra consumer demand.

Accelerator coefficient The level of induced investment as a proportion of a rise in national income: $\alpha = I_i/\Delta Y$.

Marginal capital/output ratio The amount of extra capital (in money terms) required to produce a £1 increase in national output. Since $I_i = \Delta K$, the marginal capital/output ratio $\Delta K/\Delta Y$ equals the accelerator coefficient (α).

The following example (see Table 17.5) illustrates some important features of the accelerator. It looks at the investment decisions made by a firm in response to changes in the demand for its product. The firm is taken as representative of firms throughout the economy. The example is based on various assumptions:

- The firm's machines last exactly 10 years and then need replacing.
- At the start of the example, the firm has ten machines in place, one 10 years old, one 9 years old, one 8 years old, one 7, one 6 and so on. Thus one machine needs replacing each year.
- Machines produce exactly 100 units of output per year. This figure cannot be varied.
- The firm always adjusts its output and its stock of machinery to match consumer demand.

The example shows what happens to the firm's investment over a six-year period when there is first a substantial rise in consumer demand, then a levelling off and then a slight fall. It illustrates the following features of the accelerator.

- *Investment will rise when the growth of national income (and hence consumer demand) is rising* ($\Delta Y_{t+1} > \Delta Y_t$). Years 1 to 2 illustrate this (see Table 17.5). The rise in consumer demand is zero in year 1 and 1000 units in year 2. Investment rises from 1 to 11 machines. The growth in investment may be considerably greater than the growth in consumer demand, giving a large accelerator effect. Between years 1 and 2, consumer demand doubles but investment goes up by a massive 11 times!
- *Investment will be constant even when national income is growing, if the increase in income this year is the same as last year* ($\Delta Y_{t+1} = \Delta Y_t$). In years 2 to 3, consumer demand continues to rise by 1000 units, but investment is constant at 11 machines.
- *Investment will fall even if national income is still growing, if the rate of growth is slowing down* ($\Delta Y_{t+1} < \Delta Y_t$). In years 3 to 4, consumer demand rises by 500 units (rather than 1000 units as in the previous year). Investment falls from 11 to 6 machines.
- If national income is constant, investment will be confined to replacement investment only. In years 4 to 5,

Table 17.5 The accelerator effect

	Year						
	0	1	2	3	4	5	6
Quantity demanded by consumers (sales)	1000	1000	2000	3000	3500	3500	3400
Number of machines required	10	10	20	30	35	35	34
Induced investment (I_i) (extra machines)		0	10	10	5	0	0
Replacement investment (I_r)		1	1	1	1	1	0
Total investment ($I_i + I_r$)		1	11	11	6	1	0

investment falls to the one machine requiring replacement.

- *If national income falls, even if only slightly, investment can be wiped out altogether.* In years 5 to 6, even though demand has fallen by only 1/35, investment will fall to zero. Not even the machine that is wearing out will be replaced.

in practice, the accelerator will not be as dramatic and clear-cut as this. The effect will be extremely difficult to predict for the following reasons:

- Many firms may have spare capacity and/or carry stocks. This will enable them to meet extra demand without having to invest.
- The willingness of firms to invest will depend on their confidence in *future* demand (see Box 17.3). Firms are not going to rush out and spend large amounts of money on machines that will last many years if it is quite likely that demand will fall back again the following year.
- Firms may make their investment plans a long time in advance and may be unable to change them quickly.
- Even if firms do decide to invest more, the producer goods industries may not have the capacity to meet a sudden surge in demand for machines.
- Machines do not as a rule suddenly wear out. A firm could thus delay replacing machines and keep the old ones for a bit longer if it was uncertain about its future level of demand.

All these points tend to reduce the magnitude of the accelerator and make it very difficult to predict. Nevertheless, the effect still exists. Firms still take note of changes in consumer demand when deciding how much to invest.

Box 17.6 looks at how fluctuations in investment in the UK specifically have typically been far more severe than fluctuations in national income. However, similar findings can be observed in many countries (see also Figure (b) in Box 17.3 on page 531). This tends to support the idea that significant accelerator effects contribute towards the instability of economies.

The multiplier/accelerator interaction

If there is an initial change in injections or withdrawals, then theoretically this will set off a chain reaction between the multiplier and the accelerator. For example, if there is a rise in government expenditure, this will lead to a multiplied rise in national income. But this *rise* in national income will set off an accelerator effect: firms will respond to the rise in income and the resulting rise in consumer demand by investing more. But this rise in investment constitutes a further rise in injections and thus will lead to a second multiplied rise in income. If this rise in income is larger than the first, there will then be a second rise in investment (the accelerator), which in turn will cause a third rise in income (the multiplier). And so the process continues indefinitely.

But does this lead to an exploding rise in national income? Will a single rise in injections cause national income to go on rising for ever? The answer is no, for two reasons. The first is that national income, in real terms, cannot go on rising faster than the growth in potential output. It will bump up against the ceiling of full employment, whether of labour or of other resources.

A second reason is that, if investment is to go on rising, it is not enough that national income should merely go on *rising*: instead, national income must *rise faster and faster*. Once the growth in national income slows down, investment will begin to fall, and then the whole process will be reversed. A fall in investment will lead to a fall in national income, which will lead to a massive fall in investment. The multiplier/accelerator interaction is shown more formally in Table 17.6. A numerical example is given in Case Study 17.8 on the student website.

Fluctuations in stocks

Firms hold stocks (inventories) of finished goods. These stocks tend to fluctuate with the course of the business cycle, and these fluctuations in stocks themselves contribute to fluctuations in output.

Imagine an economy that is recovering from a recession. At first, firms may be cautious about increasing production.

Table 17.6 The multiplier/accelerator interaction

Period t	$J \uparrow \rightarrow Y \uparrow$	(Multiplier)
Period $t + 1$	$Y \uparrow \rightarrow I \uparrow$ $I \uparrow \rightarrow Y \uparrow$	(Accelerator) (Multiplier)
Period $t + 2$	If $\uparrow Y_{t+1} > \uparrow Y_t$ then $I \uparrow$ If $\uparrow Y_{t+1} = \uparrow Y_t$ then I stays the same If $\uparrow Y_{t+1} < \uparrow Y_t$ then $I \downarrow$ This in turn will have a multiplied upward effect, no effect, or a multiplied downward effect respectively on national income.	(Accelerator)
Period $t + 3$	This will then lead to a further accelerator effect and so on . . .	

BOX 17.6 HAS THERE BEEN AN ACCELERATOR EFFECT IN THE UK?

The volatility of investment

If we look at the period from 1960 to 2016, the average annual rate of increase in GDP was 2.5 per cent while that for investment was only slightly higher at 2.8 per cent. But the key point is that investment is highly volatile. Economic growth has fluctuated with the business cycle; but investment has been subject to far more violent swings.

If we look at the chart we can see that the fastest annual rate of increase in GDP was 9.8 per cent (Q1 1973), while the sharpest rate of decline was 6.1 per cent (Q1 2009). By contrast, the fastest annual rate of increase in investment was 26.4 per cent (Q1 1964), while the sharpest rate of decline was 20.7 per cent (Q2 2009).

These figures are consistent with the accelerator theory, which argues that the *level* of investment depends on the *rate*

of change of national income. A relatively small percentage change in national income can give a much bigger percentage change in investment.

The ups and downs in GDP and investment do not completely match because there are additional factors that determine investment other than simply changes in national income. These factors include interest rates, the availability of finance, exchange rates and businesses' expectations of future demand.

1. Can you identify any time lags in the graph? Why might there be time lags?
2. Why does investment in the construction and producer goods industries tend to fluctuate more than investment in retailing and the service industries?

Fluctuations in UK real GDP and investment

Notes: Investment growth is the growth in Gross Fixed Capital Formation.

Source: Based on data in *Quarterly National Accounts*, series IHYR and KG7T (National Statistics).

Doing so may involve taking on more labour or making additional investment. Firms may not want to make these commitments if the recovery could soon peter out. They may, therefore, run down their stocks rather than increase output. Initially the recovery from recession will be slow.

If the recovery does continue, however, firms will start to gain more confidence and will increase production. Also, they will find that their stocks have got rather low

and will need building up. This gives a further boost to production, and for a time the growth in output will exceed the growth in demand. This extra growth in output will then, via the multiplier, lead to a further increase in demand.

Once stocks have been built up again, the growth in output will slow down to match the growth in demand. This slowing down in output will, via the accelerator and

multiplier, contribute to the ending of the expansionary phase of the business cycle.

As the economy slows down, firms will find their stocks building up. Unless they cut back on production immediately, this increase in stocks cushions the effect of falling demand on output and employment.

If the recession continues, however, firms will be unwilling to go on building up stocks. But as firms attempt to reduce their stocks back to the desired level, production will fall *below* the level of sales, despite the fact that sales themselves are lower. This could lead to a dramatic fall in output and, via the multiplier, to an even bigger fall in sales.

Eventually, once stocks have been run down to the minimum, production will have to rise again to match the level of sales. This will contribute to a recovery and the whole cycle will start again.

Fluctuations in borrowing and debt

During an upswing, when confidence is high, businesses will be more willing to borrow to invest and consumers will be more willing to borrow to spend. At the same time, banks will be more willing to lend, being confident in people's ability to repay. The extra borrowing and lending fuel the expansion. Private debt as a percentage of GDP thus tends to rise.

During a recession, banks are less willing to lend and both firms and consumers are less willing to borrow, fearing their ability to repay. Indeed, many people will seek to reduce their debts by increasing repayments. The reduction in borrowing and debt will push the economy deeper into recession.

We explored these balance sheet effects in Box 17.2 (page 528).

Determinants of the course of the business cycle

We are now in a position to paint a more complete Keynesian picture of the business cycle. We need to answer two key questions: (a) why do booms and recessions last for several months or even years, and (b) why do they eventually come to an end – what determines their turning points? Let us examine each in turn.

Why do booms and recessions persist?

Time lags. It takes time for changes in injections and withdrawals to be fully reflected in changes in national income, output and employment. The multiplier process takes time.

Moreover, consumers, firms and government may not all respond immediately to new situations.

'Bandwagon' effects. Once the economy starts expanding, expectations become buoyant. People think ahead and adjust their expenditure behaviour: they consume and invest more now. Likewise in a recession, a mood of pessimism may set in. The effect is cumulative. The multiplier and accelerator interact: they feed on each other.

Group behaviour. Individual consumers and businesses may take their lead from others and so mimic their behaviour. This helps to reinforce bandwagon effects.

For example, during the 2000s many financial institutions loosened their lending criteria. This helped to fuel unsustainable property booms in several countries, including the UK, Ireland and the USA. They engaged in a competitive race, offering ever more favourable terms for borrowers. Often the borrowers could only repay if their assets (e.g. property) appreciated in value, as they tend to do in a boom – but not in a recession.

This rush to lend meant that many banks over-extended themselves and operated with too little capital. This made them much more vulnerable to financial crises and much more likely to cut back lending dramatically in a downturn – as indeed they did from 2008.

Group behaviour can therefore help to amplify economic upturns and downturns. By modelling representative agents with rational expectations, it is argued, we may fail to understand how the interaction between economic agents can affect macroeconomic aggregates (see Chapter 16 page 514).

Why do booms and recessions come to an end?

Ceilings and floors. Actual output can go on growing more rapidly than potential output only as long as there is slack in the economy. As full employment is approached and as more and more firms reach full capacity, so a ceiling to output will be reached.

At the other extreme, there is a basic minimum level of consumption that people tend to maintain. During a recession, people may not buy many luxury and durable goods, but they will continue to buy food and other basic goods. There is thus a floor to consumption.

The industries supplying these basic goods will need to maintain their level of replacement investment. Also, there will always be some minimum investment demand as firms feel the need to install the latest equipment. There is thus a floor to investment too.

Echo effects. Durable consumer goods and capital equipment may last several years, but eventually they will need

replacing. The replacement of goods and capital purchased in a previous boom may help to bring a recession to an end.

The accelerator. For investment to continue rising, consumer demand must rise at a faster and faster rate. If this does not happen, investment will fall back and the boom will break.

Sentiment and expectations. A change of sentiment and a sense that current rates of growth will not be sustained can lead people to adjust their spending behaviour, so contributing to the very slowdown that was expected. The impact of this will be amplified by bandwagon effects and group behaviour.

Random shocks. National or international political, social, institutional or natural events can affect the mood and attitudes of firms, governments and consumers, or the conditions under which they operate, and thus affect aggregate

demand. Changes in world oil prices, a war, an election or a banking crisis are all examples.

Changes in government policy. In a boom, a government may become most worried by inflation, balance of payments deficits and rising levels of private debt, and thus pursue contractionary policies. In a recession, it may become most worried by unemployment and lack of growth and thus pursue expansionary policies. These government policies, if successful, will bring about a turning point in the cycle.

Keynesians argue that governments should attempt to reduce cyclical fluctuations by using active stabilisation policies. A more stable economy will encourage investment and allow a faster growth in output to be maintained. The policy traditionally favoured by Keynesians is *fiscal policy*. This is the subject of Chapter 22.

An analysis of the factors contributing to each of the four phases of the business cycle is given in Case Study 17.10 on the student website.

Section summary

1. Keynesians explain cyclical fluctuations in the economy by examining the causes of fluctuations in the level of aggregate demand.
2. A major part of the Keynesian explanation of the business cycle is the instability of private-sector expenditure. Investment is the most volatile component of aggregate demand. The accelerator theory explains this volatility. It relates the level of investment to changes in national income and consumer demand. An initial increase in consumer demand can result in a very large percentage increase in investment; but as soon as the rise in consumer demand begins to level off, investment will fall; and even a slight fall in consumer demand can reduce investment to virtually zero.
3. The accelerator effect will be dampened by the carrying of stocks, the cautiousness of firms, forward planning by firms and the inability of producer goods industries to supply the capital equipment.
4. The interaction of the multiplier and accelerator will cause cycles.
5. Fluctuations in stocks and in levels of borrowing and debt are also major contributors to the business cycle.
6. Keynesians identify other causes of cyclical fluctuations, such as time lags, 'bandwagon' effects, ceilings and floors to output, echo effects, swings in government policy and random shocks.

END OF CHAPTER QUESTIONS

1. An economy is currently in equilibrium. The following figures refer to elements in its national income accounts.

	£ billions
Consumption (total)	60
Investment	5
Government expenditure	8
Imports	10
Exports	7

- (a) What is the current equilibrium level of national income?
- (b) What is the level of injections?
- (c) What is the level of withdrawals?
- (d) Assuming that tax revenues are £7 billion, how much is the level of saving?
- (e) If national income now rose to £80 billion and, as a result, the consumption of domestically produced goods rose to £58 billion, what is the *mpcd*?
- (f) What is the value of the multiplier?

- (g) Given an initial level of national income of £80 billion, now assume that spending on exports rises by £4 billion, spending on investment rises by £1 billion, whilst government expenditure falls by £2 billion. By how much will national income change?
- (h) Given this new level of national income, assume that full employment is achieved at a national income of £100 billion. Is there an inflationary or a deflationary gap?
- (i) What is the size of this gap?
- What is the relationship between the *mpc*, the *mpcd* and the *mpw*?
 - Why will the short-run consumption function be different from the long-run consumption function?
 - Construct a table similar to Table 17.3 (on page 536), only this time assume that the *mpcd* is $\frac{3}{4}$. Show that national income will increase by £640 million.
 - Assume that the multiplier has a value of 3. Now assume that the government decides to increase aggregate demand in an attempt to reduce unemployment. It raises government expenditure by £100 million with no increase in taxes. Firms, anticipating a rise in their sales, increase investment by £200 million, of which £50 million consists of purchases of foreign machinery. How much will national income rise? (Assume *ceteris paribus*.)
 - What factors could explain why some countries have a higher multiplier than others?
 - How can the interaction of the multiplier and the accelerator explain cyclical fluctuations in national income?
 - Why is it difficult to predict the size of the accelerator?

Equilibrium in the money market	584
Equilibrium in the foreign exchange market	584

In this chapter and the next, we are going to look at the role that money and financial institutions play in an economy. The financial crisis that developed during the late 2000s demonstrated vividly the significance of the financial system to modern-day economies. It is generally recognised that changes in the amount of money can have a powerful effect on all the major macroeconomic indicators, such as inflation, unemployment, economic growth, interest rates, exchange rates and the balance of payments. But the financial crisis did more than this: it demonstrated the systemic importance of financial institutions.

There continues to be a vibrant debate about how, if at all, we can avoid a repeat of the recent financial crisis. Governments and regulators worldwide are grappling with many very important questions. For instance, are some financial institutions simply *too big to fail*? How can we ensure that banks operate with adequate loss-absorbing capacity? Can we prevent financial institutions from contributing to excessive cycles in the credit extended to households and firms? Can we better align the incentives of banks with those of the wider community? These and other questions about financial institutions are considered here.

The chapter begins by defining what is meant by money and examining its functions. Then in sections 18.2 and 18.3 we look at the operation of the financial sector of the economy and its role in determining the supply of money. It is here where we consider the possible causes of the financial crisis, its impact on financial institutions themselves and some of the responses by central banks to the problems faced by financial institutions and, as a result, the economy.

In section 18.4 we turn to look at the demand for money. What we are asking is: how much of people's assets do they want to hold in the form of money? Finally, in section 18.5 we put supply and demand together to see how free-market interest rates – which have a crucial impact on aggregate demand – are determined.

18.1 THE MEANING AND FUNCTIONS OF MONEY

Before going any further we must define precisely what we mean by 'money' – not as easy a task as it sounds. Money is more than just notes and coin. In fact the main component of a country's money supply is not cash, but deposits in banks and other financial institutions. Only a very small proportion of these deposits is kept by the banks in their safes or tills in the form of cash. The bulk of the deposits appear merely as bookkeeping entries in the banks' accounts.

This may sound very worrying. Will a bank have enough cash to meet its customers' demands? The answer in the vast majority of cases is yes. Only a small fraction of a bank's total deposits will be withdrawn at any one time, and banks always seek to ensure that they have the ability to meet their customers' demands. The chances of banks running out of cash are very low indeed. The only circumstance where this could become possible is if people lost confidence in a bank and started to withdraw money in what is known as a 'run on the bank'. This happened with the Northern Rock bank in 2008. But in these circumstances the central bank or government would intervene to protect people's deposits by making more cash available to the bank or, in the last resort, by nationalising the bank (as happened with Northern Rock).

What is more, the bulk of all but very small transactions are not conducted in cash at all. By the use of cheques, credit cards and debit cards, most money is simply transferred from the purchaser's to the seller's bank account without the need for first withdrawing it in cash.

What items should be included in the definition of money? To answer this we need to identify the functions of money.

The functions of money

The main purpose of money is for buying and selling goods, services and assets: i.e. as a 'medium of exchange'. It also has three other important functions. Let us examine each in turn.

A medium of exchange

In a subsistence economy, where individuals make their own clothes, grow their own food, provide their own entertainments, etc., people do not need money. If people want to exchange any goods, they will do so by barter. In other words, they will do swaps with other people.

The complexities of a modern developed economy, however, make barter totally impractical for most purposes (see Case Study 18.1 on the student website). What is necessary is a *medium of exchange* that is generally acceptable as a means of payment for goods and services and as a means of payment for labour and other factor services. 'Money' is any such medium.

To be a suitable physical means of exchange, money must be light enough to carry around, must come in a number of denominations, large and small, and must not be easy to forge (the attributes of money are explored in Case Study 18.2 on the student website). Alternatively, money must be in a form that enables it to be transferred indirectly through some acceptable mechanism. For example, money in the form of bookkeeping entries in bank accounts can be transferred from one account to another by the use of such mechanisms as debit cards and direct debits.

A means of storing wealth

People need a means whereby the fruits of today's labour can be used to purchase goods and services in the future. People need to be able to store their wealth: they want a

Definition

Medium of exchange Something that is acceptable in exchange for goods and service.

BOX 18.1

MONEY SUPPLY, NATIONAL INCOME AND NATIONAL WEALTH

EXPLORING ECONOMICS

Don't confuse the supply of money with the money value of national income. National income is a *flow* concept. It measures the value of the nation's output per year. Money supply, by contrast, is a *stock* concept. At any one point in time, there is a given amount of money in the economy.

But what if the money supply increases? Will the national income increase by that amount? No, because the extra money will usually be spent more than once per year on final goods and services. The rise in national income would thus be greater than the rise in money supply. On the other hand, some of the extra spending may simply result in higher prices. *Real* national income will rise by less than national income measured at current prices.

So if money supply is not the same as national *income*, is it the same as national *wealth*? After all, wealth is a stock concept. Again the answer is no. The nation's wealth consists of its *real* assets: land, buildings, capital equipment, works of art, etc. People may well hold part of their wealth in the form of money, it is true, but this is not wealth as far as the nation is concerned: if it were, the government could make us all wealthier by simply printing more money! Money represents wealth to the individual only to the extent that it represents a claim on *real* goods and services. It has nothing to do with national wealth.

means of saving. Money is one such medium in which to hold wealth. It can be saved.

A means of evaluation

Money allows the value of goods, services or assets to be compared. The value of goods is expressed in terms of prices, and prices are expressed in money terms. Money also allows dissimilar things, such as a person's wealth or a company's assets, to be added up. Similarly, a country's GDP is expressed in money terms. Money thus serves as a 'unit of account'.

Why may money prices give a poor indication of the value of goods and services?

A means of establishing the value of future claims and payments

People often want to agree today the price of some future payment. For example, workers and managers will want to agree the wage rate for the coming year. Firms will want to sign contracts with their suppliers specifying the price of raw materials and other supplies. Money prices are the most convenient means of measuring future claims.

What should count as money?

What items, then, should be included in the definition of money? Unfortunately, there is no sharp borderline between money and non-money.

Cash (notes and coin) obviously counts as money. It readily meets all the functions of money. Goods (fridges, cars and cabbages) do not count as money. But what about various financial assets, such as bank accounts, building society accounts and stocks and shares? Do they count as money? The answer is: it depends on how narrowly money is defined. The narrowest definition of money includes just cash (i.e. notes and coins). Broader definitions include various types of bank account, and broader definitions still include various financial assets as well. We examine the different definitions in the UK and the eurozone in Box 18.4.

In terms of the broad definition of money, would a deposit account passbook count as money?

In order to understand the significance of different measures of the money supply and the ways in which money supply can be controlled, it is first necessary to look at the various types of account in which money can be held and at the various financial institutions involved.

Section summary

1. Money's main function is as a medium of exchange. In addition, it is a means of storing wealth, a means of evaluation and a means of establishing the value of future claims and payments.
2. What counts as money depends on how narrowly it is defined. All definitions include cash, but they vary according to what other financial assets are included.

18.2 THE FINANCIAL SYSTEM

The role of the financial sector

Banks and other financial institutions are known as *financial intermediaries*. They provide a link between those who wish to lend and those who wish to borrow. In other words, they act as the mechanism whereby the supply of funds is matched to the demand for funds. In this process, they provide five important services.

Expert advice

Financial intermediaries can advise their customers on financial matters: on the best way of investing their funds and on alternative ways of obtaining finance. This should help to encourage the flow of savings and the efficient use of them.

Expertise in channelling funds

Financial intermediaries have the specialist knowledge to be able to channel funds to those areas that yield the

highest return. They also have the expertise to assess risks and to refuse loans for projects considered too risky or to charge a risk premium to others. This all encourages the flow of saving as it gives savers the confidence that their savings will earn a good rate of interest. Financial intermediaries also help to ensure that projects that are potentially profitable will be able to obtain finance. They help to increase allocative efficiency.

Definition

Financial intermediaries The general name for financial institutions (banks, building societies, etc.) which act as a means of channelling funds from depositors to borrowers.

Maturity transformation

Many people and firms want to borrow money for long periods of time, and yet many depositors want to be able to withdraw their deposits on demand or at short notice. If people had to rely on borrowing directly from other people, there would be a problem here: the lenders would not be prepared to lend for a long enough period. If you had £100 000 of savings, would you be prepared to lend it to a friend to buy a house if the friend was going to take 25 years to pay it back? Even if there was no risk whatsoever of your friend defaulting, most people would be totally unwilling to tie up their savings for so long.

This is where a bank or building society comes in. It borrows money from a vast number of small savers, who are able to withdraw their money on demand or at short notice. It then lends the money to house purchasers for a long period of time by granting mortgages, which are typically paid back over 20 to 30 years. This process whereby financial intermediaries lend for longer periods of time than they borrow is known as **maturity transformation**. They are able to do this because with a large number of depositors it is highly unlikely that they would all want to withdraw their deposits at the same time. On any one day, although some people will be withdrawing money, others will be making new deposits.

This does not mean that maturity transformation is without risks for financial institutions. Maturity transformation implies a maturity mismatch between the liabilities and assets on institutions' balance sheets. This needs managing. Box 18.2 considers the potential risks of maturity transformation for financial institutions and the wider economy.

 What dangers are there in maturity transformation for (a) financial institutions; (b) society generally?

Risk transformation

You may be unwilling to lend money directly to another person in case they do not pay up. You are unwilling to take the risk. Financial intermediaries, however, by lending to large numbers of people, are willing to risk the odd case of default. They can absorb the loss because of the interest they earn on all the other loans. This spreading of risks is known as **risk transformation**. What is more, financial intermediaries may have the expertise to be able to assess just how risky a loan is.

 Which of the above are examples of economies of scale?

Transmission of funds

In addition to channelling funds from depositors to borrowers, certain financial institutions have another important function. This is to provide a means of transmitting payments. Thus by the use of debit cards, credit cards, the Internet and telephone banking, cheques, direct debits,

etc., money can be transferred from one person or institution to another without having to rely on cash.

The banking system

Types of bank

By far the largest element of money supply is bank deposits. It is not surprising, then, that banks play an absolutely crucial role in the monetary system. Banking can be divided into two main types: retail banking and wholesale banking. Most banks today conduct both types of business and are thus known as 'universal banks'.

Retail banking. **Retail banking** is the business conducted by the familiar high street banks, such as Barclays, Lloyds, HSBC, Royal Bank of Scotland, NatWest (part of the RBS group) and Santander. They operate bank accounts for individuals and businesses, attracting deposits and granting loans at published rates of interest.

Wholesale banking. The other major type of banking is **wholesale banking**. This involves receiving large deposits from and making large loans to companies or other banks and financial institutions; these are known as **wholesale deposits and loans**.

As far as companies are concerned, these may be for short periods of time to account for the non-matching of a firm's payments and receipts from its business, or they may be for longer periods of time, for various investment purposes. As these wholesale deposits and loans are very large sums of money, banks compete against each other for them and negotiate individual terms with the firm to suit the firm's particular requirements.

In the past, there were many independent wholesale banks, known as **investment banks**. These included famous names such as Morgan Stanley, Rothschild, SG Hambros and Goldman Sachs. With the worldwide financial crisis of the

Definitions

Maturity transformation The transformation of deposits into loans of a longer maturity.

Risk transformation The process whereby banks can spread the risks of lending by having a large number of borrowers.

Retail banking Branch, telephone, postal and Internet banking for individuals and businesses at published rates of interest and charges. Retail banking involves the operation of extensive branch networks.

Wholesale banking Where banks deal in large-scale deposits and loans, mainly with companies and other banks and financial institutions. Interest rates and charges may be negotiable.

Wholesale deposits and loans Large-scale deposits and loans made by and to firms at negotiated interest rates.

late 2000s, however, most of the independent investment banks merged with universal banks which conduct both retail and wholesale activities.

The rise of large universal banks has caused concern, however. In the UK in 2010, the Coalition government set up the Independent Commission on Banking (ICB). It was charged with investigating the structure of the banking system. It proposed *functional separation*: the ring-fencing of retail and wholesale banking. It argued that the core activities of retail banks needed isolating from the potential contagion from risky wholesale banking activities.

The principal recommendations of the ICB were accepted and the Financial Services (Banking Reform) Act became law in December 2013. The Act defines *core activities* as facilities for accepting deposits, facilities for withdrawing money or making payments from deposit accounts and the provision of overdraft facilities. It gives regulators the power to exercise ring-fencing rules to ensure the effective provision of core activities. These include restricting the power of a ring-fenced body to enter into contracts and payments with other members of the banking group. The Act also gives the regulator powers to restructure or split banks up to safeguard their future.

It was agreed that the ring-fencing of UK banking groups would become effective from the start of January 2019. The UK government decided that banks with more than £25 billion of core retail deposits would be ring-fenced. Banks which were to be functionally separated from the rest of their groups were to be known as ring-fenced banks or RFBs.

Building societies

These UK institutions specialise in granting loans (mortgages) for house purchase. They compete for the savings of the general public through a network of high street branches. Unlike banks, they are not public limited companies, their 'shares' being the deposits made by their investors. In recent years, many of the building societies have converted to banks (including all the really large building societies except the Nationwide).

In the past, there was a clear distinction between banks and building societies. Today, however, they have become much more similar, with building societies now offering current account facilities and cash machines, and retail banks granting mortgages. As with the merging of retail and wholesale banks, this is all part of a trend away from the narrow specialisation of the past and towards the offering of a wider and wider range of services. This was helped by a process of *financial deregulation*.

In fact, banks and building societies are both examples of what are called *monetary financial institutions (MFIs)*. This term is used to describe all deposit-taking institutions, including central banks (e.g. the Bank of England).

MFIs also lend and borrow wholesale funds to and from each other, and deposit with and borrow from the central bank. Up to the financial crisis of 2008/9, there had been a marked growth in wholesale funding. In many countries, including the UK, this contributed to the growth in the size

of banks' balance sheets. Wholesale funds can be distributed amongst banks by means of a series of financial instruments. These instruments are typically short term and acquired in markets known as *money markets*.

During the financial crisis many forms of inter-bank lending virtually dried up in many countries. MFIs became increasingly fearful of other MFIs defaulting on loans. In response to the crisis, the Bank of England and other central banks, such as the Federal Reserve Bank in the USA, supplied extra money to MFIs to ensure the security of these institutions and the stability of the financial system. It did this by purchasing various assets from them with money it had, in effect, created (see Box 18.4).

Deposit taking and lending

Balance sheets

Banks and building societies provide a range of *financial instruments*. These are financial claims, either by customers on the bank (e.g. deposits) or by the bank on its customers (e.g. loans). They are best understood by analysing the balance sheets of financial institutions, which itemise their liabilities and assets. A financial institution's liabilities are those financial instruments involving a financial claim on the financial institution itself. As we shall see, these are largely *deposits* by customers, such as current and savings accounts. Its assets are financial instruments involving a financial claim on a third party: these are *loans*, such as personal and business loans and mortgages.

The total liabilities and assets for UK MFIs are set out in a balance sheet in Table 18.1. The aggregate size of the balance sheet in 2017 was equivalent to almost four times the UK's annual GDP. This is perhaps the simplest indicator of the significance of banks in modern economies, like the UK.

Both the *size* and *composition* of banks' balance sheets have become the focus of the international community's effort to ensure the stability of countries' financial systems. The growth of the aggregate balance sheet in the UK is considered in Box 18.2. But, it is to the composition of the balance sheet that we now turn. To do this, we focus on banks' liabilities and assets.

Definitions

Liabilities

Customers' deposits in banks (and other deposit-taking institutions such as building societies) are **liabilities** to these institutions. This means simply that the customers have the claim on these deposits and thus the institutions are liable to meet the claims.

There are five major types of liability: sight deposits, time deposits, certificates of deposit (CDs), 'repos' and capital.

Sight deposits. *Sight deposits* are any deposits that can be withdrawn on demand by the depositor without penalty. In the past, sight accounts did not pay interest. Today, however, there are many sight accounts that do. In fact, there is quite aggressive competition nowadays between banks to offer apparently very attractive interest rates on such accounts, although these are often on balances up to a relatively small amount.

The most familiar form of sight deposits are current accounts at banks. Depositors are issued with chequebooks and/or debit cards (e.g. Visa debit or MasterCard's Maestro) that enable them to spend the money directly without first having to go to the bank and draw the money out in cash. In the case of debit cards, the person's account is electronically debited when the purchase is made. This process is known as EFTPOS (electronic funds transfer at point of sale). Money can also be transferred between individuals and businesses through direct debits, standing orders and Internet banking transfers.

An important feature of current accounts is that banks often allow customers to be overdrawn. That is, they can draw on their account and make payments to other people in excess of the amount of money they have deposited.

Time deposits. *Time deposits* require notice of withdrawal. However, they normally pay a higher rate of interest than

sight accounts. With some types of account, a depositor can withdraw a certain amount of money on demand, but there will be a penalty of so many days' lost interest. They are not chequebook or debit-card accounts, although some allow customers to use cash cards. The most familiar form of time deposits are the deposit and savings accounts in banks and the various savings accounts in building societies. No overdraft facilities exist with time deposits.

A substantial proportion of time deposits are from the banking sector. Inter-bank lending grew over the years as money markets were deregulated and as deposits were moved from one currency to another to take advantage of different rates of interest between different countries. A large proportion of overseas deposits are from foreign banks.

Certificates of deposit. *Certificates of deposit* are certificates issued by banks to customers (usually firms) for large deposits of a fixed term (e.g. £100 000 for 18 months). They can be sold by one customer to another, and thus provide a

Definitions

Liabilities All legal claims for payment that outsiders have on an institution.

Sight deposits Deposits that can be withdrawn on demand without penalty.

Time deposits Deposits that require notice of withdrawal or where a penalty is charged for withdrawals on demand.

Certificates of deposit (CDs) Certificates issued by banks for fixed-term interest-bearing deposits. They can be resold by the owner to another party.

means whereby the holders can get money quickly if they need it without the banks that have issued the CDs having to supply the money. (This makes them relatively 'liquid' to the depositor but 'illiquid' to the bank: we examine this below.) The use of CDs has grown rapidly over the past two decades. Their use by firms has meant that, at a wholesale level, sight accounts have become less popular.

Sale and repurchase agreements (repos). If banks have a temporary shortage of funds, they can sell some of their financial assets to other banks or to the central bank – the Bank of England in the UK and the European Central Bank in the eurozone (see below) – and later repurchase them on some agreed date, typically a fortnight later. These *sale and repurchase agreements (repos)* are in effect a form of loan – the bank borrowing for a period of time using some of its financial assets as the security for the loan. One of the major assets to use in this way are government bonds (issued when the government borrows), normally called 'gilt-edged securities' or simply 'gilts' (see below). Sale and repurchase agreements involving gilts are known as gilt repos. Gilt repos play a vital role in the operation of monetary policy (see section 22.3).

Capital and other funds. This consists largely of the share capital in banks. Since shareholders cannot take their money out of banks (although they can sell them to other investors on the stock market), share capital provides a source of funding to meet sudden increases in withdrawals from depositors and to cover bad debts.

It is vital that banks have sufficient capital. As we shall see, an important part of the response to the financial crisis has been to require banks to hold relatively larger amounts of capital. At the beginning of 2017, the aggregate amount of sterling capital held by banks based in the UK was equivalent to 12 per cent of their sterling liabilities.

Assets

A bank's financial *assets* are its claims on others. There are three main categories of assets.

Cash and reserve balances in the central bank (Bank of England in the UK, ECB in the eurozone). Banks need to hold a certain amount of their assets as cash. This is largely used to meet the day-to-day demands of customers. They also keep 'reserve balances' in the central bank. In the UK these earn interest at the Bank of England's repo rate (or 'Bank Rate' as it is called). These are like the banks' own current accounts and are used for clearing purposes (i.e. for settling the day-to-day payments between banks). They can be withdrawn in cash on demand. With inter-bank lending being seen as too risky during the crisis of the late 2000s, many banks resorted to depositing surplus cash in the Bank of England, even though Bank Rate was lower than the inter-bank lending rate or LIBOR ('London inter-bank offered rate') (see Box 18.3).

In the UK, banks and building societies are also required to deposit a small fraction of their assets as 'cash ratio

deposits' with the Bank of England. These cannot be drawn on demand and earn no interest.

As you can see from Table 18.1, cash and balances in the Bank of England account for a very small proportion of banks' assets. The vast majority of banks' assets are in the form of various types of loan – to individuals and firms, to other financial institutions and to the government. These are 'assets' because they represent claims that the banks have on other people. Loans can be grouped into two types: short and long term.

Short-term loans. These are in the form of market loans, bills of exchange or reverse repos. The market for these various types of loan is known as the money market.

- **Market loans** are made primarily to other financial institutions. This inter-bank lending consists of (a) money lent 'at call' (i.e. reclaimable on demand or at 24 hours' notice); (b) money lent for periods up to one year, but typically a few weeks; (c) CDs (i.e. certificates of deposits made in other banks or building societies).
- **Bills of exchange** are loans either to companies (*commercial bills*) or to the government (*Treasury bills*). These are, in effect, an IOU, with the company issuing them (in the case of commercial bills), or the government (in the case of Treasury bills), promising to pay the holder a specified sum on a particular date (the 'maturity date'), typically three months later. Since bills do not pay interest, they are sold below their face value, i.e. at a 'discount', but redeemed on maturity at face value. This enables the purchaser, in this case the bank, to earn a return. The market for new or existing bills is therefore known as the *discount market*.

Definitions

Sale and repurchase agreements (repos) An agreement between two financial institutions whereby one in effect borrows from another by selling its assets, agreeing to buy them back (repurchase them) at a fixed price and on a fixed date.

Assets Possessions or claims on others.

Market loans Short-term loans (e.g. money at call and short notice).

Bills of exchange Certificates promising to repay a stated amount on a certain date, typically three months from the issue of the bill. Bills pay no interest as such, but are sold at a discount and redeemed at face value, thereby earning a rate of discount for the purchaser.

Commercial bills Bills of exchange issued by firms.

Treasury bills Bills of exchange issued by the Bank of England on behalf of the government. They are a means whereby the government raises short-term finance.

Discount market An example of a money market in which new or existing bills, such as Treasury bills or Commercial bills, are bought and sold at a discount below their face value: i.e. the value at which they will be redeemed on maturity.

BOX 18.2 THE GROWTH OF BANKS' BALANCE SHEETS

The rise of wholesale funding

Banks' traditional funding model relied heavily on deposits as the source of funds for loans. However, new ways for financial institutions to access funds to generate new loans evolved. These reflected the deregulation of financial markets and the rapid pace of financial innovation.

Seeds of the crisis

Increasingly, financial institutions made greater use of *wholesale funds*. These are funds from other financial institutions. This coincided with the growth in a process known as securitisation. This involves the conversion of non-marketable banks' assets, such as residential mortgages, which have regular income streams (e.g. from payments of interest and capital) into securities, which can be bought and sold on financial markets. These provide lenders who originate the loans with a source of funds for further loans. The growth of securitisation is discussed in more detail in Box 18.3.

With an increasing use of money markets by financial institutions, vast sums of funds became available for lending. One consequence of this, as illustrated in the chart, was an expansion of the aggregate balance sheet of banks. The balance sheet grew from £2.6 trillion (2¾ times GDP) at the start of 1998 to £8.5 trillion (5½ times GDP) at the start of 2010.

The growth in banks' balance sheets was accompanied by a change in their composition. First, the profile of banks' assets became less liquid as they extended more long-term credit to households and firms. Assets generally became more risky too, as banks increasingly granted mortgages of 100 per cent or more of the value of houses – a problem for banks if house prices fell and they were forced to repossess.

Second, there was a general increase in the use of fixed-interest bonds as opposed to ordinary shares (equities) for raising capital. The ratio of bonds to shares is known as the **gearing** (or **leverage**) ratio. The increase in leverage meant

that, prior to the financial crisis, banks were operating with lower and lower levels of loss-absorbing capital, such as ordinary shares. If banks run at a loss, dividends on shares can be suspended; payments to bond holders cannot. This meant that as the crisis unfolded, policy makers were facing a liquidity problem, not among one or two financial institutions, but across the financial system generally.

The market failure we are describing is a form of **co-ordination failure** and is an example of the *fallacy of composition*. When one bank pursues increased earnings by borrowing from and lending to other financial institutions, this is not necessarily a problem. But, if many institutions expand their balance sheets by borrowing from and lending to *each other*, then it becomes a problem for the whole financial system. The apparent increase in liquidity for individual banks, on which they base credit, is not an overall increase in liquidity for the financial system as a whole. The effect is to create a credit bubble.

The dangers of the bubble for the financial system and beyond were magnified by the increasingly tangled web of interdependencies between financial institutions, both nationally and globally. There was a danger that this complexity was masking fundamental weaknesses of many financial institutions and too little overall liquidity.

Financial crisis

Things came to a head in 2007 and 2008. Once one or two financial institutions failed, such as Northern Rock in the UK in August 2007 and Lehman Brothers in the USA in September 2008, the worry was that failures would spread like a contagion. Banks could no longer rely on each other as their main source of liquidity.

The problems arising from the balance sheet expansion, increased leverage and a heightened level of maturity

The price paid for bills will depend on demand and supply. For example, the more Treasury bills that are offered for sale (i.e. the higher the supply), the lower will be their equilibrium price, and hence the higher will be their rate of return (i.e. their rate of interest, or 'rate of discount').

Normally, a bank will buy commercial bills only if they have been first 'accepted' by another financial institution (typically an investment bank). This means that the investment bank will redeem the bill (i.e. pay up) on

the maturity date, if the firm issuing the bill defaults on payment. Of course the investment bank charges for this insurance (or 'underwriting'). Bills that have been accepted in this way are known as **bank bills**.

- **Reverse repos.** When a sale and repurchase agreement is made, the financial institution purchasing the assets (e.g. gilts) is, in effect, giving a short-term loan. The other party agrees to buy back the assets (i.e. pay back the loan) on a set date. The assets temporarily held by the bank making the loan are known as 'reverse repos'. Reverse

Definitions

Gearing or leverage (US term) The ratio of debt capital to equity capital: in other words, the ratio of borrowed capital (e.g. bonds) to shares.

Co-ordination failure When a group of firms (e.g. banks) acting independently could have achieved a more desirable outcome if they had co-ordinated their decision making.

Bank bills Bills that have been accepted by another financial institution and hence insured against default.

Reverse repos Gilts or other assets that are purchased under a sale and repurchase agreement. They become an asset to the purchaser.

Aggregate balance sheet of UK banks and building societies

Note: Since 2010 all loans securitised by MFIs are recorded on MFI balance sheets.

Sources: (i) Data showing liabilities of banks and building societies based on series LPMALOA and RPMTBJF (up to the end of 2009) and RPMB3UQ (from 2010) from *Statistical Interactive Database*, Bank of England (data published 29 September 2017, not seasonally adjusted). (ii) GDP data from *Quarterly National Accounts* series YBHA, Office for National Statistics (GDP figures are the sum of the latest four quarters).

mismatch meant that central banks around the world, including the Bank of England, were faced with addressing a liquidity problem of huge proportions. They had to step in to supply central bank money to prevent a collapse of the banking system.

Subsequently, the Basel Committee on Banking Supervision (see pages 564–5) agreed a set of measures, to be applied globally, designed to ensure the greater financial resilience of banks and banking systems. It is notable from the chart how from the early 2010s there was a reduction of

the aggregate balance sheet of banks resident in the UK. By the middle of 2017 the aggregate balance sheet was close to £8 trillion, the equivalent to four times GDP: this compares with a figure of nearly £8.5 trillion in early 2010 – over 550 per cent of GDP.

What are the potential costs and benefits for financial institutions, lenders and borrowers and for the wider economy arising from maturity transformation? Are these dangers an inherent and unavoidable consequence of maturity transformation?

repos are typically for one week, but can be for as little as overnight or as long as one year.

Longer-term loans. These consist primarily of loans to customers, both personal customers and businesses. These loans, also known as advances, are of four main types: fixed-term (repayable in instalments over a set number of years – typically, six months to five years), overdrafts (often for an unspecified term), outstanding balances on credit card accounts, and mortgages (typically for 25 years).

Banks also make investments. These are partly in government bonds (gilts), which are effectively loans to the government. The government sells bonds, which then pay a fixed sum each year as interest. Once issued, they can then be bought and sold on the stock exchange. Banks are normally only prepared to buy bonds that have less than five years to maturity (the date when the government redeems the bonds). Banks also invest in various subsidiary financial institutions and in building societies.

Taxing the banks

Bank levy. In January 2011, the UK introduced the bank levy: a tax on the *liabilities* of banks and building societies operating in the UK. For banking groups with their headquarters in the UK the levy applies to their global balance sheet; for subsidiaries of non-UK banks it applies just to their UK activities. The tax is founded on two key principles. First, the revenues raised should be able to meet the full fiscal costs of any future support for financial institutions. Second, it should provide banks with incentives to reduce risk-taking behaviour and so reduce the likelihood of future financial crises.

The UK bank levy has two rates: a full rate on taxable liabilities with a maturity of less than one year and a half rate on taxable liabilities with a maturity of more than one year. This differential is intended to discourage excessive short-term borrowing by the banks in their use of wholesale funding.

Not all liabilities are subject to the levy. First, it is not imposed on the first £20 billion of liabilities. This is to encourage small banks (note that the largest UK banks, such

as HSBC, Barclays and RBS, each have liabilities of over £2 trillion). Second, various liabilities are excluded. These are: (a) gilt repos; (b) retail deposits insured by public schemes such as the UK's Financial Services Compensation Scheme, which guarantees customers' deposits of up to £85 000; (c) a large part of a bank's capital known as Tier 1 capital (see below) – the argument here is that it is important for banks to maintain sufficient funds to meet the demands of its depositors.

Banks are also able to offset against their taxable liabilities holdings of highly liquid assets, such as Treasury bills and cash reserves at the Bank of England. These exclusions and deductions are designed to encourage banks to engage in less risky lending.

The levy rates were initially set at 0.075 and 0.0375 per cent with the intention that the levy raise at least £2.5 billion each year. As the aggregate balance sheets of banks began to shrink, the rates were increased several times. Then in the 2015 Budget it was announced that the levy rates, which at time were 0.21 and 0.105 per cent, were to be gradually reduced until in 2021 they would be 0.1 and 0.05 per cent. With some expressing concerns about the effect of the levy on the international competitiveness of UK global banks, it was also announced that from 2021 the levy would apply only to UK balance sheets.

Bank corporation tax surcharge. The 2015 Budget also saw the announcement of a new 8 per cent corporation tax surcharge on banks. This marked a shift in the tax base from banks' balance sheets to their profits. The 8 per cent surcharge was introduced in January 2016 for all banks with annual profits over £25 million. With the main corporation tax rate at 18 per cent when introduced, the surcharge on banks meant that their effective corporation tax rate was 26 per cent. The Office for Budget Responsibility estimated at the time of the announcement that the surcharge would raise £6.5 billion between 2016/17 and 2020/21. It also forecast that revenues from the bank levy would fall from £3.1 billion to £2.2 billion.

Liquidity, profitability and capital adequacy

As we have seen, banks keep a range of liabilities and assets. The balance of items in this range is influenced by three important considerations: profitability, liquidity and capital adequacy.

Profitability

Profits are made by lending money out at a higher rate of interest than that paid to depositors. The average interest rate received by banks on their assets is greater than that paid by them on their liabilities.

Liquidity

The *liquidity* of an asset is the ease with which it can be converted into cash without loss. Cash itself, by definition, is perfectly liquid.

Some assets, such as money lent at call to other financial institutions, are highly liquid. Although not actually cash, these assets can be converted into cash virtually on demand with no financial penalty. Other short-term inter-bank lending is also very liquid (at least to individual banks: see Box 18.2). The only issue here is one of confidence that the money will actually be repaid. This was a worry in the financial crisis of 2008/9 when many banks stopped lending to each other on the inter-bank market for fear that the borrowing bank might become insolvent.

Other assets, such as gilts, can be converted into cash straight away by selling them on the Stock Exchange, but with the possibility of some financial loss, given that their market price fluctuates. Such assets, therefore, are not as liquid as money at call.

Other assets are much less liquid. Personal loans to the general public or mortgages for house purchase can be redeemed by the bank only as each instalment is paid. Other advances for fixed periods are repaid only at the end of that period.

Banks must always be able to meet the demands of their customers for withdrawals of money. To do this, they must hold sufficient cash or other assets that can be readily turned into cash. In other words, banks must maintain sufficient liquidity.

1. If a bank buys a £500 000 Treasury bill at the start of its 91-day life for £480 000, at roughly what price could it sell it to another financial institution after 45 days? Why is it not possible to predict the precise price when the bill is first purchased?
2. Suppose there were a sudden surge in demand for cash from the general public. Would the existence of inter-bank market loans help to meet the demand in any way?

The balance between profitability and liquidity

Profitability is the major aim of banks and most other financial institutions. However, the aims of profitability and liquidity tend to conflict. In general, the more liquid an asset, the less profitable it is, and vice versa. Personal and business loans to customers are profitable to banks, but highly illiquid. Cash is totally liquid, but earns no profit. Thus financial institutions like to hold a range of assets with varying degrees of liquidity and profitability.

For reasons of profitability, the banks will want to 'borrow short' (at low rates of interest, as are generally paid on current accounts) and 'lend long' (at higher rates of interest, as are normal on personal loans). The difference in the average maturity of loans and deposits is known as the *maturity gap*. In general terms, the larger the maturity gap between loans

Definitions

Liquidity The ease with which an asset can be converted into cash without loss.

Maturity gap The difference in the average maturity of loans and deposits.

and deposits, the greater the profitability. For reasons of liquidity, however, banks will want a relatively small gap: if there is a sudden withdrawal of deposits, banks will need to be able to call in enough loans.

The ratio of an institution's liquid assets to total assets is known as its **liquidity ratio**. For example, if a bank had £100 million of assets, of which £10 million were liquid and £90 million were illiquid, the bank would have a 10 per cent liquidity ratio. If a financial institution's liquidity ratio is too high, it will make too little profit. If the ratio is too low, there will be the risk that customers' demands may not be able to be met: this would cause a crisis of confidence and possible closure. Institutions thus have to make a judgement as to what liquidity ratio is best – one that is neither too high nor too low.

Balances in the central bank, short-term loans (i.e. those listed above) and government bonds with less than 12 months to maturity would normally be regarded as liquid assets.

Why are government bonds that still have 11 months to run regarded as liquid, whereas overdrafts granted for a few weeks are not?

111
p76

As Box 18.2 explains, over the years, banks had reduced their liquidity ratios (i.e. the ratio of liquid assets to total assets). This was not a problem as long as banks could always finance lending to customers by borrowing on the inter-bank market. In the late 2000s, however, banks became increasingly worried about bad debt. They thus felt the need to increase their liquidity ratios and hence cut back on lending and chose to keep a higher proportion of deposits in liquid form. In the UK, for example, banks substantially increased their reserve accounts at the Bank of England.

Secondary marketing and securitisation

As we have seen, one way of reconciling the two conflicting aims of liquidity and profitability is for financial institutions to hold a mixture of liquid and illiquid assets. Another way is through the **secondary marketing** of assets. This is where holders of assets sell them to someone else before the maturity date. This allows banks to close the maturity gap for liquidity purposes, but maintain the gap for profitability purposes.

Certificates of deposit (CDs) are a good example of secondary marketing. CDs are issued for fixed-period deposits in a bank (e.g. one year) at an agreed interest rate. The bank does not have to repay the deposit until the year is up. CDs are thus illiquid liabilities for the bank, and they allow it to increase the proportion of illiquid assets without having a dangerously high maturity gap. But the holder of the CD in the meantime can sell it to someone else (through a broker). It is thus liquid to the holder. Because CDs are liquid to the holder, they can be issued at a relatively low rate of interest and thus allow the bank to increase its profitability.

Another example of secondary marketing is when a financial institution sells some of its assets to another financial

institution. The advantage to the first institution is that it gains liquidity. The advantage to the second one is that it gains profitable assets. The most common method for the sale of assets has been through a process known as **securitisation**.

Securitisation occurs when a financial institution pools some of its assets, such as residential mortgages, and sells them to an intermediary known as a **special purpose vehicle (SPV)**. SPVs are legal entities created by the financial institution. In turn, the SPV funds its purchase of the assets by issuing bonds to investors (noteholders). These bonds are known as **collateralised debt obligations (CDOs)**. The sellers (e.g. banks) get cash now rather than having to wait and can use it to fund loans to customers. The buyers make a profit if the income yielded by the CDOs are as expected. Such bonds can be very risky, however, as the future cash flows may be *less* than anticipated.

The securitisation chain is illustrated in Figure 18.1. The financial institution looking to sell its assets is referred to as the 'originator' or the 'originator-lender'. Working from left to right, we see that the originator-lender sells its assets to another financial institution, the SPV, which then bundles assets together into CDOs and sells them to investors (e.g. banks or pension funds) as bonds. Now working from right to left, we see that by purchasing the bonds issued by the SPV, the investors provide the funds for the SPV's purchase

Definitions

Liquidity ratio The proportion of a bank's total assets held in liquid form.

Secondary marketing Where assets are sold before maturity to another institution or individual. The possibility of secondary marketing encourages people or institutions to buy assets/grant loans in the primary market, knowing that they can sell them if necessary in the secondary market. The sale of existing shares and bonds on the stock market is an example of secondary marketing.

Securitisation Where future cash flows (e.g. from interest rate or mortgage payments) are turned into marketable securities, such as bonds. The sellers (e.g. banks) get cash immediately rather than having to wait and can use it to fund loans to customers. The buyers make a profit by buying below the discounted value of the future income. Such bonds can be very risky, however, as the future cash flows may be less than anticipated.

Special purpose vehicle (SPV) Legal entity created by financial institutions for conducting specific financial functions, such as bundling assets together into fixed-interest bonds and selling them.

Collateralised debt obligations (CDOs) These are a type of security consisting of a bundle of fixed-income assets, such as corporate bonds, mortgage debt and credit card debt.

BOX 18.3 THE RISE OF SECURITISATION**Spreading the risk or securing a crisis?**

The conflict between profitability and liquidity may have sown the seeds for the credit crunch that affected economies across the globe in the second half of the 2000s.

To understand this, consider the size of the 'advances' item in the banking sector's balance sheet – nearly 53 per cent of the value of sterling assets (see Table 18.1). The vast majority of these are to households. Advances secured against property have, in recent times, accounted for around 80 per cent by value of all household advances. Residential mortgages involve institutions lending long.

Securitisation of debt

One way in which individual institutions can achieve the necessary liquidity to expand the size of their mortgage lending (illiquid assets) is through *securitisation*. Securitisation grew especially rapidly in the UK and USA. In the UK this was particularly true amongst banks; building societies have historically made greater use of retail deposits to fund advances.

Securitisation is a form of financial engineering. It provides banks (originator-lenders) with liquidity and enables them to engage in further lending opportunities. It provides the special purpose vehicles with the opportunity to issue profitable securities.

In the period up to 2010 most securitisations in the UK saw the original loans moving off the balance sheet of MFIs and onto the balance sheet of the special purpose vehicle (SPV) issuing the collateralised debt obligations (CDOs). From 2010, however, all securitisations are detailed on the balance sheets of MFIs, including previous securitisations which, as a result, have been brought back on to the balance sheets of MFIs.

The chart shows the rapid growth in the flows of securitised secured loans from an estimated £8 billion in 2000 to over £100 billion by 2008. This increase in securitisation reflects the strong demand amongst investors for CDOs. The attraction of these fixed-income products for the noteholders was the potential for higher returns than on (what were) similarly rated products. However, investors have no recourse should people with mortgages fall into arrears or, worse still, default on their mortgages.

Risk and the sub-prime market

The securitisation of assets is not without risks for all those in the securitisation chain and consequently for the financial system as a whole.

The pooling of advances in itself *reduces* the cash-flow risk facing investors. However, there is a **moral hazard** problem here (see page 135). The pooling of the risks may encourage originator-lenders to lower their credit criteria by offering higher income multiples (advances relative to annual household incomes) or higher loan-to-value ratios (advances relative to the price of housing).

Towards the end of 2006, the USA witnessed an increase in the number of defaults by households on residential mortgages. This was a particular problem in the sub-prime market – higher-risk households with poor credit ratings. Similarly, the number falling behind with their payments rose. This was on the back of rising interest rates.

These problems in the US sub-prime market were the catalyst for the liquidity problem that beset financial systems in 2007 and 2008. Where these assets were securitised, investors, largely other financial institutions, suffered from the contagion arising from arrears and defaults.

of the lender's assets. The SPV is then able to use the proceeds from the bond sales (CDO proceeds) to provide the originator-lender with liquidity.

The effect of secondary marketing is to reduce the liquidity ratio that banks feel they need to keep. It has the effect of increasing their maturity gap.

Dangers of secondary marketing. There are dangers to the banking system, however, from secondary marketing. To the extent that banks individually feel that they can operate with a lower liquidity ratio, so this will lead to a lower

national liquidity ratio. This may lead to an excessive expansion of credit (illiquid assets) in times of economic boom.

Definitions

Moral hazard The temptation to take more risks when you know that someone else will cover the risks if you get into difficulties. In the case of banks taking risks, the 'someone else' may be another bank, the central bank or the government.

Figure 18.1 Securitisation chain

Net securitisations of secured lending to individuals

Note: Data up to 2010 relate to changes in other specialist lenders' sterling net securitisations of secured lending to individuals and housing associations. From 2010 data relate to changes in resident MFI sterling securitised loans secured on dwellings to individuals.

Sources: Based on data from *Statistical Interactive Database*, Bank of England, series LPMVUJD (up to 2010) and LPMB8GO (data published 29 March 2017).

Securitisation also spread the contagion across the world. Investors are global, so that advances, such as an American family's residential mortgage, supporting CDOs are effectively travelling across national borders. This resulted in institutions having to write off debts, a deterioration of their balance sheets, the collapse in the demand for securitised assets and the drying up of liquidity.

The chart shows the collapse of the market for securitised secured lending after the financial crisis. Indeed, the 2010s

were to be characterised by banks *buying back* CDOs from SPVs, including unsold ones. A similar pattern was observed in many countries. This process was accelerated by central banks, which began to accept securitised assets in exchange for liquidity, either as part of programmes of quantitative easing (see Box 22.10) or other liquidity insurance mechanisms (see pages 568–9 for a discussion of liquidity insurance in the UK).

Does securitisation necessarily involve a moral hazard problem?

Also, there is an increased danger of banking collapse. If one bank fails, this will have a knock-on effect on those banks which have purchased its assets. In the specific case of securitisation, the strength of the chain is potentially weakened if individual financial institutions move into riskier market segments, such as *sub-prime* residential mortgage markets. Should the income streams of the originator's assets dry up – for instance, if individuals default on their loans – then the impact is felt by the whole of the chain. In other words, institutions and investors are exposed to the risks of the originator's lending strategy.

The issue of securitisation and its impact on the liquidity of the financial system during the 2000s is considered in Box 18.3.

payment. Capital adequacy is a measure of a bank's capital relative to its assets, where the assets are weighted according to the degree of risk. The more risky the assets, the greater the amount of capital that will be required.

A measure of capital adequacy is given by the *capital adequacy ratio (CAR)*. This is given by the following formula:

$$\text{CAR} = \frac{\text{Common Equity Tier 1 capital} + \text{Additional Tier 1 capital} + \text{Tier 2 capital}}{\text{Risk-weighted assets}}$$

Definitions

Sub-prime debt Debt where there is a high risk of default by the borrower (e.g. mortgage holders who are on low incomes facing higher interest rates and falling house prices).

Capital adequacy ratio (CAR) The ratio of a bank's capital (reserves and shares) to its risk-weighted assets.

K11 Capital adequacy

In addition to sufficient liquidity, banks must have sufficient capital (i.e. funds) to allow them to meet all demands from depositors and to cover losses if borrowers default on

Common equity Tier 1 capital includes bank reserves (from retained profits) and ordinary share capital (equities), where dividends to shareholders vary with the amount of profit the bank makes. Such capital thus places no burden on banks in times of losses as no dividend need be paid. What is more, unlike depositors, shareholders cannot ask for their money back.

Additional Tier 1 (AT1) capital consists largely of preference shares. These pay a fixed dividend (like company bonds). But although preference shareholders have a prior claim over ordinary shareholders on company profits, dividends need not be paid in times of loss.

Tier 2 capital is 'subordinated debt' with a maturity greater than five years. Subordinated debt holders only have a claim on a failing company after the claims of all other bondholders have been met.

Risk-weighted assets are the value of assets, where each type of asset is multiplied by a risk factor. Under the internationally agreed Basel II accord, cash and government bonds have a risk factor of zero and are thus not included. Inter-bank lending between the major banks has a risk factor of 0.2 and is thus included at only 20 per cent of its value; residential mortgages have a risk factor of 0.35; personal loans, credit card debt and overdrafts have a risk factor of 1; loans to companies carry a risk factor of 0.2, 0.5, 1 or 1.5, depending on the credit rating of the company. Thus the greater the average risk factor of a bank's assets, the greater will be the value of its risk-weighted assets, and the lower will be its CAR.

The greater the CAR, the greater the capital adequacy of a bank. Under Basel II, banks were required to have a CAR of at least 8 per cent (i.e. 0.08). They were also required to meet two supplementary CARs. First, banks needed to hold a ratio of Tier 1 capital to risk-weighted assets of at least 4 per cent and, second, a ratio of ordinary share capital to risk-weighted assets of at least 2 per cent. It was felt that these three ratios would provide banks with sufficient capital to meet the demands from depositors and to cover losses if borrowers defaulted. The financial crisis, however, meant a rethink.

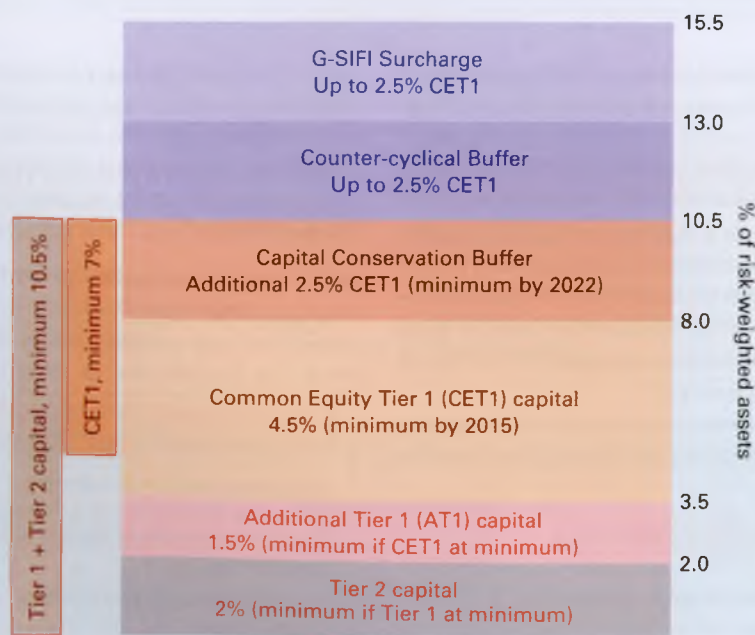

Strengthening international regulation of capital adequacy and liquidity

Capital adequacy. In the light of the financial crisis of 2008/9, international capital adequacy requirements were strengthened by the *Basel Committee on Banking Supervision*, with a first draft in 2010/11 and a final agreement in December 2017. The new 'Basel III' capital requirements, as they are called, will be phased in by 2022. They are summarised in Figure 18.2.

From 2013, banks continued to need a CAR of at least 8 per cent (i.e. 0.08). But, by 2015 were required to operate with a ratio of CET1 to risk-weighted assets of at least 4.5 per cent. From 2016 began a phased introduction of a *capital conservation buffer* raising the CET1 ratio to no less than 7 per cent by 2022. This increases the overall CAR to at least 10.5 per cent.

On top of this, national regulators are required to assess the financial resilience across all financial institutions under

Figure 18.2 Basel III minimum capital requirements, by 1/1/2022

its jurisdiction, particularly in light of economic conditions. This is **macro-prudential regulation**. If necessary, regulators will then apply a *counter-cyclical buffer* to all banks so increasing the CET1 ratio by up to a further 2.5 per cent. This will allow financial institutions to build up a capital buffer in boom times to allow it to be drawn on in times of recession or financial difficulty. It should also help to reduce the likelihood of financial institutions destabilising the economy by amplifying the business cycle.

Large global banks, known as **global systemically important banks** (G-SIBs), will be required to operate with a CET1 ratio of up to 3.5 per cent higher than other banks. The global and systemic importance of these institutions is scored against a series of indicators which determine the magnitude of their additional capital requirements. These indicators include their size and the extent of cross-border activity. The reason for this extra capital requirement – or a *G-SIB systemic buffer* – is that the failure of such an institution could trigger a global financial crisis. This means that the overall CAR for very large financial institutions from 2022 can be as high as 15.5 per cent (see Figure 18.2).

What are the economic arguments for larger 'systemically important banks' (SIBs) having an additional capital requirement?

In the UK it was decided that individual ring-fenced banks (RFBs), as well as large building societies which hold more than £25 billion in deposits, would be required to hold an additional capital buffer in excess of the Basel III requirements. These financial institutions have been identified as domestic systemically important banks (D-SIBs). Hence, this buffer is also referred to as the *D-SIB systemic buffer*. UK bank groups identified as G-SIBs containing a ring-fenced bank are subject to two systemic buffers: the G-SIB systemic buffer at the group level and the D-SIB buffer at the level of the ring-fenced bank.

The UK's domestic systemic buffer depends on the size of risk-weighted assets, with the initial plan for additional capital requirement of up to 3 per cent of these assets. However, depending on the judgement of the Financial Policy Committee, whose job is to ensure the financial resilience of the UK financial sector, the asset bands and the systemic buffer rates applied can be reviewed and adjusted if necessary.

To supplement the risk-based capital requirements, the Basel III framework introduced a *non-risk-based leverage ratio*. Described by regulators as a complementary to the risk-based framework, this requires financial institutions to operate with a Tier 1 capital-to-asset ratio of 3 per cent. In contrast to the risk-based ratios, the assets in the denominator in this ratio are *not* weighted by risk factors.

The impact of the Basel III's capital adequacy requirements was to increase the capital cushions of many banks significantly. Indeed, many exceeded the Basel III requirements, even those for 2022.

Nonetheless, discussions were to continue around the calculation of risk-weighted assets. Because of the

complexity of banks' asset structures, which tend to vary significantly from country to country, it is difficult to ensure that banks are meeting the Basel III requirements. Under proposed amendments, banks would have to compare their own calculations with a 'standardised' model. Their own calculations of risk-based assets would then not be allowed to be lower than 60–90 per cent (known as 'the output floor') of the standardised approach.

There were some concerns raised by some European banks which claimed that this would penalise them, as some of their assets are less risky than the equivalent assets in other countries. For example, Germany argued that mortgage defaults have been rare and thus German mortgage debt should be given a lower weighting than US mortgage debt, where defaults have been more common. If all assets were assessed according to the output floor, several banks, especially in Europe, would be judged to be undercapitalised.

In December 2017 the Basel Committee finally agreed to adopt a revised standardised approach to assessing credit risk. First, financial institutions would not be required to adopt such a 'mechanistic' approach to assessing asset risk. Second, the output floor for the risk weighting of assets was set at 72.5 per cent, meaning that the risk of an asset, such as a mortgage, could not be set at less than 72.5 per cent of the level used by regulators in their standardised models.

Liquidity. The financial crisis highlighted the need for banks not only to hold adequate levels of capital but also to manage their liquidity better. The Basel III framework includes a *liquidity coverage ratio* (LCR). This requires that financial institutions have high quality liquid assets (HQLAs) to cover the expected net cash flow over the next 30 days. From its implementation in 2015, the minimum LCR ratio (HQLAs relative to the expected 30-day net cash flow) will rise from 60 per cent to 100 per cent by 2022.

Net stable funding ratio (NSFR). As part of the Basel III reforms, a *net stable funding ratio* (NSFR) was to become a regulatory standard from 2018. This takes a longer-term view of the funding profile of banks by focusing on the reliability of liabilities as a source of funds, particularly in circumstances of extreme stress. The NSFR is the ratio of stable liabilities to assets likely to require funding (i.e. assets where there is a likelihood of default).

On the liabilities side, these will be weighted by their expected reliability – in other words, by the stability of these

Definitions

Macro-prudential regulation Regulation which focuses not on a single financial institution but on the financial system as a whole and which monitors its impact on the wider economy.

Global systemically important banks (SIBs) Bank identified by a series of indicators as being significant players in the global financial system.

funds. This weighting will reflect the maturity of the liabilities and the propensity of lenders to withdraw their funds. For example, Tier 1 and 2 capital will have a weighting of 100 per cent; term deposits with less than one year to maturity will have a weighting of 50 per cent; and unsecured whole-sale funding will have a weighting of 0 per cent. The result of these weightings is a measure of *stable funding*.

On the assets side, these will be weighted by the likelihood that they will have to be funded over the course of one year. This means that they will be weighted by their liquidity, with more liquid assets requiring less funding. Thus cash will have a zero weighting, while more risky assets will have weightings up to 100 per cent. The result is a measure of *required funding*.

Banks will need to hold a stable-liabilities-to-required-funding ratio (NSFR) of at least 100 per cent.

The central bank

The Bank of England is the UK's *central bank*. The European Central Bank (ECB) is the central bank for the countries using the euro. The Federal Reserve Bank of America (the Fed) is the USA's central bank. All countries with their own currency have a central bank. They fulfil two vital roles in the economy.

The first is to oversee the whole monetary system and ensure that banks and other financial institutions operate as stably and as efficiently as possible.

The second is to act as the government's agent, both as its banker and in carrying out monetary policy.

The Bank of England traditionally worked in very close liaison with the Treasury, and there used to be regular meetings between the Governor of the Bank of England and the Chancellor of the Exchequer. Although the Bank may have disagreed with Treasury policy, it always carried it out. In 1997, however, the Bank of England was given independence to decide the course of monetary policy. In particular, this meant that the Bank of England and not the government would now decide interest rates.

Another example of an independent central bank is the European Central Bank (ECB), which operates the monetary policy for the eurozone countries. Similarly, the Fed is independent of both the President and Congress, and its chair is generally regarded as having great power in determining the country's economic policy. Although the degree of independence of central banks from government varies considerably around the world, there has been a general move in recent years to make central banks more independent.

Within their two broad roles, central banks typically have a number of different functions. Although we will consider the case of the Bank of England, the same principles apply to other central banks, such as the ECB and the Fed.

It issues notes

The Bank of England is the sole issuer of banknotes in England and Wales. (In Scotland and Northern Ireland, retail banks issue notes.) The issue of notes is done through the Issue Department, which organises their printing. This is one of two departments of the Bank of England. The other is the Banking Department, through which it deals with banks.

Table 18.2 shows the consolidated balance sheet across the two departments of the Bank of England for the end of March 2016. As we shall discuss shortly, the balance sheet of the Bank of England was to expand markedly following the financial crisis. This was the case for many central banks across the world.

On the balance sheet we see the outstanding value of the banknote issue (notes in circulation). The amount of

banknotes issued by the Bank of England depends largely on the demand for notes from the general public. If people draw more cash from their bank accounts, the banks will have to draw more cash from their balances in the Bank of England. These balances are held in the Banking Department. The Banking Department will thus have to acquire more notes from the Issue Department, which will simply print more in exchange for extra government or other securities supplied by the Banking Department.

It acts as a bank

To the government. It keeps the two major government accounts: the 'Exchequer' and the 'National Loans Fund'. Taxation and government spending pass through the Exchequer. Government borrowing and lending pass through the National Loans Fund. The government tends to keep its deposits in the Bank of England (the public deposits item in the balance sheet) to a minimum. If the deposits begin to build up (from taxation), the government will probably spend them on paying back government debt. If, on the other hand, it runs short of money, it will simply borrow more.

To banks. Banks' deposits in the Bank of England consist of reserve balances and cash ratio deposits (see Table 18.2). The reserve balances are used for clearing purposes between the banks but are also a means by which banks can manage their liquidity risk. Therefore, the reserve balances provide banks with an important buffer stock of liquid assets.

To overseas central banks. These are deposits of sterling (or euros in the case of the ECB) made by overseas authorities as part of their official reserves and/or for purposes of intervening in the foreign exchange market in order to influence the exchange rate of their currency.

It operates the government's monetary policy

The Bank of England's Monetary Policy Committee (MPC) sets Bank Rate at its regular meetings. This nine-member committee consists of four experts appointed by the Chancellor of the Exchequer and four senior members of the Bank of England, plus the Governor in the chair.

By careful management of the liquidity of the financial system the Bank of England aims to keep interest rates in line with the level decided by the MPC. It is able to do this through operations in the money markets. These are known as *open-market operations (OMOs)*. If shortages of liquidity are driving up short-term interest rates above the desired level, the Bank of England purchases securities (gilts and/or Treasury bills) on the open market: e.g. through reverse repos (a repo to the banks). This releases liquidity into the financial system and puts downward pressure on interest rates. Conversely, if excess liquidity is driving down interest rates, the Bank of England will sell more securities. When these are purchased, this will reduce banks' reserves and thereby put upward pressure on interest rates.

In normal times the Bank of England manages the aggregate amount of reserves through weekly auctions of

1-week repos. It also agrees with commercial banks an *average* amount of overnight reserve balances they would hold over the period between MPC meetings. Individual banks are then able to deposit or borrow reserves using the Bank of England's *operational standing facilities*. Banks deposit reserves at the deposit facility rate if they have an excess of reserves or borrow reserves from the Bank of England if they are short of reserves through overnight repo operations priced at the lending facility rate. The deposit rate is set below the Bank Rate, while the borrowing rate is set above the Bank Rate. This process is known as *reserve averaging*.

The operational standing facilities are designed to provide banks with excess or surplus reserves an incentive to trade them with other banks. Banks would prefer to borrow reserves at a lower interest rate or deposit reserves at a higher interest rate than they can through the operational standing facilities. By managing the aggregate amount of reserves, agreeing an average overnight holding of reserves and providing operational standing facilities, the Bank of England aims to establish a 'corridor' for inter-bank rates between its lending and deposit rates.

From its inception in March 2006 up until the middle of 2007 the corridor system kept short-term money market rates close to Bank Rate. But then, with growing concerns about the solvency of banks, the inter-bank market ceased to operate effectively and banks were forced to make greater use of the more costly operational standing facilities and draw reserves from the Bank. In other words, banks could no longer trade reserves with each other (in order to meet their average reserve target) at a lower cost than by using the Bank's standing facilities.

As the financial crisis unfolded it became increasingly difficult for the Bank to meet its monetary policy objectives while maintaining financial stability. New policies were thus adopted. October 2008 also saw the Bank of England stop short-term open-market operations. The key priority was now ensuring sufficient liquidity and so the focus switched to longer-term OMOs.

Definitions

Open-market operations (OMOs) The sale (or purchase) by the authorities of government securities in the open market in order to reduce (or increase) money supply and thereby affect interest rates.

Operational standing facilities Central bank facilities by which individual banks can deposit reserves or borrow reserves.

Reserve averaging The process whereby individual banks manage their average level of overnight reserves between MPC meetings using the Bank of England's operational standing facilities and/or the inter-bank market.

The advent of quantitative easing. March 2009 saw the Bank begin its programme of **quantitative easing (QE)** (see Box 22.10). The aim was to increase the amount of money in the financial system and thereby stimulate bank lending and hence aggregate demand. QE involved the Bank creating electronic money and using it to purchase assets, mainly government bonds, predominantly from non-deposit-taking financial institutions, such as unit trusts, insurance companies and pension funds. These institutions would then deposit the money in banks, which could lend it to businesses and consumers for purposes of spending.

Given this large quantity of 'new money' being supplied to the banking system it was decided to end the practice of banks voluntarily setting their own reserve targets between meetings of the MPC. Instead, all reserves were now to be remunerated at the official Bank Rate. The effect of remunerating all reserves was to replace the 'corridor system' with a 'floor system' since no commercial bank would be willing to lend surplus reserves at any rate lower than the Bank Rate. Therefore, the inter-bank rate would not fall below the Bank Rate.

The Bank of England's programme of asset purchases were conducted by a subsidiary of the Bank of England, known as the Asset Purchase Facility (APF). We can see the effect of these asset purchases in the Bank of England's balance sheet in Table 18.2: by far the largest item on the assets side is 'Loans to Asset Purchase Facility'. Another way of seeing their effect is through the increase in the Bank of England's sterling reserve liabilities (see Figure 18.3). These are the monies held by commercial banks in their accounts with the central bank, either for purposes of settling accounts with other commercial banks or for managing their liquidity.

Although the financial crisis saw changes to the Bank's monetary framework, the Bank argued that, in normal times, the reserves averaging framework remained an effective framework for implementing monetary policy. The case for resuming the framework was thus to be kept under review.

It provides liquidity, as necessary, to banks

Financial institutions engage in maturity transformation. While most customer deposits can be withdrawn instantly, financial institutions will have a variety of lending commitments, some of which span many years. Hence, the Bank of England acts as a 'liquidity backstop' for the banking system. It attempts to ensure that there is always an adequate supply of liquidity to meet the legitimate demands of depositors in banks.

Banks' reserve balances provide them with some liquidity insurance. However, the Bank of England needs other means by which to provide both individual banks and the banking system with sufficient liquidity. The financial crisis, for instance, saw incredible pressure on the aggregate liquidity of financial system. The result is that the UK has three principal insurance facilities:

Definitions

Quantitative easing (QE) A deliberate attempt by the central bank to increase the money supply by buying large quantities of securities through open-market operations. These securities could be securitised mortgage and other private-sector debt or government bonds.

Figure 18.3 Bank of England sterling reserve liabilities

Source: Based on data from *Statistical Interactive Database*, series LPMBL22 (Bank of England) (data published 29/9/17).

Index long-term repos (ILTRS). Each month the Bank of England provides MFIs with reserves for a six-month period secured against collateral and indexed against the Bank Rate. Financial institutions can borrow reserves against different levels of collateral. These levels reflect the quality and liquidity of the collateral. The reserves are distributed through an auction where financial institutions indicate, for their particular level of collateral, the number of basis points over the Bank Rate (the ‘spread’) they are prepared to pay. Successful bidders pay a uniform price: this is the clearing price at which the Bank of England’s preparedness to lend reserves has been met. The Bank of England will provide a greater quantity of reserves if, from the bids, it observes a greater demand for it to provide liquidity insurance.

Discount window facility (DWF). This on-demand facility allows financial institutions to borrow government bonds (gilts) for 30 days against different classes of collateral. They pay a fee to do so. The size of the fee is determined by both the level of collateral and the size of the collateral being traded. Gilts are long-term government debt instruments used by government as a means of financing its borrowing. Gilts can be used in repo operations as a means of securing liquidity. In this way, financial institutions are performing a liquidity upgrade of their collateral. However, the Bank may agree to lend cash rather than gilts if gilt repo markets cease to provide the necessary amount of liquidity, perhaps because the cost of doing so becomes prohibitively high. Financial institutions can look to roll over the funds obtained from the DWF beyond the normal 30 days.

Contingent term repo facility (CTRP). This is a facility which the Bank of England can activate in exceptional circumstances. As with the ILTRS, financial institutions can obtain liquidity secured against different levels of collateral through an auction. However, the terms, including the maturity of the funds, are intended to be more flexible.

It oversees the activities of banks and other financial institutions

The Bank of England requires all recognised banks to maintain adequate liquidity: this is called **prudential control**.

In May 1997, the Bank of England ceased to be responsible for the detailed supervision of banks’ activities. This responsibility passed to the Financial Services Authority (FSA). But the financial crisis of the late 2000s raised concerns about whether the FSA, the Bank of England and HM Treasury were sufficiently watchful of banks’ liquidity and the risks of liquidity shortage. Some commentators argued that a much tighter form of prudential control needed to be imposed.

In 2013, a new regulatory framework came into force, with an enhanced role for the Bank of England.

First, the Bank’s *Financial Policy Committee* became responsible for **macro-prudential regulation**. This type of regulation takes a broader view of the financial system. It considers, for instance, its health or resilience to possible

shocks and its propensity to create macroeconomic instability through credit creation.

Second, the prudential regulation of individual firms was transferred from the FSA to the *Prudential Regulation Authority*, a subsidiary of the Bank of England.

Third, the *Financial Conduct Authority (FCA)* took responsibility for consumer protection and the regulation of markets for financial services. The FCA is an independent body accountable to HM Treasury. The FSA was wound up.

1. *Would it be possible for an economy to function without a central bank?*
2. *What effect would a substantial increase in the sale of government bonds and Treasury bills have on interest rates?*

It operates the government’s exchange rate policy

The Bank of England manages the country’s gold and foreign currency reserves on behalf of the Treasury. This is done through the **exchange equalisation account**. The Treasury sets the Bank an annual remit for the management of the account (for example, setting a limit on changes in the level of reserves).

By buying and selling foreign currencies on the foreign exchange market, the Bank of England can affect the exchange rate. For example, if there were a sudden selling of sterling (due, say, to bad trade figures and a resulting fear that the pound would depreciate), the Bank of England could help to prevent the pound from falling by using reserves to buy up pounds on the foreign exchange market. Intervention in the foreign exchange market is examined in detail in Chapter 25.

The money markets

We now turn to the money markets where participants, including financial institutions, are able to lend and borrow to and from each other. In these markets debts typically have maturities of less than one year.

It has been traditional to distinguish money markets from another set of financial markets known as **capital markets**. In capital markets borrowing typically takes place over a longer

Definitions

Capital market A financial market where longer-term debt instruments, like government bonds (gilts), can be bought and sold.

duration. Capital markets include the market for ordinary shares and longer-term government debt instruments, known in the UK as gilts, which pay periodic fixed payments (known as 'coupons'). However, as we shall see, the boundaries in practice between these markets are rather difficult to pinpoint.

Central banks are also important participants in money markets. It is through the money markets that a central bank exercises control over interest rates. As we have seen throughout this chapter, the financial system has evolved rapidly and the money markets are no exception. This has widened the lending and borrowing opportunities for financial institutions.

We take the case of the London money market, which is normally divided into the 'discount' and 'repo' markets and the 'parallel' or 'complementary' markets.

 *What how might the development of new financial instruments affect a central bank's conduct of monetary policy?*

The discount and repo markets

The discount market. The discount market is the market for commercial or government bills. In the UK, government bills are known as Treasury bills and operations are conducted by the Debt Management Office, usually on a weekly basis. Treasury Bills involve short-term lending, say for one or three months, which, in conjunction with their low default risk, make them highly liquid assets. These markets are examples of **discount markets** because the instruments being traded are issued at a discount. In other words, the redemption price of the bills is greater than the issue price. The redemption price is fixed, but the issue price depends on demand and supply in the discount market. The rate of discount on bills can be calculated by the size of the discount relative to the redemption value and is usually expressed as an annual rate.

The discount market is also known as the 'traditional market' because it was the market in which many central banks traditionally used to supply central bank money to financial institutions. For instance, if the Bank of England wanted to increase liquidity in the banking system it could purchase from the banks Treasury bills which had yet to reach maturity. This process is known as **rediscounting**. The Bank of England would pay a price below the face value, thus effectively charging interest to the banks. The price could be set so that the 'rediscount rate' reflected the Bank Rate.

The repo market The emergence of the repo market is a more recent development dating back in the UK to the 1990s. As we saw earlier, repos have become an important source of wholesale funding for financial institutions. But they have also become an important means by which central banks can affect the liquidity of the financial system both to implement monetary policy and to ensure financial stability.

By entering into a repo agreement the Bank of England can buy securities, such as gilts, from the banks (thereby

supplying them with money) on the condition that the banks buy them back at a fixed price and on a fixed date. The repurchase price will be above the sale price. The difference is the equivalent of the interest that the banks are being charged for having what amounts to a loan from the Bank of England. The repurchase price (and hence the 'repo rate') is set by the Bank of England to reflect the Bank Rate chosen by the MPC.

The Bank of England first began using repo operations to manage the liquidity of the financial system in 1997 when it undertook daily operations, with the repurchases of securities usually occurring two weeks after the initial sale. This system was refined so that in 2006 operations became weekly and the repurchase period typically shortened to one week.

However, the financial crisis caused the Bank to modify its repo operations to manage liquidity for both purposes of monetary policy, but increasingly to ensure financial stability. These changes included a widening of the securities eligible as collateral for loans, a move to longer-term repo operations and a suspension of short-term repo operations.

So central banks, like the Bank of England, are prepared to provide central bank money through the creation of bank reserves. Central banks are thus the ultimate guarantor of sufficient liquidity in the monetary system and, for this reason, are known as the **lender of last resort**.

The parallel money markets

Like repo markets, complementary or parallel money markets have grown rapidly in recent years. In part, this reflects the opening up of markets to international dealing, the deregulation of banking and money market dealing and the desire of banks to keep funds in a form that can be readily switched from one form of deposit to another, or from one currency to another.

Examples of parallel markets include the markets for *certificates of deposit* (CDs), *foreign currencies markets* (dealings in foreign currencies deposited short term in the country) and *the inter-bank market*. We focus here on the important inter-bank market (details on other parallel markets can be found in Case Study 18.11 on the student website).

The inter-bank market. The inter-bank market involves wholesale loans from one bank to another over periods from one day to up to several months. Banks with surplus liquidity lend to other banks, which then use this as the basis for loans to individuals and companies.

Figure 18.4 One-month LIBOR and Bank Rate

Source: Based on data from *Statistical Interactive Database*, series IUMABEDR and IUMAVYRA (Bank of England) (data published 1/11/17).

The rate at which banks lend to each other is known as the IBOR (inter-bank offered rate). The IBOR has a major influence on the other rates that banks charge. In the euro-zone, the IBOR is known as Euribor. In the UK, it is known as the LIBOR (where 'L' stands for 'London'). As inter-bank loans can be anything from overnight to 12 months, the IBOR will vary from one length of loan to another.

Inter-bank interest rates tend to be higher than those in the discount and repo markets and sensitive to the aggregate

level of liquidity in the financial system. As Figure 18.4 shows, during the financial crisis of 2008 inter-bank lending rates rose significantly above the Bank Rate. At the same time lending virtually ceased as banks became worried that the bank they were lending to might default.

Why should Bank of England determination of the rate of interest in the discount and repo markets also influence rates of interest in the parallel markets?

Section summary

1. Central to the financial system are the retail and wholesale arms of banks. Between them they provide the following important functions: giving expert advice, channelling capital to areas of highest return, maturity transformation, risk transformation and the transmission of payments. During the financial crisis the systemic importance of some of these banks meant they had to be rescued by governments. They were seen as too important or too big to fail (TBF).
2. Banks' liabilities include both sight and time deposits. They also include certificates of deposit and repos. Their assets include: notes and coin, balances with the Bank of England, market loans, bills of exchange (Treasury bills and commercial bills), reverse repos, advances to customers (the biggest item – including overdrafts, personal loans, credit card debt and mortgages) and investments (government bonds and inter-bank investments). In the years up to 2008 they had increasingly included securitised assets.
3. Banks aim to make profits, but they must also have a sufficient capital base and maintain sufficient liquidity. Liquid assets, however, tend to be relatively unprofitable and profitable assets tend to be relatively illiquid. Banks therefore need to keep a balance of profitability and liquidity in their range of assets.
4. The Bank of England is the UK's central bank. It issues notes; it acts as banker to the government, to banks and to various overseas central banks; it ensures sufficient liquidity for the financial sector; it operates the country's monetary and exchange rate policy.
5. The money market is the market in short-term deposits and loans. It consists of the discount and repo markets and the parallel money markets.
6. Through repos the Bank of England can provide liquidity to the banks at the rate of interest chosen by the Monetary Policy Committee (Bank Rate). It is always prepared to lend in this way in order to ensure adequate liquidity in the economy. The financial crisis saw the Bank adapt its operations in the money market and introduce new mechanisms for providing liquidity insurance, including the Discount Window Facility and longer-term repos.
7. The parallel money markets consist of various markets in short-term finance between various financial institutions.

18.3 THE SUPPLY OF MONEY

Definitions of the money supply

If money supply is to be monitored and possibly controlled, it is obviously necessary to measure it. But what should be included in the measure? Here we need to distinguish between the monetary base and broad money.

The **monetary base** (or 'high-powered money') consists of cash (notes and coin) in circulation outside the central bank. Thus, in the eurozone, the monetary base is given by cash (euros) in circulation outside the ECB.¹ In 1970, the stock of notes and coins in circulation in the UK was around £4 billion, equivalent to 7 per cent of annual GDP. By 2017 this had grown to over £80 billion, but equivalent to only just over 4 per cent of annual GDP.

But the monetary base gives us a very poor indication of the effective money supply, since it excludes the most important source of liquidity for spending: namely, bank deposits. The problem is which deposits to include. We need to answer three questions:

- Should we include just sight deposits, or time deposits as well?
- Should we include just retail deposits, or wholesale deposits as well?
- Should we include just bank deposits, or building society (savings institution) deposits as well?

In the past there has been a whole range of measures, each including different combinations of these accounts. However, financial deregulation, the abolition of foreign exchange controls and the development of computer technology have led to huge changes in the financial sector throughout the world. This has led to a blurring of the distinctions between different types of account. It has also made it very easy to switch deposits from one type of account to another. For these reasons, the most usual measure that countries use for money supply is **broad money**, which in most cases includes both time and sight deposits, retail and wholesale deposits, and bank and building society (savings institution) deposits.

In the UK, this measure of broad money is known as M4. In most other European countries and the USA it is known as M3. There are, however, minor differences between countries in what is included. (Official UK and eurozone measures of money supply are given in Box 18.4.)

In 1970, the stock of M4 in the UK was around £25 billion, equivalent to 48 per cent of annual GDP. By 2017 this had

grown to £2.3 trillion, equivalent to about 115 per cent of annual GDP.

As we have seen, bank deposits of one form or another constitute by far the largest component of (broad) money supply. To understand how money supply expands and contracts, and how it can be controlled, it is thus necessary to understand what determines the size of bank deposits. Banks can themselves expand the amount of bank deposits, and hence the money supply, by a process known as 'credit creation'.

The creation of credit: the simplest case

To illustrate this process in its simplest form, assume that banks have just one type of liability – deposits – and two types of asset – balances with the central bank (to achieve liquidity) and advances to customers (to earn profit).

Banks want to achieve profitability while maintaining sufficient liquidity. Assume that they believe that sufficient liquidity will be achieved if 10 per cent of their assets are held as balances with the central bank. The remaining 90 per cent will then be in advances to customers. In other words, the banks operate a 10 per cent liquidity ratio.

Assume initially that the combined balance sheet of the banks is as shown in Table 18.3. Total deposits are £100 billion, of which £10 billion (10 per cent) are kept in balances with the central bank. The remaining £90 billion (90 per cent) are lent to customers.

Now assume that the government spends more money – £10 billion, say, on roads or hospitals. It pays for this with cheques drawn on its account with the central bank. The people receiving the cheques deposit them in their banks. Banks return these cheques to the central bank and their balances correspondingly increase by £10 billion. The combined banks' balance sheet now is shown in Table 18.4.

But this is not the end of the story. Banks now have surplus liquidity. With their balances in the central bank having

Monetary base Notes and coin outside the central bank.

Broad money Cash in circulation plus retail and wholesale bank and building society deposits.

¹ Before 2006, there used to be a measure of narrow money called 'M0' in the UK. This included cash in circulation outside the Bank of England and banks' non-interest-bearing 'operational balances' in the Bank of England, with these balances accounting for a tiny proportion of the whole. Since 2006, the Bank of England has allowed banks to hold interest-bearing reserve accounts, which are much larger than the former operational balances. The Bank of England thus decided to discontinue M0 as a measure and focus on cash in circulation as its measure of the monetary base.

BOX 18.4

UK AND EUROZONE MONETARY AGGREGATES

CASE STUDIES AND APPLICATIONS

How long is a piece of string?

UK measures

There are two main measures of the money supply in the UK: cash in circulation (i.e. outside the Bank of England) and M4. Cash in circulation is referred to as the 'monetary base' or 'narrow money' and M4 is referred to as 'broad money' or simply as 'the money supply'. In addition, there is a measure called 'Retail deposits and cash in M4' (previously known as M2). This measure excludes wholesale deposits.

The definitions are as follows:

Cash in circulation. This is all cash held outside the Bank of England: in other words by individuals, firms, banks and the public sector.

Retail deposits and cash in M4. Cash in circulation with the public (but not cash in banks and building societies) + private-sector retail sterling deposits in banks and building societies.

M4. Retail deposits and cash in M4 + private-sector wholesale sterling deposits (including repos) in banks and building societies + private-sector holdings of sterling certificates of deposit, commercial paper and other short-term paper issued by MFIs.

Table (a) gives the figures for these aggregates for the end of August 2017.

(a) UK monetary aggregates, end August 2017 (not seasonally adjusted)

	£ billion
Cash in circulation (i.e. outside the Bank of England) ^a	82.46
– Cash in banks and cash held outside the UK ^{a,b}	–8.10
+ Private-sector retail bank and building society deposits	1 586.07
= Retail deposits and cash in M4	1 660.44
+ Private-sector wholesale bank and building society deposits + CDs	667.83
= M4	2 328.26

a Cash in circulation is calculated mid-month and thus the figure slightly understates the end-month value.

b Row 4 minus rows 3 and 1.

Why is cash in banks and building societies not included in M4?

Eurozone measures

Although the ECB uses three measures of the money supply, they are different from those used by the Bank of England. The narrowest definition (M1) includes overnight deposits (i.e. call money) as well as cash, and is thus much broader than the UK's narrow money measure. The broadest eurozone measure (M3) is again broader than the UK's broadest measure (M4), since the eurozone measure includes various other moderately liquid assets. The definitions of the three eurozone aggregates are:

M1. Cash in circulation with the public + overnight deposits.

M2. M1 + deposits with agreed maturity up to two years + deposits redeemable up to three months' notice.

M3. M2 + repos + money-market funds and paper + debt securities with residual maturity up to two years.

Table (b) gives the figures for UK money supply for each of these three ECB measures – again, for the end of August 2017.

(b) UK money supply using ECB measures: end August 2017 (not seasonally adjusted)

	£ billion
Currency in circulation	75.09
+ Overnight deposits	1 610.09
= M1	1 685.49
+ Deposits with agreed maturity up to 2 years	168.93
+ Deposits redeemable up to 3 months' notice	485.45
= M2	2 339.87
+ Repos	327.65
+ Money market funds and paper	114.47
= M3	2 781.99

Note: M1, M2 and M3 estimates relate to non-MFI residents, excluding central government and contain deposits in all currencies.

Data published September 2017.

What are the benefits of including these additional items in the broad measure of money supply?

increased to £20 billion, they now have a liquidity ratio of 20/110, or 18.2 per cent. If they are to return to a 10 per cent liquidity ratio, they need only retain £11 billion as balances at the central bank (£11 billion/£110 billion = 10 per cent). The remaining £9 billion they can lend to customers.

Assume now that customers spend this £9 billion in shops and the shopkeepers deposit the cheques in their bank

accounts. When the cheques are cleared, the balances in the central bank of the *customers'* banks will duly be debited by £9 billion, but the balances in the central bank of the *shopkeepers'* banks will be credited by £9 billion, leaving overall balances in the central bank unaltered. There is still a surplus of £9 billion over what is required to maintain the 10 per cent liquidity ratio. The new deposits of £9 billion in the

Table 18.4 The initial effect of an additional deposit of £10 billion

Liabilities	£bn	Assets	£bn
Deposits (old)	100	Balances with the central bank (old)	10
Deposits (new)	10	Balances with the central bank (new)	10
		Advances	90
Total	110	Total	110

shopkeepers' banks, backed by balances in the central bank, can thus be used as the basis for further loans. Ten per cent (i.e. £0.9 billion) must be kept back in the central bank, but the remaining 90 per cent (i.e. £8.1 billion) can be lent out again.

When the money is spent and the cheques are cleared, this £8.1 billion will still remain as surplus balances in the central bank and can therefore be used as the basis for yet more loans. Again, 10 per cent must be retained and the remaining 90 per cent can be lent out. This process goes on and on until eventually the position is as shown in Table 18.5.

The initial increase in balances with the central bank of £10 billion has allowed banks to create new advances (and hence deposits) of £90 billion, making a total increase in money supply of £100 billion.

This effect is known as the **bank deposits multiplier**. In this simple example with a liquidity ratio of 1/10 (i.e. 10 per cent), the bank deposits multiplier is 10. An initial increase in deposits of £10 billion allowed total deposits to rise by £100 billion. In this simple world, therefore, the bank deposits multiplier is the inverse of the liquidity ratio (l).

$$\text{Bank deposits multiplier} = 1/l$$

- ?** If banks choose to operate a 20 per cent liquidity ratio and receive extra cash deposits of £10 million,
- How much credit will ultimately be created?
 - By how much will total deposits have expanded?
 - What is the size of the bank deposits multiplier?

Table 18.5 The full effect of an additional deposit of £10 billion

Liabilities	£bn	Assets	£bn
Deposits (old)	100	Balances with the central bank (old)	10

(new: subsequent)	90	Advances (old)	90
		Advances (new)	90
Total	200	Total	200

* LOOKING AT THE MATHS

The process of credit creation can be expressed mathematically as the sum of an infinite series. If a is the proportion of any deposit that is lent by banks, where $a = 1 - l$, then total deposits will expand by

$$\begin{aligned} D_t &= D_0(1 + a + a^2 + a^3 + \dots) \\ &= D_0(1/1 - a) \\ &= D_0(1/l) \end{aligned} \quad (1)$$

Thus if there were an initial additional deposit (D_0) of £100 and if $a = 0.8$, giving a liquidity ratio (l) of 0.2, total deposits would expand by $£100 \times 1/0.2 = £500$. The bank deposits multiplier is 5.

Proof of equation (1) is given in Maths Case 18.1 on the student website.

Note that the maths of the bank deposits multiplier is very similar to that of the Keynesian expenditure multiplier of section 17.2 (see Maths Case 17.1 on the student website). The economics, however, is quite different. The Keynesian multiplier is concerned with the effects of increased demand on real national output. The bank deposits multiplier is simply concerned with money creation.

TC 15
p535

The creation of credit: the real world

In practice, the creation of credit is not as simple as this. There are three major complications.

Banks' liquidity ratio may vary

Banks may choose a different liquidity ratio. At certain times, banks may decide that it is prudent to hold a bigger proportion of liquid assets. For example, if banks are worried about increased risks of default on loans, they may choose to hold a higher liquidity ratio to ensure that they have enough to meet customers' needs. This was the case in the late 2000s when many banks became less willing to lend to other banks for fear of the other banks' assets containing sub-prime debt. Banks, as a result, hoarded cash and became more cautious about granting loans.

On the other hand, there may be an upsurge in consumer demand for credit. Banks may be very keen to grant additional loans and thus make more profits, even though they have acquired no additional assets. They may simply go ahead and expand credit, and accept a lower liquidity ratio.

Customers may not want to take up the credit on offer. Banks may wish to make additional loans, but customers may not want to borrow. There may be insufficient demand. But will

Definition

Bank deposits multiplier The number of times greater the expansion of bank deposits is than the additional liquidity in banks that causes it: $1/l$ (the inverse of the liquidity ratio).

the banks not then lower their interest rates, thus encouraging people to borrow? Possibly; but if they lower the rate they charge to borrowers, they must also lower the rate they pay to depositors. But then depositors may switch to other institutions such as building societies.

How will an increased mobility of savings and other capital between institutions affect this argument?

Banks may not operate a simple liquidity ratio

The fact that banks hold a number of fairly liquid assets, such as short-term loans to other banks on the inter-bank market, bills of exchange and certificates of deposit, makes it difficult to identify a simple liquidity ratio. For example, if banks use £1 million in cash to purchase £1 million of bills, can we assume that the liquidity ratio has remained exactly the same? In other words, can we assume that *near money* assets, such as bills, are just as liquid as cash? If we assume that they are not, then has the liquidity ratio fallen? If so, by how much?

Banks do not see a clear-cut dividing line between liquid and non-liquid assets. They try to maintain a rough balance across the liquidity range, but the precise composition of assets will vary as interest rates on the various assets vary, and as the demands for liquidity vary.

In practice, therefore, the size of the bank deposits multiplier will vary and is thus difficult to predict in advance.

Is the following statement true: 'The greater the number of types of asset that are counted as being liquid, the smaller will be the bank deposits multiplier'?

Some of the extra cash may be withdrawn by the public

If extra cash comes into the banking system, and as a result extra deposits are created, part of them may be held by households and non-bank firms (known in this context as the *non-bank private sector*) as cash outside the banks. In other words, some of the extra cash leaks out of the banking system. This will result in an overall multiplier effect that is smaller than the full bank deposits multiplier. This overall multiplier is known as the *money multiplier*. It is defined as the rise in total money supply expressed as a proportion of the rise in the monetary base that caused it: $\Delta M_s / \Delta M_b$ (where M_s is total broad money supply and M_b is the monetary base). Box 18.5 shows how the money multiplier is calculated.

The broad money multiplier in the UK

In the UK, the principal money multiplier measure is the broad money multiplier. This is given by $\Delta M_4 / \Delta M_b$, where M_b in this case is defined as cash in circulation with the public plus banks' interest-bearing deposits (reserve accounts) at the Bank of England.

Another indicator of the broad money multiplier is simply the ratio of the *level* of (as opposed to the change in) M_4 relative to the *level* of cash in circulation with the public and banks' reserve accounts at the central bank. This 'levels'

relationship is shown in Figure 18.5 and helps us to analyse the longer-term relationship between the stocks of broad money and the monetary base.

From Figure 18.5 we can see how broad money grew rapidly relative to the monetary base during the late 1980s and into the early 1990s. From the early 1990s to the mid-2000s, the level of M_4 relative to the monetary base fluctuated in a narrow range.

From May 2006 the Bank of England began remunerating banks' reserve accounts at the official Bank Rate. This encouraged banks to increase their reserve accounts at the Bank of England and led to a sharp fall in the broad money multiplier. It then decreased further during 2009. The significant decline in the ratio of broad to narrow money in 2009, in 2011/12 and again in 2016/17 coincided with the Bank of England's programme of asset purchases (quantitative easing) which led to a large increase in banks' reserves. The point is that the increase in the monetary base did not lead to the same percentage increase in broad money, as banks were more cautious about lending and chose to keep higher reserves. The policy of quantitative easing is discussed more in Chapter 22.

In the next section we focus on those factors which help to explain movements in the money multiplier and changes in the money supply.

Which would you expect to fluctuate more, the money multiplier ($\Delta M_4 / \Delta \text{cash}$), or the simple ratio, M_4 / cash , illustrated in Figure 18.4?

What causes money supply to rise?

Money supply can change for a number of reasons. We consider five sets of circumstances which can cause the money supply to rise.

Central bank action

The central bank may decide that the stock of money is too low and that this is keeping up interest rates and restraining spending in the economy. In such circumstances, it may choose to create additional money.

As we saw above, this was the case following the financial crisis of 2007/8 when the Bank of England and the US Federal Reserve Bank embarked on programmes of quantitative easing. QE involves the central bank creating electronic (narrow) money which is used to purchase assets, mainly government bonds. When the recipients of this money

Definitions

Near money Highly liquid assets (other than cash).

Non-bank private sector Households and non-bank firms. In other words, everyone in the country other than banks and the government (central and local).

Money multiplier The number of times greater the expansion of money supply is than the expansion of the monetary base that caused it: $\Delta M_s / \Delta M_b$.

Figure 18.5 UK money multiplier

Source: Based on series LPMBL22 (reserves), LPMVAV (notes and coin) and LPMAUYN (M4) from Statistical Interactive Database, Bank of England (data published 29 September 2017, seasonally adjusted except for reserves)

(mainly non-bank financial institutions) deposit it in banks, the banks can then lend it to businesses and consumers for spending and, through the bank deposits multiplier, broad money would increase.

As we can see from Figure 18.6, however, this was not enough to prevent UK broad money supply falling for much of the first half of the 2010s.

Banks choose to hold a lower liquidity ratio

If banks collectively choose to hold a lower liquidity ratio, they will have surplus liquidity. The banks have tended to choose a lower liquidity ratio over time because of the increasing use of direct debits and debit card and credit card transactions.

Surplus liquidity can be used to expand advances, which will lead to a multiplied rise in broad money supply (e.g. M4).

*BOX 18.5 CALCULATING THE MONEY MULTIPLIER

EXPLORING ECONOMICS

The money multiplier (m) is the rise in total money supply (ΔM_s) divided by the rise in the monetary base (ΔM_b):

$$m = \Delta M_s / \Delta M_b \quad (1)$$

The total money supply (M_s) consists of deposits in banks and building societies (D) plus cash held by the public (C). Thus a rise in money supply would be given by

$$\Delta M_s = \Delta D + \Delta C \quad (2)$$

The monetary base (M_b) consists of bank and building society reserves (R) plus cash held by the public (C). Thus a rise in the monetary base would be given by

$$\Delta M_b = \Delta R + \Delta C \quad (3)$$

Thus, by substituting equations (2) and (3) into equation (1), the money multiplier is given by

$$m = \frac{\Delta D + \Delta C}{\Delta R + \Delta C} \quad (4)$$

Assume now that banks wish to hold a given fraction (r) of any rise in deposits in the form of reserves, i.e.

$$r = \Delta R / \Delta D \quad (5)$$

and that the public wishes to hold a given fraction (c) of any rise in its deposits as cash, i.e.

$$c = \Delta C / \Delta D \quad (6)$$

If we now divide the top and bottom of equation (4) by ΔD , we get

$$m = \frac{\Delta D / \Delta D + \Delta C / \Delta D}{\Delta R / \Delta D + \Delta C / \Delta D} = \frac{1 + c}{r + c} \quad (7)$$

Thus if c were 0.2 and r were 0.1, the money multiplier would be $(1 + 0.2) / (0.1 + 0.2) = 1.2 / 0.3 = 4$

i.e.

$$\Delta M_s = 4 \times \Delta M_b$$

1. If c were 0.1 and r were 0.01, by how much would money supply expand if the monetary base rose by £1 million?
2. Money supply (M4) includes wholesale as well as retail deposits. Given that firms will wish to keep only a very small fraction of a rise in wholesale deposits in cash (if any at all), how will a change in the balance of wholesale and retail deposits affect the value of c and hence of the money multiplier?

Figure 18.6 Annual rate of growth of M4

Source: Statistical Interactive Database (Bank of England), series LPMVQJW (data published 29/9/17, seasonally adjusted).

An important trend up to the late 2000s was the growth of the use of wholesale funds by financial institutions. Table 18.1 showed that short-term loans to other banks (including overseas banks) are now the largest element in banks' liquid assets. These assets may be used by a bank as the basis for expanding loans and thereby starting a chain of credit creation.

But although these assets are liquid to an individual bank, they do not add to the liquidity of the banking system as a whole. By using them for credit creation, the banking system is operating with a lower *overall* liquidity ratio.

This was a major element in the banking crisis of 2008. By operating with a collectively low liquidity ratio, banks were vulnerable to people defaulting on debt, such as mortgages. The problem was compounded by the holding of sub-prime debt in the form of securitised assets. Realising the vulnerability of other banks, banks became increasingly unwilling to lend to each other. The resulting decline in inter-bank lending reduced the amount of credit created, thereby depressing the money supply (see Figure 18.6).

? What effects do debit cards and cash machines (ATMs) have on (a) banks' prudent liquidity ratios; (b) the size of the bank deposits multiplier?

The non-bank private sector chooses to hold less cash

Households and firms may choose to hold less cash. Again, the reason may be a greater use of cards, direct debits, etc. This means that a greater proportion of the cash base will be held as deposits in banks rather than in people's wallets, purses or safes outside banks. The extra cash deposits allow banks to create more credit.

The previous two reasons for an expansion of broad money supply (M4) are because more credit is being created for a given monetary base. As Figure 18.5 showed, the money multiplier rose substantially in the late 1980s and early 1990s and then gradually up to 2006.

The next two reasons for an expansion of money supply are reasons why the monetary base itself might expand.

An inflow of funds from abroad

When sterling is used to pay for UK exports and is deposited in UK banks by the exporters, credit can be created on the basis of it. This leads to a multiplied increase in the domestic money supply.

The money supply will also expand if depositors of sterling in banks overseas then switch these deposits to banks in the UK. This is a direct increase in the money supply. In an open economy like the UK, movements of sterling and other currencies into and out of the country can be very large, leading to large fluctuations in the money supply.

A public-sector deficit

A public-sector deficit is the difference between public-sector expenditure and public-sector receipts. To finance a public-sector deficit, the government has to borrow money by selling interest-bearing securities (Treasury bills and gilts). The precise amount of money the public sector requires to borrow in any one year is known in the UK as the **public-sector net cash requirement (PSNCR)**. In general, the bigger the deficit, the greater will be the growth in the money supply. Just how the money supply will be affected, however, depends on who buys the securities.

Consider first the case where government securities are purchased by the non-bank private sector. When people or

Definitions

Public-sector net cash requirement (PSNCR) The (annual) deficit of the public sector, and thus the amount that the public sector must borrow.

firms buy the bonds or bills, they will draw money from their banks. When the government spends the money, it will be re-deposited in banks. There is no increase in money supply. It is just a case of existing money changing hands.

This is not the case when the securities are purchased by monetary financial institutions, including the central bank. Consider the purchase of Treasury bills by commercial banks: there will be a multiplied expansion of the money supply. The reason is that, although banks' balances at the central bank will go down when the banks purchase the bills, they will go up again when the government spends the money. In addition, the banks will now have additional liquid assets (bills), which can be used as the basis for credit creation. This effect could be partly mitigated if the government is able to issue debt instruments of longer maturity (gilts) since these are less liquid.

If there is a public-sector *surplus* this will either reduce the money supply or have no effect, depending on what the government does with the surplus. The fact that there is a surplus means that the public sector is spending less than it receives in taxes, etc. The initial effect, therefore, is to reduce the money in the economy: it is being 'retired' in the central bank.

If, however, the government then uses this money to buy back securities from the non-bank private sector, the money will merely return to the economy, and there will be no net effect on money supply.

If the government borrows but does not spend the proceeds, what effect will this have on the money supply if it borrows from:

- the banking sector;
- the non-bank private sector?

The flow-of-funds equation

All these effects on money supply can be summarised using a **flow-of-funds equation**. This shows the components of a change in money supply (ΔM_t). The following flow-of-funds equation is the one most commonly used in the UK, that for M4. It consists of four items (or 'counterparts' as they are known):

ΔM_4	<i>equals</i>	PSNCR	(Item 1)
	<i>minus</i>	Sales of public-sector debt to (or plus purchases of public-sector debt from) the non-bank private sector	(Item 2)
	<i>plus</i>	Banks' and building societies' sterling net lending to the UK private sector	(Item 3)
	<i>plus</i>	External effect	(Item 4)

Public-sector borrowing (item 1) will lead to a direct increase in the money supply, but not if it is funded by selling bonds and bills to the non-bank private sector. Such sales (item 2) have therefore to be subtracted from the public-sector net cash requirement (PSNCR). But conversely, if the government buys back old bonds from the non-bank private sector, this will further increase the money supply.

The initial increase in liquidity from the sale of government securities to the banking sector is given by item 1. This increase in their liquidity will enable banks to create credit. To the extent that this extra lending is to the UK private sector (item 3), money supply will increase, and by a multiple of the initial increase in liquidity (item 1). Bank lending may also increase (item 3) even if there is no increase in liquidity or even a reduction in liquidity (item 1 is zero or negative), if banks respond to increases in the demand for loans by accepting a lower liquidity ratio, or if, through securitisation and other forms of secondary marketing, individual banks gain extra liquidity from each other, even though there is no total increase in liquidity in the banking system. Item 3 will be reduced if banks choose to hold more capital.

Finally, if there is a net inflow of funds from abroad (item 4), this too will increase the money supply.

Table 18.6 shows the components of changes in M4 since 2004. As Figure 18.6 showed, in the five years from 2010 to 2014, M4 contracted in four of the years and only rose slightly in the other one (2013). The period was also characterised by large public-sector deficits. Consider 2011, when the public-sector net cash requirement (item 1) was close to £120 billion. Deficits tend to increase the money supply. However, this effect was counteracted by sales of government debt to the non-bank private sector (item 2), by an outflow of funds abroad (item 4), but, more especially, by a very large decrease in the flow of bank lending (item 3). Indeed, the negative figure for net lending indicates that the private non-bank sector was repaying existing debts more than it was acquiring new debt. This phenomenon was observed frequently throughout the early 2010s. It is an example of a balance-sheet effect (see pages 450–51) which helped to reduce the growth of the money supply.

The relationship between money supply and the rate of interest

Simple monetary theory often assumes that the supply of money is totally independent of interest rates. This is illustrated in Figure 18.7. The money supply is **exogenous**. It is assumed to be determined by the government or central bank ('the authorities'): what the authorities choose it to be, or what they allow it to be by their choice of the level and method of financing the public-sector deficit.

In practice, however, even if narrow money were to be tightly controlled by the central bank (which it is not), it

Figure 18.7 The supply of money curve: exogenous money supply**Figure 18.8** The supply of money curve: endogenous money supply

would be very hard to have a precise control of broad money. More complex models, therefore, and especially Keynesian models, assume that money supply is *endogenous*: that it depends on the demand for money. The argument is that higher money demand will result in higher interest rates and in higher levels of money supplied. The result is an upward-sloping money supply curve, as in Figure 18.8. The reasons for this are as follows:

- Increases in money supply may occur as a result of banks expanding credit in response to the demand for credit. This assumes that banks have surplus liquidity in the first place, or are happy to operate with lower liquidity, or can increase liquidity through secondary marketing of

otherwise illiquid assets, or can obtain liquidity from the central bank through repos. Higher demand for credit will drive up interest rates, making it more profitable for banks to supply more credit.

- Higher interest rates may encourage depositors to switch their deposits from sight accounts (earning little or no interest) to time accounts. Since money is less likely to

Definition

Endogenous money supply Money supply that is determined (at least in part) by the demand for money.

be withdrawn quickly from time accounts, banks may feel the need to hold less liquidity, and therefore may decide to increase credit, thus expanding the money supply.

- Higher interest rates attract deposits from overseas. This increases the money supply to the extent that the Bank of England does not allow the exchange rate to appreciate in response.

To summarise: an increase in demand for money raises interest rates, which in turn increases the quantity of money

supplied (see sections 18.4 and 18.5): a movement along an upward-sloping money supply curve.

Some economists go further still. They argue that not only is money supply endogenous, but the 'curve' is effectively horizontal; money supply expands passively to match the demand for money. In practice, the shape varies with the confidence of MFIs. In periods of optimism, banks may be willing to expand credit to meet the demand from customers. In periods of pessimism, such as that following the financial crisis, banks may be very unwilling to grant credit when customers seek it.

Section summary

1. Money supply can be defined in a number of different ways, depending on what items are included. A useful distinction is between narrow money and broad money. Narrow money includes just cash, and possibly banks' balances at the central bank. Broad money also includes deposits in banks and possibly various other short-term deposits in the money market. In the UK, M4 is the preferred measure of broad money. In the eurozone it is M3.
2. Bank deposits are a major proportion of broad money supply. The expansion of bank deposits is the major element in the expansion of the money supply.
3. Bank deposits expand through a process of credit creation. If banks' liquid assets increase, they can be used as a base for increasing loans. When the loans are redeposited in banks, they form the base for yet more loans, and thus a process of multiple credit expansion takes place. The ratio of the increase of deposits to an expansion of banks' liquidity base is called the 'bank deposits multiplier'. It is the inverse of the liquidity ratio.
4. In practice, it is difficult to predict the precise amount by which money supply will expand if there is an increase in cash. The reasons are that banks may choose to hold a different liquidity ratio; customers may not take up all the credit on offer; there may be no simple liquidity ratio given the range of near money assets; and some of the extra cash may leak away into extra cash holdings by the public.
5. Money supply will rise if (a) banks choose to hold a lower liquidity ratio and thus create more credit for an existing amount of liquidity; (b) people choose to hold less cash outside the banks; (c) there is a net inflow of funds from abroad; (d) the government runs a public-sector deficit and finances it by borrowing from the banking sector or from abroad.
6. The flow-of-funds equation shows the components of any change in money supply. A rise in money supply equals the public-sector net cash requirement (PSNCR) *minus* sales of public-sector debt to the non-bank private sector, *plus* banks' lending to the private sector (less increases in banks' capital), *plus* inflows of money from abroad.
7. Simple monetary theory assumes that the supply of money is independent of interest rates. In practice, a rise in interest rates (in response to a higher demand for money) will often lead to an increase in money supply.

18.4 THE DEMAND FOR MONEY

The motives for holding money

The demand for money refers to the desire to hold money: to keep your wealth in the form of money, rather than spending it on goods and services or using it to purchase financial assets such as bonds or shares. It is usual to distinguish three reasons why people want to hold their assets in the form of money. Note that we are talking here about broad money: M4 in the UK.

The transactions motive

Since money is a medium of exchange, it is required for conducting transactions. But since people receive money

only at intervals (e.g. weekly or monthly) and not continuously, they require to hold balances of money in cash or in current accounts.

The precautionary motive

Unforeseen circumstances can arise, such as a car breakdown. Thus individuals often hold some additional money as a precaution. Firms too keep precautionary balances because of uncertainties about the timing of their receipts and payments. If a large customer is late in making payment, a firm may be unable to pay its suppliers unless it has spare liquidity.

The speculative or assets motive

Certain firms and individuals who wish to purchase financial assets, such as bonds, shares or other securities, may prefer to wait if they feel that their price is likely to fall. In the meantime, they will hold money balances instead. This speculative demand can be quite high when the price of securities is considered certain to fall. Money when used for this purpose is a means of temporarily storing wealth.

Similarly, people who will require foreign currency at some time in the future (people such as importers, holidaymakers, or those thinking of investing abroad or in foreign securities) may prefer to wait before exchanging pounds into the relevant foreign currencies if they believe that the sterling price of these currencies is likely to fall (the pound is likely to appreciate).

The transactions plus precautionary demand for money: L_1

The transactions plus precautionary demand for money is termed L_1 . 'L' stands for **liquidity preference**: that is, the desire to hold assets in liquid form. Money balances held for these two purposes are called **active balances**: money to be used as a medium of exchange. What determines the size of L_1 ?

The major determinant of L_1 is nominal national income (i.e. national income at current prices). The higher people's money income, the greater their (nominal) expenditure and the bigger their demand for active balances. The frequency with which people are paid also affects L_1 . The less frequently they are paid, the greater the level of money balances they will require to tide them over until the next payment.

? Will students in receipt of a loan, grant or an allowance who receive the money once per term have a high or a low transactions demand for money relative to their income?

The rate of interest has some effect on L_1 , albeit rather small (see Figure 18.9). At high rates of interest, people may

choose to spend less and save more of their income, e.g. by buying shares. The effect is likely to be bigger on the precautionary demand: a higher interest rate may encourage people to risk tying up their money. Firms' active balances are more likely to be sensitive to changes in r than those of individuals.

Other determinants of L_1 include the season of the year: people require more money balances at Christmas, for example. Also, any other factors that affect consumption will affect L_1 .

The increased use of credit cards in recent years has reduced both the transactions and precautionary demands. Paying once a month for goods requires less money on average than paying separately for each item purchased. Moreover, the possession of a credit card reduces or even eliminates the need to hold precautionary balances for many people. On the other hand, the increased availability of cash machines, the convenience of debit cards and the ability to earn interest on current accounts have all encouraged people to hold more money in bank accounts. The net effect has been an increase in the demand for (broad) money.

The speculative (or assets) demand for money: L_2

The speculative demand for money balances is termed L_2 . Money balances held for this purpose are called **idle balances**.

People who possess wealth, whether they are wealthy or simply small savers, have to decide the best form in which to hold that wealth. Do they keep it in cash in a piggy bank, or in a current account in a real bank; or do they put it in some interest-bearing time account; or do they buy stocks and shares or government bonds; or do they buy some physical asset such as a car or property?

In making these decisions, people will have to weigh up the relative advantages and disadvantages of the various alternative assets. Assets can be compared according to two criteria: liquidity and the possibility of earning income.

Just as we saw in the case of a bank's assets, these two criteria tend to conflict. The more liquid an asset is, the lower is likely to be the income earned from holding it. Thus cash is totally liquid to the holder: it can be used to buy other assets (or spent on goods) instantly, but it earns no interest. Shares, on the other hand, are not very liquid since they cannot be

Figure 18.9 The demand for money

Definitions

Liquidity preference The demand for holding assets in the form of money.

Active balances Money held for transactions and precautionary purposes.

Idle balances Money held for speculative purposes: money held in anticipation of a fall in asset prices.

sold instantly at a guaranteed price. (They can be sold pretty well instantly, but if share prices are depressed, a considerable loss may be incurred in so doing. In other words, they are a risky means of holding wealth.) But shares have the potential of earning quite a high income for the holder, not only in terms of the dividends paid out of the firms' profits, but also in terms of the capital gain from any increase in the shares' prices.

? *Buying something like a car is at the other end of the spectrum from holding cash. A car is highly illiquid, but yields a high return to the owner. In what form is this 'return'?*

There are three major determinants of the speculative demand for money. Let us examine each in turn.

The rate of interest (or rate of return) on assets

In terms of the operation of money markets, this is the most important determinant. The higher the rate of return on assets, such as shares and bonds, the greater the opportunity cost of holding money and therefore the lower the speculative demand for money.

The rate of return on assets varies inversely with their price. Take the case of a government bond (which pays a fixed sum of money throughout its life). Assume that the government issued a £100 bond at a time when interest rates were 10 per cent. Thus the bond must pay £10 per year. Although the government will not redeem bonds until their maturity date, which could well be 20 years from when they were issued, holders can sell bonds at any time on the stock market. Their market price will reflect (nominal) market rates of interest. Assume, for example, that interest rates fall to 5 per cent. What will happen to the market price of the bond paying £10 per year? It will be driven up to £200. At that price, the £10 per year is worth the current market rate of 5 per cent. Thus the market price of bonds varies inversely with the rate of interest.

Expectations of changes in the prices of securities and other assets

If people believe that share prices are about to rise rapidly on the stock market, they will buy shares and hold smaller speculative balances of money. If they think that share prices will fall, they will sell them and hold money instead. Some clever (or lucky) individuals anticipated the 2007–8 stock market decline (see figure in Box 2.3 on page 54). They sold shares and 'went liquid'.

If the market price of securities is high, the rate of interest (i.e. the rate of return) on these securities will be low. Potential purchasers of these securities will probably wait until their prices fall and the rate of interest rises. Similarly, existing holders of securities will probably sell them while the price is high, hoping to buy them back again when the price falls, thus making a capital gain. In the meantime, therefore, large speculative balances of money will be held. L_2 is high.

If, on the other hand, the rate of interest is high, then L_2 is likely to be low. To take advantage of the high rate of return on securities, people buy them now instead of holding on to their money.

Would the demand for securities be low if their price was high, but was expected to go on rising?

The relationship between L_2 and the rate of interest is again shown in Figure 18.9. The inverse relationship between the rate of interest and L_2 gives a downward-sloping curve.

Speculative demand and the exchange rate

In an open economy like the UK where large-scale movements of currencies across the foreign exchanges take place, expectations about changes in the exchange rate are a major determinant of the speculative demand for money.

If people believe that the pound is likely to appreciate, they will want to hold sterling until it does appreciate. For example, if the current exchange rate is £1 = \$1.25 and speculators believe that it will shortly rise to £1 = \$1.50, then if they are correct they will make a 25¢ per £1 profit by holding sterling. The more quickly is the exchange rate expected to rise, the more will people want to hold sterling (as money). If, however, people believe that it will be a slow rise over time, they will want to buy sterling assets (such as UK government bonds) rather than money, since such assets will also earn the holder a rate of interest.

Conversely, if people believe that the exchange rate is likely to fall in the near future, they will economise on their holdings of sterling, preferring to hold their liquid assets in some other currency – the one most likely to appreciate against other currencies.

Graphically, changes in expectations about the exchange rate will have the effect of shifting the L_2 curve in Figure 18.9.

There is a further complication here. Expectations about changes in the exchange rate will themselves be influenced by the interest rate (relative to overseas interest rates). If the UK rate of interest goes up, people will want to deposit their money in the UK. This will increase the demand for sterling on the foreign exchange market: there will be a short-term financial inflow into the UK (the financial account of the balance of payments will go into surplus). The effect will be to drive up the exchange rate. Thus if people believe that the UK rate of interest will rise, they will also believe that the rate of exchange will appreciate, and they will want to hold larger speculative balances of sterling.

The introduction of the 'foreign exchange dimension' into our analysis will have two effects on the L_2 curve. First, the curve will become more *elastic*. If the rate of interest is low and is thought likely to rise, the speculative demand is likely to be very high. Not only will people hold money in anticipation of a fall in security prices, but they will also hold money (sterling) in anticipation of an appreciation of the exchange rate.

Second, the curve will become more *unstable*. Expectations of changes in the exchange rate do not just depend on current domestic interest rates. They depend on the current and anticipated future state of the balance of trade, the rate of inflation, the current and anticipated levels of interest rates in other major trading countries, the price of oil, and so on. If any of these cause people to expect a lower exchange rate, the speculative demand for money will fall: L_2 will shift to the left.

Which way is the L_2 curve likely to shift in the following cases?

- The balance of trade moves into deficit.
- People anticipate that foreign interest rates are likely to rise substantially relative to domestic ones.
- The domestic rate of inflation falls below that of other major trading countries.
- People believe that the pound is about to depreciate.

The total demand for money: $L_1 + L_2$

Figure 18.9 also shows the total demand for money balances (L). This is found by the horizontal addition of curves L_1 and L_2 . This curve is known as the 'liquidity preference curve' or simply the demand for money curve.

Any factor, other than a change in interest rates, that causes the demand for money to rise will shift the L curve to the right. For example, a rise in national income will cause L_1 to increase, and thus L will shift to the right.

Additional effects of expectations

We have talked about expectations and their importance in determining the speculative demand for money. In particular, we have looked at (a) the effect of interest rates on people's anticipations of future security prices and (b) the effect of expectations about exchange rate movements. There are

two other ways in which expectations can influence the demand for money, and make it more unstable.

Expectations about prices. If people expect prices to rise, they may reduce their money balances and purchase goods and assets now, before prices do rise. This will tend to shift L to the left. (Note, though, that once prices have risen, people will need more money to conduct the same amount of transactions.)

Expectations of interest rate levels over the longer term. If people come to expect that interest rates will normally be higher than they used to be, then any given interest rate will seem lower relative to the 'normal' rate than it used to be. People will be more inclined to hold speculative balances of money in anticipation of a rise in interest rates. This will tend to shift L upwards.

In an era of uncertainty about inflation, interest rates and exchange rates, people's expectations will be hard to predict. They will be volatile and susceptible to rumours and political events. In such circumstances, the L curve itself will be hard to predict and will be subject to considerable shifts. Generally, it is likely that the greater the uncertainty, the greater will be the preference for liquidity, and the greater the risk of tying wealth up in illiquid assets.

* LOOKING AT THE MATHS

The demand for money (L) can be expressed by the following function:

$$\begin{aligned} L &= L_1 + L_2 \\ &= l_1(PY, f, i) + l_2(i, er^e) \\ &= l_1(PY, f, (r + \pi^e) + l_2((r + \pi^e), er^e) \end{aligned} \quad (1)$$

This states that L_1 is a function l_1 of nominal national income (i.e. real national income (Y) multiplied by the price index (P)), the frequency with which people are paid (f) and the nominal rate of interest (i), which equals the real rate of interest (r) on alternative assets to money plus the expected rate of inflation (π^e). L_2 is a function of the nominal rate of interest (i) and the expected value of the exchange rate er^e .

The advantage of specifying a relationship in this way is that it gives a simple way of representing a situation where something

depends on a number of determinants. It is a convenient shorthand. Indeed, a more complex function could easily be specified where the demand for money depends on a longer list of variables. The one above, however, identifies the main determinants. By putting plus and minus signs under each of the terms, we could also identify whether the relationship with each of the determinants is a positive or negative one (i.e. whether the respective partial derivative is positive or negative). Equation (1) could thus be written

$$L = l_1(PY, f, i) + l_2(i, er^e) \quad (2)$$

+ - - - +

This merely states that the demand for money will rise as PY and er^e rise and f and i fall.

Section summary

- The three motives for holding money are the transactions, precautionary and speculative (or assets) motives.
- The transactions-plus-precautionary demand for money (L_1) depends primarily on the level of nominal national income, the frequency with which people are paid and institutional arrangements (such as the use of credit or debit cards). It also depends to some degree on the rate of interest.
- The speculative demand for money (L_2) depends on the rate of return on assets and on anticipations about future movements in security prices (and hence their rate of return) and future movements in exchange rates. If security prices are anticipated to fall or the exchange rate to rise, people will hold more money balances.
- The demand for money is also influenced by expectations of price changes and the levels of interest rates over the longer term.

18.5 EQUILIBRIUM

Equilibrium in the money market

Equilibrium in the money market is where the demand for money (L) is equal to the supply of money (M_s). This equilibrium is achieved through changes in the *nominal* rate of interest (i). To make the analysis more straightforward, we assume there is no inflation (π). Hence, the nominal rate of interest (i) is the same as the real rate of interest (r) (we drop this assumption in later chapters).

In Figure 18.10, equilibrium is achieved with a nominal rate of interest i_e and a quantity of money M_e . If the rate of interest were above i_e , people would have money balances surplus to their needs. They would use these to buy shares, bonds and other assets. This would drive up the price of these assets and drive down the rate of interest.

As the rate of interest fell, so there would be a contraction of the money supply (a movement down along the M_s curve) and an increase in the demand for money balances, especially speculative balances (a movement down along the liquidity preference curve). The interest rate would go on falling until it reached i_e . Equilibrium would then be achieved.

Similarly, if the rate of interest were below i_e , people would have insufficient money balances. They would sell securities, thus lowering their prices and raising the rate of interest until it reached i_e .

A shift in either the M_s or the L curve will lead to a new equilibrium quantity of money and rate of interest at the new intersection of the curves. For example, a rise in the supply of money will cause the rate of interest to fall.

In practice, there is no one single rate of interest. Equilibrium in the money markets, therefore, will be where demand and supply of each type of financial asset separately balance.

If, for example, there were excess demand for short-term loans (such as one-month inter-bank lending) and excess supply of money to invest in long-term assets (such as bonds), short-term rates of interest would rise relative to long-term rates. Generally, however, different interest rates tend to move roughly together as the overall demand for money and other liquid assets (or their supply) changes. Thus interest rates may generally rise or generally fall.

Table 18.7 gives some examples of the rates of interest on various financial instruments in the UK. It shows how the various rates of interest move together. As we saw in section 18.2, the Bank of England conducts open-market operations to affect the general structure of the economy's interest rates and, in turn, the inflation rate. We can see how significant reductions to the policy rate (Bank Rate) were mirrored by falls in other interest rates.

What patterns in interest rates emerged between 2008 and 2017?

Equilibrium in the foreign exchange market

Changes in the money supply also affect the foreign exchange market. In a free foreign exchange market, equilibrium will be achieved by changes in the exchange rate. Assume that the money supply increases. This has three direct effects:

- Part of the excess money balances will be used to purchase foreign assets. This will therefore lead to an increase in the supply of domestic currency coming on to the foreign exchange markets.
- The excess supply of money in the domestic money market will push down interest rates. This will reduce the return on

Figure 18.10 Equilibrium in the money market

Table 18.7 Selected rates of interest: January 1997 to September 2017 (monthly averages)

Financial instrument	Period of loan	Rate of interest, per cent per annum					
		Average Jan 1997– Sept 2008	Average Oct 2008– Sept 2017	Jan 1997	Sept 2008	Jan 2009	Sept 2017
Call money	Overnight	4.89	0.51	5.90	4.89	1.33	0.21
Gilt repos	1 week	5.09	0.54	5.91	4.92	1.43	0.21
Inter-bank loans	1 month	5.25	0.64	6.14	5.57	1.71	0.29
Treasury bills	3 months	5.05	0.44	6.07	4.95	1.29	0.08
British government securities ¹	20 years	4.81	3.32	7.74	4.64	4.48	1.91
Bank and building society mortgages ²	Variable (25 years typical)	6.87	4.32	7.18	6.95	4.73	4.32
Credit card	–	17.58	17.26	22.14	16.12	16.09	17.96
Official Bank Rate (policy rate)	–	5.18	0.56	5.94	5.00	1.60	0.25

domestic assets below that on foreign assets. This, like the first effect, will lead to an increased demand for foreign assets and thus an increased supply of the domestic currency on the foreign exchange market. It will also reduce the demand for domestic assets by those outside the country, and thus reduce the demand for the domestic currency.

- Speculators will anticipate that the higher supply of the domestic currency will cause the exchange rate to

depreciate. They will therefore sell domestic currency and buy foreign currencies before the expected depreciation takes place.

The effect of all three is to cause the exchange rate to depreciate.

 Trace through the effects on the foreign exchange market of a fall in the money supply.

LOOKING AT THE MATHS

Equilibrium in the money market is where demand and supply of money are equal. From Box 18.5, the money supply (M_s) equals the monetary base (M_b) multiplied by the money multiplier:

$$M_s = M_b \left(\frac{1 + c}{r_s + c} \right)$$

Note that this is the more complex version of the money multiplier that we examined in Box 18.5, not the simple bank deposits multiplier developed in the text.

From the 'Looking at the maths' panel on page 583, the demand for money (L) is given by

$$L = l_1(PY, f, (r + \pi^e)) + l_2((r + \pi^e), er^e)$$

Thus, in equilibrium,

$$M_s = L$$

that is

$$M_b \left(\frac{1 + c}{r_s + c} \right) = l_1(PY, f, (r + \pi^e)) + l_2((r + \pi^e), er^e) \quad (1)$$

At first sight, this equation looks quite daunting, but what we have done is to bring together money supply and demand, each of which has been separately derived in a set of simple stages. In one single equation (equation (1)) we have completed a jigsaw made up of several simple parts.

Section summary

1. Equilibrium in the money market is where the supply of money is equal to the demand. Equilibrium will be achieved through changes in the nominal rate of interest.
2. A rise in money supply causes money supply to exceed money demand. This causes interest rates to fall and a movement down along both the supply of money curve and the demand for money curve until money supply is equal to money demand.
3. Equilibrium in the foreign exchange market is where the demand and supply of a currency are equal. A rise in money supply causes interest rates to fall. The rise in money supply plus the fall in interest rates causes an increased supply of domestic currency to come on to the foreign exchange market and a reduced demand for the domestic currency. This causes the exchange rate to depreciate.

END OF CHAPTER QUESTIONS

- Imagine that the banking system receives additional deposits of £100 million and that all the individual banks wish to retain their current liquidity ratio of 20 per cent.
 - How much will banks choose to lend out initially?
 - What will happen to banks' liabilities when the money that is lent out is spent and the recipients of it deposit it in their bank accounts?
 - How much of these latest deposits will be lent out by the banks?
 - By how much will *total* deposits (liabilities) eventually have risen, assuming that none of the additional liquidity is held outside the banking sector?
 - How much of these are matched by (i) liquid assets; (ii) illiquid assets?
 - What is the size of the bank deposits multiplier?
 - If one-half of any additional liquidity is held *outside* the banking sector, by how much less will deposits have risen compared with (d) above?
- What is meant by the terms *narrow money* and *broad money*? Does broad money fulfil all the functions of money?
- How does money aid the specialisation and division of labour?
 - What enables banks safely to engage in both maturity transformation and risk transformation?
 - Why do banks hold a range of assets of varying degrees of liquidity and profitability?
 - What is meant by the securitisation of assets? How might this be (a) beneficial and (b) harmful to banks and the economy?
 - What were the causes of the credit crunch and the banking crisis of the late 2000s?
 - If the government reduces the size of its public-sector net cash requirement, why might the money supply nevertheless increase more rapidly?
 - Why might the relationship between the demand for money and the rate of interest be an unstable one?
 - What effects will the following have on the equilibrium rate of interest? (You should consider which way the demand and/or supply curves of money shift.)
 - Banks find that they have a higher liquidity ratio than they need.
 - A rise in incomes.
 - A growing belief that interest rates will rise from their current level.

In Chapter 17 we saw how equilibrium national output was determined. In other words, we looked at macro-economic equilibrium in goods markets. In Chapter 18 we saw how equilibrium was determined in the money market. In this chapter we combine the analysis of the two chapters.

In section 19.1 we examine how changes in money supply affect real national income. In other words, we see how changes in money markets are transmitted through to goods markets: how monetary changes affect real output. Then, in section 19.2, we look at things the other way round. We examine the effects on money markets and interest rates of changes in the goods market. For example, if aggregate demand increases and firms start to produce extra goods, to what extent will money markets act as a constraint on this process?

In the remaining sections we look at the interplay of goods and money markets. In doing so, we introduce models which allow us to study how these markets interact. In section 19.3 the interaction is analysed in the contemporary context of central banks setting interest rates to target the rate of inflation. In doing so, we introduce a relatively new model: the *IS/MP* model. In the Appendix to the chapter we introduce the more traditional model: the *IS/LM* model. This helps us to see how the two markets interact when interest rates adjust to bring about equilibrium in the money market.

19.1 THE EFFECTS OF MONETARY CHANGES ON NATIONAL INCOME

In this section we examine the impact on the economy of changes in money supply and interest rates: how they affect aggregate demand and how this, in turn, affects national income and prices. A simple way of understanding the issues is in terms of the *quantity theory of money*.

The quantity theory of money

In section 16.2 (page 495), we looked at the following version of the quantity equation:

$$MV = PY$$

In case you did not study Chapter 16, let us state the theory again. First a definition of the terms: M is the supply of money; V is the income velocity of circulation (the number of times money is spent per year on national output (GDP)); P is the price index (where the index = 1 in the base year); and Y is the real value of national income (= national output) for the year in question (i.e. GDP measured in base-year prices).

MV is the total spending on national output. For example, if total money supply (M) was £1 trillion and each pound was spent on average twice per year (V) on national output, then total spending on national output (MV) would equal £2 trillion for that year. MV is thus simply (nominal) aggregate demand, since total spending on national output consists of the four elements of aggregate demand: consumer spending (C), investment expenditure (I), government purchases (G), and expenditure on exports less expenditure on imports ($X - M$), all measured in current prices.

PY is the money value of national output: in other words, GDP measured at *current* prices. For example, if real national income (Y) (i.e. in base-year prices) were £1 trillion, and the price index (P) were 2 (in other words, prices were twice as high as in the base year), then the value of national output in current prices would be £2 trillion.

Because of the way we have defined the terms, MV must equal PY . A simple way of looking at this is that MV and PY are both ways of measuring GDP. MV measures it in terms of national *expenditure*. PY measures it in terms of the value of what is *produced*.

The effect of a change in money supply

If money supply (M) changes, how will it affect the other three elements of the quantity equation? Will a rise in money supply simply lead to a rise in prices (P), or will there be a rise in real national income (Y): i.e. a rise in real GDP? What will happen to the velocity of circulation (V)? Can we assume that it will remain constant, or will it change?

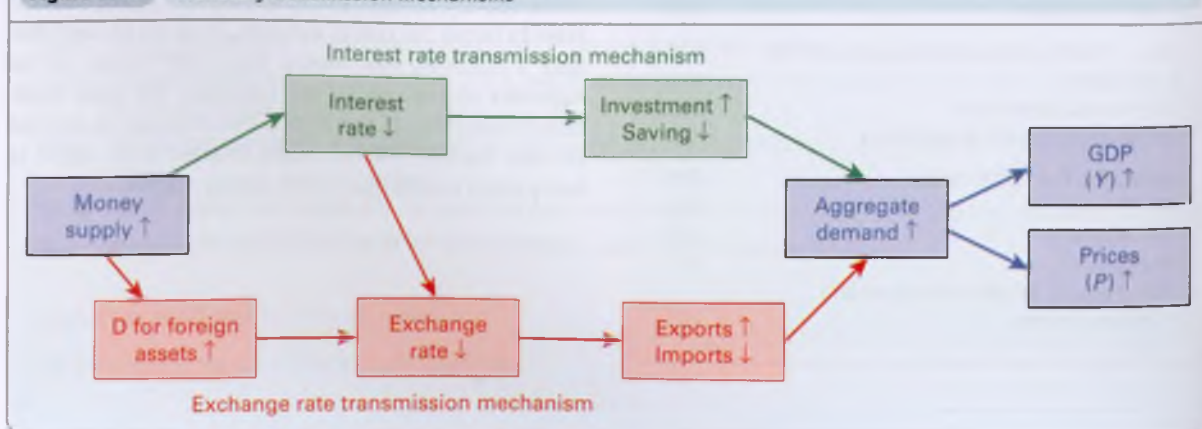

Clearly the relationship between money supply and prices depends on what happens to V and Y . What happens to them has been the subject of considerable debate between economists over the years. Keynesians have generally had different views from monetarists and new classical economists.

Essentially there are two issues. In this chapter we look at the first one: the variability of V . If V is constant, a change in money supply (M) will directly affect nominal aggregate demand (MV) and hence nominal national income (PY). If, however, V varies, a change in M may have a much less predictable effect on PY .

The second issue is examined in Chapter 20. This concerns the variability of Y . Will a rise in aggregate demand lead to increased employment and output (Y), or will it simply lead to higher prices (P), or some combination of the two?

- ?
1. If V is constant, will (a) a £10 million rise in M give a £10 million rise in MV ; (b) a 10 per cent rise in M give a 10 per cent rise in MV ?
 2. If both V and Y are constant, will (a) a £10 million rise in M lead to a £10 million rise in P ; (b) a 10 per cent rise in M lead to a 10 per cent rise in P ?

Figure 19.1 Monetary transmission mechanisms

Two principal means by which a rise in money supply can cause a rise in aggregate demand are the **interest rate transmission mechanism** and the **exchange rate transmission mechanism**. These are illustrated in Figure 19.1. We start with the interest rate transmission mechanism.

The interest rate transmission mechanism

The interest rate transmission mechanism is summarised in the top part of Figure 19.1. It shows the process by which changes in interest rates, following a change in the money supply, can affect aggregate demand.

When analysing expenditure decisions, it is typically *real* interest rates that are important. Consumers and producers are interested in the additional future volumes of consumption and production respectively that their investment, borrowing or saving today will enable them to enjoy.

The *realised* ('*ex post*') real rate of interest (r) received on savings or paid on borrowing is the nominal (actual) interest rate (i) less the rate of inflation (π). However, for savers and borrowers it is the future rate of inflation that is relevant in their decision making. Of course, future inflation rates cannot be known with certainty and, instead, people must form *expectations* of inflation. Hence, the perceived real interest rate when the decision is made ('*ex ante*') is the nominal interest rate (i) less the *expected* rate of inflation (π^e).

We assume in the following analysis of the short term that prices are constant and that the expected rate of

inflation is zero. Therefore, a change in real interest rates is equivalent to that in nominal interest rates.

Figure 19.2 allows us to analyse the interest rate transmission mechanism in more detail. It is a three-stage process.

Money market and interest rates (stage 1). Figure 19.2(a) shows the money market. The horizontal axis shows real money balances (the real purchasing power of money); the vertical axis shows the real interest rate (r). With the economy's price level held constant, an increase in nominal money supply increases the supply of real balances (M): e.g. from M to M' . This, in turn, leads to a surplus of real money balances at the initial equilibrium real interest rate r_1 , and hence a fall in the real rate of interest from r_1 to r_2 .

What is the opportunity cost of holding money? Is it the real or the nominal rate of interest? Explain.

Interest rates and investment (stage 2). Figure 19.2(b) shows the relationship between real investment levels (I) and the real rate of interest. A fall in the real rate of interest from r_1 to r_2 leads to a rise in investment (and any other interest-sensitive expenditures) from I_1 to I_2 . Note that it also encourages consumers to spend, since borrowing through credit cards and personal loans is now cheaper. At the same time, it discourages saving.

Investment and national income (stage 3). Figure 19.2(c) is the Keynesian withdrawals and injections diagram we discussed in Chapter 17. With no change in the economy's price level, a rise in investment leads to a full multiplied rise in real national income from Y_1 to Y_2 . If saving fell, there would also be a downward shift in the W line, which would further amplify the effects on real national income and national output from the fall in the real rate of interest.

However, the increase in real income to Y_2 shown in Figure 19.2(c) does not take into account the likelihood that any rise in real income will lead to a rise in the demand for real balances from the rise in the transactions demand

Definitions

Interest rate transmission mechanism How a change in money supply affects aggregate demand via a change in interest rates.

Exchange rate transmission mechanism How a change in money supply affects aggregate demand via a change in exchange rates.

Figure 19.2 Effect of a rise in money supply: the interest rate transmission mechanism

for money, L_1 . In other words, L will shift to the right in Figure 19.2(a), and thus r will not fall as much as illustrated. Thus investment (Figure 19.2(b)) and real national income (Figure 19.2(c)) will not rise as much as illustrated either.

The overall effect of a change in money supply on national income will depend on the size of the effect in each of the three stages. This will depend on the shapes of the curves in each of the three diagrams and whether they are likely to shift. The effect will be bigger:

- the less elastic the liquidity preference curve (L): this will cause a bigger change in the rate of interest;
- the more interest-elastic the investment curve (I): this will cause a bigger change in investment;
- the lower the marginal propensity to withdraw (mpw), and hence the flatter the withdrawals function: this will cause a bigger multiplied change in national income and aggregate demand.

The problem is that stages 1 and 2 may be both weak and unreliable, especially in the short run. This problem is stressed by Keynesians.

Problems with stage 1: the money–interest link

An interest-elastic demand for money. According to Keynesians, the speculative demand for money is highly responsive to changes in interest rates. If people believe that the rate of interest will rise, and thus the price of bonds and other securities will fall, few people will want to buy them now. Instead there will be a very high demand for money and near money as people prefer to hold their assets in liquid form. The demand for money will therefore be very elastic in response to changes in interest rates.

If demand for money is interest elastic, the demand-for-money curve (the liquidity preference curve, L) will be relatively flat and may even be infinitely elastic at some minimum interest rate. This is the point where everyone believes interest rates cannot go any lower and sooner or later will rise, and therefore no one wants to buy bonds.

With a very gently sloping L curve (as in Figure 19.3), a rise in (real) money supply from M to M' will lead to only a small fall in the real rate of interest from r_1 to r_2 . Once people believe that the rate of interest will not go any lower, any further rise in money supply will have no effect on r . The additional money will be lost in what Keynes called the **liquidity trap**. People simply hold the additional money as idle balances.

Keynes himself saw the liquidity trap as merely a special case: the case where the economy is in deep recession. In normal times, an expansion of money supply would be likely to

Figure 19.3 An elastic liquidity preference curve

have *some* effect on interest rates. But in a deep recession an expansion of money supply may have no effect on the economy.

The possibility that additional real money balances might simply find themselves lost in a liquidity trap, with individuals and firms unwilling to spend it, was of concern to policy makers who responded to the financial crisis of the late 2000s by increasing the money supply.

In the UK, with the Bank of England's base rate at 0.5 per cent, the money supply was increased by the Bank purchasing gilts in exchange for central bank money (see Box 22.10 on quantitative easing). The hope was that this would increase bond prices as well as other asset prices, so reducing interest rates even further throughout the economy and hence further reducing the cost of borrowing. In turn, it was hoped that this would generate higher rates of spending growth than would otherwise have been the case.

In practice, the effectiveness of such policies is constrained by a liquidity trap. Extra real money balances may be held as additional liquidity rather than boosting spending.

? How might we go about assessing whether quantitative easing actually worked?

An unstable demand for money. Another problem is that the liquidity preference curve (L) is unstable. People hold speculative balances when they anticipate that interest rates will rise (security prices will fall). But it is not just the current interest rate that affects people's expectations of the future direction of interest rates. Many factors could affect such expectations. These could include, for instance, economic policy announcements from government or newly released inflation figures indicating the possibility of imminent changes to monetary policy.

Thus the L curve can be highly volatile. With an unstable demand for money, it is difficult to predict the effect on various interest rates of a change in money supply.

Definition

Liquidity trap The absorption of any additional money supply into idle balances at very low rates of interest, leaving aggregate demand unchanged.

A policy of *targeting* money supply (whether nominal or real) can be criticised for similar reasons. A volatile demand for money can cause severe fluctuations in interest rates if the supply of money is kept constant (see Figure 19.4). These fluctuations will cause further uncertainty and further shifts in the speculative demand for money. Targeting the money supply can therefore add to the volatility of the velocity of circulation (V).

Problems with stage 2: the interest rate–investment link

An *interest-inelastic investment demand*. In the 1950s and 1960s, many Keynesians argued that investment was unresponsive to interest rate changes: that the I curve in Figure 19.2(b) was steep (as in Figure 19.5). In these circumstances, a very large change in real interest rates would be necessary to have any significant effect on investment and aggregate demand.

Investment, it was argued, depends on confidence in future markets. If confidence is high, firms will continue to invest even if interest rates are high. They can always pass the higher costs on to the consumer. If confidence is low, firms will not invest even if interest rates are low and borrowing is cheap. Evidence seemed to confirm the interest inelasticity of investment demand.

Few Keynesians hold this extreme position today. The evidence for an inelastic investment demand has been challenged. Just because interest rates were low, it does not follow that investment is unresponsive to interest rate changes. There may have been changes in *other* factors that helped to curb investment: in other words, the I curve shifted to the left. For example, a fall in consumer demand would both cause the low interest rate *and* discourage investment.

? Figure 19.5 shows a steep investment demand curve. If the real rate of interest falls from r_1 to r_2 , there is only a small rise in investment from I_1 to I_2 . Now draw a much more elastic I curve passing through point a . Assume that this is the true I curve. Show how the rate of interest could still fall to r_2 and investment still only rise to I_2 if this curve were to shift.

Figure 19.4 The effect on interest rates of a fluctuating demand for money

Figure 19.5 Does a fall in interest rates cause only a small rise in investment?

Even if fixed investment in plant and machinery is not very interest sensitive, other components of aggregate demand may well be: for example, investment in stocks, consumer demand financed through credit cards, bank loans or hire purchase, and the demand for houses financed through mortgages.

The process of financialisation (see section 15.1), some economists argue, may have made aggregate demand more interest-rate sensitive. Increased levels of indebtedness to financial institutions, for example, means that the real expenditure of people and firms is potentially more sensitive to interest rate changes than in the past. This is because debt-servicing costs have a more significant effect on the income they have to spend.

Interest rate changes can generate sizeable *cash flow effects* for highly indebted people and firms. For example, when interest rates fall, the interest payments on those debts subject to variable interest rates fall too, giving people/firms more money to spend. However, it does reduce the interest receipts on savings. The net effect on aggregate demand will depend on which of these two counteracting effects is stronger. Evidence tends to suggest that it is debtors who have the higher marginal propensity to consume. Therefore, the overall effect of a fall in interest rates would be to generate a positive cash flow. This helps to boost aggregate expenditure and so reinforce the interest rate mechanism.

An *unstable investment demand*. Investment is notoriously volatile (see section 17.5). It is sensitive to a multitude of factors other than the rate of interest, which means that the investment curve in Figure 19.5 can shift *erratically*. These factors include, for example, business optimism, credit conditions and the availability of finance.

To analyse the effect of interest rate changes given an unstable investment curve consider Figure 19.6. Assume that the initial investment demand curve is given by I_1 . Now assume that the central bank reduces interest rates from r_0 to r_1 . Other things being equal, the level of investment will rise from Q_0 to Q_1 . However, the fall in real interest rates might be accompanied by other changes that affect investment too. For example, if firms believe that the economy will now pull out of recession, their confidence will increase. Firms may also believe that this growth will help to improve their balance sheets and hence their financial well-being, while financial institutions might be more confident to provide finance. The investment curve will shift to I_2 and investment will increase quite markedly to Q_2 .

If, on the other hand, firms become more pessimistic about the business environment in which they operate, their confidence may well decrease. Again, this could affect credit conditions, with financial institutions now less confident to provide finance. The investment curve will shift to I_3 and the level of investment will actually fall to Q_3 .

What we have seen here is that the effectiveness of monetary (and fiscal policy) is dependent on how people respond. Its effectiveness is therefore dependent on a range of factors, many of which are peculiar to that moment in time. Nonetheless, monetary policy is likely to be more effective if people have confidence in its effectiveness. This *psychological* effect can be quite powerful. This helps to explain the coordinated responses of central bankers to the financial crisis of 2007–9 and the concerted attempts to inject extra liquidity into the banking system. By doing so they were trying to reassure individuals and firms that the measures would work. Further expansions of liquidity by central banks during the 2010s were again, in part, an attempt to reassure investors, despite the tightening of fiscal policy as governments grappled with mounting public-sector debt.

The exchange rate transmission mechanism

A second transmission mechanism is the *exchange rate transmission mechanism*. This is illustrated in the bottom half of Figure 19.1 on page 588 and graphed in Figure 19.7. This mechanism backs up the interest rate mechanism. It includes the exchange rate as an intermediate variable between changes in the money supply and changes in aggregate demand.

Figure 19.7 shows that there are four stages in this exchange rate transmission mechanism. We continue to assume that the economy's price level is constant in the short term and that the expected rate of inflation is 'anchored' at zero.

Money market and interest rates (stage 1). In Figure 19.7(a), a rise in money supply causes a fall in domestic interest rates from r_1 to r_2 .

Interest rates and foreign exchange market (stage 2). In Figure 19.7(b), the fall in domestic interest rates leads to an increased outflow of short-term finance from the country as people demand more foreign assets instead. There will also be a reduced inflow, as depositors seek to take advantage of relatively higher interest rates abroad. The supply of the domestic currency on the foreign exchange market rises from S_1 to S_2 and the demand falls from D_1 to D_2 . This causes a depreciation of the exchange rate from e_{r1} to e_{r2} (assuming the authorities allow it). In addition, part of the increased money supply will be used to buy foreign assets directly, further contributing to the rightward shift in the supply curve. What is more, the depreciation in the exchange rate may be speeded up or amplified by speculation.

Exchange rates and net exports (stage 3). In Figure 19.7(c), the depreciation of the exchange rate causes a rise in demand for exports (X), since they are now cheaper for people abroad to buy (there is a movement down along the X curve). It also causes a fall in demand for imports (M), since they are now more expensive (there is a movement up along the M curve). Note that the rise in exports and fall in imports gives a current account balance of payments surplus (assuming a previous balance). This is matched by the financial account deficit resulting from the lower interest rate encouraging people to buy foreign assets and people abroad buying fewer of this country's assets. We examine these balance of payments effects in more detail in Chapter 25.

Net exports and national income (stage 4). In Figure 19.7(d), the rise in exports (an injection) and a fall in imports (a withdrawal) will cause a multiplied rise in national income. The equilibrium level of real national income rises from Y_1 to Y_2 .

Stage 1 will tend to be more powerful in a more open economy. The liquidity preference curve will tend to be less

Figure 19.7 The exchange rate transmission mechanism

elastic because, as interest rates fall, people may fear a depreciation of the domestic currency and switch to holding other currencies. Just how strong stage 1 will be depends on how much people think the exchange rate will depreciate.

Stage 2 is likely to be very strong indeed. Given the openness of international financial markets, international financial flows can be enormous in response to interest rate changes. Only a relatively small change in interest rates is necessary to cause a relatively large financial flow. Monetarists and new classical economists stress the importance of this effect. Any fall in interest rates, they argue, will have such a strong effect on international financial flows and the exchange rate that the rise in money supply will be relatively quickly and fully transmitted through to aggregate demand.

Stage 3 may be rather limited in the short run as the demand and supply of both imports and exports may be relatively inelastic in the short run. Given time, however, consumers and firms may be more responsive and the effects on imports and exports correspondingly larger. However, the size of the effect depends on people's expectations of exchange rate movements. If people think that the exchange rate will fall further, importers will buy *now* before the rate does fall. Exporters, on the other hand, will hold back as long as possible before shipping their exports. These actions will tend to push the exchange rate down. But such speculation is very difficult to predict as it depends on often highly volatile expectations.

? If importers and exporters believe that the exchange rate has 'bottomed out', what will they do?

Stage 4 is the familiar multiplier, only this time triggered by a change in imports and exports.

Again, as with the interest rate transmission mechanism, the full effect is unlikely as to be as large as that illustrated. This is because the increased real national income (Y) will cause an increased *transactions* demand for money. This will shift the L curve to the right in Figure 19.7(a), and thus lead to a smaller fall in the rate of interest than that illustrated.

The overall effect via the exchange rate transmission mechanism can still be quite strong, but the precise magnitude is usually highly unpredictable.

The effects of changes in money supply will also depend on just how free the exchange rate is. If the government intervenes to 'peg' (i.e. fix) the exchange rate or to prevent excessive fluctuations, the transmission mechanism will not work in the way described. Alternative exchange rate systems (or 'regimes', as they are called) are examined in Chapter 25.

The portfolio balance effect

Money can also impact on the economy through a process of 'portfolio adjustment': a mechanism that was stressed by monetarists. If money supply increases, people will have more money than they need to hold. They will spend this

BOX 19.1

CHOOSING THE EXCHANGE RATE OR THE MONEY SUPPLY

EXPLORING
ECONOMICS

You can't choose both

If the government expands the money supply, then interest rates will fall and aggregate demand will tend to rise. With a floating exchange rate, this will cause the currency to depreciate.

But what if the government attempts to maintain a fixed exchange rate? To do this it must keep interest rates comparable with world rates. This means that it is no longer free to choose the level of money supply. The money supply has become endogenous.

The government can't have it both ways. It can choose the level of the money supply (providing it has the techniques to

do so) and let interest rates and the exchange rate be what they will. Or it can choose the exchange rate, but this will then determine the necessary rate of interest and hence the supply of money. These issues are explored in Chapter 25.

Can the government choose both the exchange rate and the money supply if it is prepared to use the reserves to support the exchange rate?

surplus. Much of this spending will go on goods and services, thereby directly increasing aggregate demand:

$$M_s \uparrow \rightarrow M_s > M_d \rightarrow AD \uparrow$$

The theoretical underpinning for this is given by the *theory of portfolio balance*. People have a number of ways of holding their wealth: as money, or as financial assets such as bills, bonds and shares, or as physical assets such as houses, cars and televisions. In other words, people hold a whole portfolio of assets of varying degrees of liquidity – from cash to property.

If money supply expands, people may find themselves holding more money than they require: their portfolios are unnecessarily liquid. Some of this money will be used to purchase financial assets, and some to purchase *goods and services*. As more assets are purchased, this will drive up their price. This will effectively reduce their 'yield'. For bonds and other financial assets, this means a reduction in their rate of interest. For goods and services, this means a reduction in their marginal utility/price ratio: a higher level of consumption will reduce their marginal utility and drive up their price. The process will stop when a balance has been restored in people's portfolios. In the meantime, there will have been extra consumption and hence a rise in aggregate demand.

Do you think that this is an accurate description of how people behave when they acquire extra money?

Definition

Portfolio balance The balance of assets, according to their liquidity, that people choose to hold in their portfolios.

Many Keynesian economists, however, argue that this mechanism may be weak and unreliable. What is more, a rise in money supply may itself come about as a result of a direct change in one of the components of aggregate demand, making it difficult to identify how much of any effect is due solely to the change in money supply.

Consider an increase in government expenditure financed by purchases of Treasury bills by the banking system. Will any impact on output and prices come primarily from the extra liquidity in the balance sheets of households and firms, or will it come directly from the higher government expenditure?

Even if there is a direct increase in liquidity (e.g. through quantitative easing) without any accompanying change in government expenditure or taxation, the effect of this additional liquidity will depend on the extent to which banks use it to extend new credit. This, in turn, will depend on the *demand* for credit, which in a recession may fall as people try to rein in their spending.

The question then is the extent to which any extra money will be passed on around the economy. Box 19.2 looks at this process.

Portfolio balance and the interest rate mechanism

The holding of a range of assets in people's portfolios can strengthen the interest rate transmission mechanism by making the liquidity preference curve less elastic (curve *L* in Figure 19.2(a) on page 589 is relatively steep). The reason is that speculative balances of money may now have a much smaller role. But why?

A reduction in the rate of interest (*r*) following an increase in the money supply may well make bond holding less attractive, but this does not mean that the extra money will be mainly held in idle balances. Again, it can be used to

purchase other assets such as property. Idle balances may expand only slightly.

Redraw the three diagrams of Figure 19.2 with a steeper L curve. Show how an increase in money supply will have a larger effect on national income.

How stable is the velocity of circulation?

Short-run variability of V

Most economists agree that there is some variability of the velocity of circulation (V) in the short run if the money supply is changed. To the extent that interest rates and yields do fall with an expansion of the money supply, people may well hold somewhat larger money balances: after all, the interest sacrificed by not holding bonds, etc., has been reduced. If people hold relatively more money, the velocity of circulation is thereby reduced, thus reducing the effect on aggregate demand. Furthermore, the direct mechanism (i.e. the portfolio balance mechanism) may take time to operate. In the meantime, V will fall.

Also, the demand for money can shift unpredictably in the short run with changing expectations of prices, interest rates and exchange rates. Thus V is unpredictable in the short run, and so is the effect of monetary policy on aggregate demand. For these reasons, changing the money supply may not be an effective means of short-run demand management.

Long-run stability of V

The main claim of monetarists is that the velocity of circulation (V) is relatively stable over the longer run, and any changes that do occur are the predictable outcome of institutional changes, such as the increased use of credit cards (see Box 19.3).

One explanation of why V remains relatively stable in the long run, despite an increase in money supply, is that sufficient time has elapsed for the direct mechanism to have worked fully through.

Another explanation is the effect on inflation and consequently on interest rates. This works as follows.

Assume an initial increase in money supply. Interest rates fall. V falls. But if money supply goes on rising and hence expenditure goes on rising, inflation will rise. This will drive up *nominal* interest rates (even though *real* interest rates will stay low). But in choosing whether to hold money or to buy assets, it is the nominal rate of interest that people look at, since that is the opportunity cost of holding money. Thus people economise on money balances and V rises back again.

In extreme cases, V will even rise to levels higher than before. This is likely if people start speculating that prices will rise further. People will rush to buy goods and assets before their prices rise further. This action will help to push the prices up even more. This form of destabilising speculation took place in the hyperinflation of Germany in the 1920s and in Zimbabwe in the years up to 2008, as people spent their money as quickly as possible (see Case Study 15.12 on the student website).

With a predictable V in the longer run, monetarists have claimed that monetary policy is the essential means of controlling long-term aggregate demand. For this reason, they have favoured a longer-term approach to monetary policy, including targets for the growth of the money supply (see page 503).

In the 1990s and 2000s, most governments adopted a policy of setting a target for the rate of inflation. This involves the central bank controlling aggregate demand by choosing an appropriate rate of interest. In these circumstances, the money supply must be *passively* adjusted to ensure that the chosen rate of interest is the equilibrium rate. This means expanding the money supply in line with the increase in real national income (Y) and the targeted increase in the price level (P). These rules were somewhat relaxed, however, following the recession of 2008/9 and subsequent rises in inflation. Preventing a double-dip recession became more important than strictly adhering to a (short-run) inflation target.

We explore inflation targeting and its effects in section 19.4. We explore the operation of monetary policy in section 22.3.

BOX 19.2 PARTY GAMES AND THE VELOCITY OF MONEY**Are you ready for a game of pass-the-parcel?**

What will be the effect of an increase in money supply on spending, output and prices? To address this we need to understand how money supply interacts with money demand. This requires an analysis of the velocity of circulation of money (V).

An interesting way of thinking about V and what it might mean for the economy is to consider changes in money in the context of a game of pass-the-parcel! Assume there has been an increase in money supply and that this causes individuals and firms to have excess money balances. In response, they can look to pass the excess on to somebody else and, of course, if that individual or firm also has excess money balances they too will look to pass it on. The consequence is a game of pass-the-parcel, where the parcel is money and the passing occurs through spending. The quicker the 'parcel' is passed, the higher will V be. If the extra spending is not matched by extra output (Y), then we would expect prices (P) to rise too.

But what if the increase in money occurred at a time when people are looking to increase their money holdings? This time there will be little impact on spending (and, in turn, output and prices) as people hold on tightly to the parcel and refuse to play the game. In this case the velocity of circulation would fall.

The growth in money and spending

One way of assessing the extent to which the non-bank private sector might be holding excess money balances is to

compare the annual growth in broad money with the annual growth in nominal spending (nominal GDP). Chart (a) is an indicator of the *excess nominal money balances* of the UK's non-bank private sector.

Positive values show excess money holdings: the velocity of circulation has slowed. This was the situation through the second half of the 1980s and much of the 2000s. To restore the balance of their portfolios, individuals and firms would be expected to pass the parcel more quickly, so causing the velocity of circulation to increase again. In turn, this increased spending would be expected to result in increasing economic activity, but perhaps in inflationary pressures too.

On the other hand, negative values indicate a deficit of liquid funds: the velocity of circulation has increased. This was the situation during the first half of the 2010s. To restore balance in this case, individuals and firms would be expected to increase money balances and so pass the parcel more slowly. The reduction in spending would act to constrain economic activity and limit any potential inflationary pressures.

Money balances in different sectors

Our excess money balance indicator is an imperfect indicator of short-term activity and potential price movements, however, not least because the non-bank private sector comprises three groups: households, non-financial corporations (firms) and other financial corporations (e.g. insurance companies, pension funds and unit trusts). The key

(a) Annual money growth minus annual spending growth

Source: (i) *Statistical Interactive Database*, Bank of England, series LPQVQJW (data published 29 September 2017) and (ii) *Quarterly National Accounts*, Office for National Statistics, series YBHA.

point is that the implications for spending, economic activity and prices may depend on which of these three groups is experiencing excess or deficit money balances. Moreover, the ways in which these groups adjust their portfolios can have quite different economic effects.

Chart (b) shows, alongside the annual rate of growth of M4, the growth in the stock of M4 held by each of the groups comprising the non-bank private sector since 2000. From the second half of the 2000s we observe markedly contrasting rates of growth in their money holdings. The particular concern of the Bank of England was the dramatic slowdown from 2008 in the growth of broad money holdings of households and firms (non-financial corporations). This was not entirely surprising given the substantial retrenchment of lending and so of credit creation by financial institutions.

As if the negative impact of this on spending growth was not enough, households and firms were also looking to rebuild their balance sheets and reduce their debt exposure. An important element of this was their increased demand for money balances. In what were incredibly uncertain times, and with the markets for shares and housing depressed, households and firms looked to increase the liquidity of their portfolios. It was almost as if the music for our game of

pass-the-parcel had stopped. Inevitably, the growth in nominal spending fell sharply, economic activity floundered and the economy entered into recession.

By contrast, broad money holdings of other financial corporations (OFCs) grew rapidly in the late 2000s before declining in the early 2010s.

Some of the initial rise in money holdings by OFCs related to unsold liquid securities issued by Special Purpose Vehicles (SPVs) to fund the purchase of securitised assets, such as residential mortgages, from banks (see section 18.2). However, some of the increased money holdings were the result of quantitative easing, with OFCs exchanging gilts for money from the Bank of England. This increased the liquidity of OFCs' balance sheets. If money holdings are excessive, they can be passed on by purchasing other assets. In doing so, asset prices tend to rise and their yields fall. Therefore, it was hoped that amongst the positive effects of passing-the-parcel would be lower borrowing costs, a boost to the wealth of asset holders and increased economic activity.

What can we infer from charts (a) and (b) about the stability of the velocity of circulation in the short run? What can we learn from chart (b) about the association between the growth of money holdings and that in nominal GDP?

(b) Annual growth rates of broad money and nominal GDP

BOX 19.3 THE STABILITY OF THE VELOCITY OF CIRCULATION

What is the evidence?

How stable is the velocity of circulation (V) in practice? Does the evidence support the monetarist case that it is relatively stable or the Keynesian case that it fluctuates unpredictably, at least in the short run? Unfortunately, the facts do not unequivocally support either side.

The evidence

How has V behaved over time? To answer this we need to measure V . A simple way of doing this is to use the formula $V = PY/M$ (rearranging the terms in the quantity equation $MV = PY$). Thus we need to measure PY and M . PY is simply the money value of national output: in other words, GDP at current prices. The value of M (and hence V) will depend on which measure of the money supply we use.

The diagram shows how the velocities of circulation in the UK of both broad money (M4) and narrow money (notes and coin) have changed over the years.

The long run

Broad money. Long-term increases in the velocity of broad money from 1973 to 1979 are explained by the increase in money substitutes and credit cards, and thus smaller holdings of money balances.

The decrease after 1980 reflects falling inflation and nominal interest rates, with people being increasingly prepared to hold money in sight accounts; the growth in wholesale deposits (which earn interest); and people putting a larger proportion of their savings into bank and building society accounts, attracted by higher real interest rates and new types of high-interest instant-access accounts. As the pace of these changes slowed, so the fall in velocity became gentler after 1990.

However, in the second half of the 2000s the velocity of broad money once again fell sharply. The financial and

Velocities of circulation for narrow and broad money

Sources: (i) *Statistical Interactive Database*, Bank of England, series LPMVAB and LPQAUYN (data published 1 November 2017) and (ii) *Quarterly National Accounts*, Office for National Statistics, series YBHA.

economic upheaval of this period is likely to have increased the demand for liquid assets.

Then, after the effects of the financial crisis waned and spending began to grow again, so the velocity of circulation increased. The size of people's desired money balances gradually decreased as confidence slowly grew.

Narrow money. The velocity of narrow money more than doubled between 1974 and 1993. One reason for this was the increased use of credit and debit cards, which reduced the amount of cash people needed to hold. The growth of cash machines also reduced the need to hold so much cash, given that many people could easily obtain more at any time. The relatively smaller amount of cash thus circulated faster. But, as with broad money, these changes in the velocity of narrow money ceased in the early 1990s.

During the 2000s, the velocity of narrow money actually fell back to levels seen in the late 1980s. Low inflation rates, by reducing the opportunity cost of holding cash, contributed to the fall during the first half of 2000s. As with broad money, the impact of the economic and financial crisis contributed to a further fall in the velocity of narrow money during the second half of the 2000s.

But, unlike broad money velocity, narrow money velocity has continued to fall. Part of the reason has to do with the continuing rapid growth of purchases with cards. This has been fuelled by the growth in online sales and by the use of contactless card payments. At the same time, with continuing record low interest rates, the opportunity cost of holding narrow money has been very low.

The point made by monetarists is that these changes are predictable and gradual and do not, therefore, undermine the close relationship between M and PY .

The short run

Evidence shows periods when the velocity of circulation has been relatively stable in the short run, especially during the 1990s. However, this is largely because changes in money

supply were not used to manipulate aggregate demand and hence national income. However, in response to the financial crisis of the late 2000s, the Bank of England embarked on a policy known as quantitative easing to increase the money supply. As we discussed in Box 19.2 the success of this was to depend on the responses of individuals and firms and so the extent to which V would fluctuate.

The direction of causality

Monetary and real changes often work together – especially in the long run. An expansionary fiscal policy over a number of years will increase public-sector borrowing, which, in turn, will lead to an increase in money supply (M). If the fiscal policy increases nominal national income (PY), V may well as a result remain constant. But it does not follow from this that it was the growth in M that *caused* the growth in PY . On the few occasions when fiscal and monetary policy work in opposite directions, the evidence is unclear as to which has the bigger effect – especially as the time period is rarely long enough for the full effects to be identified.

What we are concerned about here is the direction of causality. Changes in aggregate demand may go together with changes in money supply. But is it higher money supply causing higher aggregate demand, or the other way round, or the two simply occurring simultaneously?

Monetarists argue that increases in money supply cause (nominal) aggregate demand to expand (with a lag of perhaps a few months). For them money supply is exogenous: determined independently by the central bank. Keynesians, by contrast, argue that higher aggregate demand causes an increased demand for bank loans, and banks are only too happy to create the necessary credit, thus expanding the money supply. For them, money supply is endogenous.

Why might it be difficult to establish the direction of causality from the evidence?

Section summary

1. The quantity equation $MV = PY$ can be used to analyse the possible relationship between money and prices. Whether and how much increases in money supply (M) affect the price level (P) depends on whether the velocity of circulation (V) and the level of real national income (Y) are independent of money supply (M).
2. The interest rate transmission mechanism works as follows: (a) a rise in money supply causes money supply to exceed money demand; assuming that expected inflation is fixed, real interest rates fall; (b) this causes investment to rise; (c) this causes a multiplied rise in national income; but (d) as national income rises, so the transactions demand for money rises, thus preventing quite such a large fall in interest rates.
3. The effect will be weak if the demand-for-money curve (L) is elastic and the investment demand curve is inelastic. The effects may also be unreliable because of an unstable and possibly inelastic investment demand.
4. The exchange rate transmission mechanism works as follows: (a) a rise in money supply causes interest rates to fall; (b) the rise in money supply plus the fall in interest rates causes an increased supply of domestic currency to come on to the foreign exchange market; this causes the exchange rate to fall; (c) this causes increased exports and reduced imports, and hence a multiplied rise in national income.
5. According to the theory of portfolio balance, if people have an increase in money in their portfolios, they will attempt to restore portfolio balance by purchasing assets, including goods. Thus an increase in money supply is transmitted directly into an increase in aggregate demand.
6. The demand for money is more stable in the long run than in the short run. This leads to a greater long-run stability in V (unless it changes as a result of other factors, such as institutional arrangements for the handling of money).

19.2 THE MONETARY EFFECTS OF CHANGES IN THE GOODS MARKET

If there is an expansion in one of the components of aggregate demand (C, I, G or $X - M$), what will be the monetary effects? Will the current level of money supply act as a constraint on the growth in national income? In other words, will an expansion of one component of aggregate demand, such as government expenditure, be at the expense of another component, such as investment?

The monetary effects of an increase in injections

Let us assume that business confidence grows and that, as a result, the level of investment increases. Let us also assume that there is a given quantity of real money balances in the economy and, further, that prices are constant in the short term. Will the rise in investment lead to a full multiplier effect on national income?

The effect of the rise in investment is illustrated in Figure 19.8. In Figure 19.8(a), the rise in investment leads to a rise in injections to J_2 . Other things being equal, the real level of national income would rise to Y_2 . But this increase in real national income also leads to a rise in the transactions demand for money. The rise in demand for real money balances leads to the demand-for-money curve in Figure 19.8(b) shifting from L to L' .

If the central bank does not wish to allow the real value of the economy's money supply to rise, the higher demand for money will force it to raise interest rates to r_2 . The effect of higher real interest rates is to reduce the level of investment. The overall rise in injections will be smaller than the rise from J_1 to J_2 . Also net saving (i.e. saving minus borrowing) will rise as the higher real interest rate acts as both an incentive for

households to save and a disincentive for them to borrow. This causes an upward shift in the W curve. The result is that the real level of national income will not rise as far as Y_2 . In the extreme case, there would be no rise in real national income at all.

If, however, the central bank responds to the increase in investment by expanding the real money supply to M_s' , there will be no change in the real rate of interest and hence no dampening effect on either the volume of investment or consumption.

 Assume that the government cuts its expenditure and thereby runs a public-sector surplus.

- (a) What will this do initially to equilibrium national income?
- (b) What will it do to the demand for money and initially to interest rates?
- (c) Under what circumstances will it lead to
 - (i) a decrease in money supply;
 - (ii) no change in money supply?
- (d) What effect will (i) and (ii) have on the rate of interest compared with its original level?

Crowding out

Another example of the monetary constraints on expansion in the goods market is the phenomenon known as **financial crowding out**. This is where an increase in public-sector spending reduces private-sector spending (see Box 16.2 on page 497).

Definition

Financial crowding out Where an increase in government borrowing diverts money away from the private sector.

To illustrate the effects, assume that previously the government has had a balanced budget, but that now it chooses to expand the level of government expenditure without raising additional taxes. As a result, it runs a budget deficit ($G > T$). But this deficit will have to be financed by borrowing. This increased borrowing will lead to an increase in the money supply if it is financed by sales of government debt to financial institutions, especially debt with shorter maturity. Alternatively, if it is financed by selling bills or bonds outside the banking sector, there will be no increase in the money supply.

The effect can once more be shown in Figure 19.8. A rise in government spending on goods and services will cause injections to rise to J_2 and, other things being equal, real national income will rise to Y_2 . But, as with the case of increased investment, this increase in real national income will lead to a rise in the demand for real money balances. In Figure 19.8(b), the demand-for-money curve shifts from L to L' .

If public-sector borrowing is financed in such a way as to allow the real money supply to expand to M_2' , there will be

no change in the real interest rate and no crowding-out effect. If, however, the real money supply is not allowed to expand, interest rates will rise to r_2 . This in turn will reduce investment: crowding out will occur. Injections will fall back again below J_2 . In the extreme case, injections could even fall back to J_1 and thus real national income return to Y_1 . Here crowding out is total.

The extent of crowding out

Just how much crowding out will occur when there is an expansionary fiscal policy, but when the supply of real money balances is *not* allowed to expand, depends on two things.

The responsiveness (elasticity) of the demand for money to a change in interest rates. If the demand is relatively elastic (as in Figure 19.9(a)), the increase in demand, represented by a horizontal shift in the liquidity preference curve from L to L' , will lead to only a small rise in real interest rates. If, however, the demand is relatively inelastic (as in Figure 19.9(b)), the same horizontal shift will lead to a bigger rise in real interest rates.

Figure 19.9 Different views on the demand for money

BOX 19.4 CROWDING OUT IN AN OPEN ECONOMY

EXPLORING
ECONOMICS

Taking exchange rate effects into account

Will fiscal policy be crowded out in an open economy with floating exchange rates? Assume that the government increases its expenditure but does not allow the money supply to expand: a case of pure fiscal policy. What will happen?

- The increased government expenditure will increase the demand for money (see Figure 19.8(b)).
- This will drive up interest rates – the amount depending on the elasticity of the liquidity preference curve.
- This will lead to an inflow of finance from abroad, which in turn will lead to an appreciation of the exchange rate.
- The higher exchange rate will reduce the level of exports

(an injection) and increase the level of imports (a withdrawal). This will add to the degree of crowding out.

Thus in an open economy with floating exchange rates, an expansionary fiscal policy will be crowded out not only by higher interest rates, but also by a higher exchange rate.

? We have argued that the short-term inflow of finance following a rise in the rate of interest will drive up the exchange rate. Are there any effects of expansionary fiscal policy on the demand for imports (and hence on the current account) that will go some way to offsetting this?

As we saw in section 19.1, Keynesians generally see the liquidity preference curve as being more elastic than do monetarists and new classical economists. They therefore argue that a rise in money demand normally leads to only a relatively modest rise in interest rates.

The responsiveness (elasticity) of investment to a change in interest rates. As we saw on page 591, Keynesians argue that investment is relatively unresponsive to changes in real interest rates. Businesspeople are much more likely to be affected by the state of the market for their product than by interest rates. Thus in Figure 19.10(a), there is only a small fall in the volume of investment. Monetarists and new classical economists, however, argue that investment is relatively responsive to changes in interest rates. Thus in Figure 19.10(b), there is a bigger fall in investment.

In the Keynesian case, therefore, the rise in demand for money arising from an expansionary fiscal policy will have only a small effect on interest rates and an even smaller effect on investment. Little or no crowding out takes place.

In fact, the expansion of demand might cause an increase in investment through the accelerator effect (see pages 542–5).

Monetarists and new classical economists argue that interest rates will rise significantly and that there will be a severe effect on investment. Crowding out is substantial. For this reason, they argue that, if money supply is to be kept under control to prevent inflation rising, it is vital for governments to reduce the size of their budget deficit. They argue that, in the long run, crowding out is total, given the long-run stability of the velocity of circulation.

The debate about crowding out in the early 2010s

There was a general tightening of fiscal policy around the world in the early 2010s, as governments sought to tackle the huge rises in public-sector debt that had resulted from bank bailouts and the fiscal stimulus packages that had been used to tackle the recession. Many governments, including the UK Coalition government, were unwilling to

Figure 19.10 Different views on the demand for investment

adopt a more expansionary fiscal policy for fear of crowding out private-sector investment and ‘spooking’ the markets that they were not serious about deficit reductions.

However, bankers and many economists were urging a relaxing of fiscal restraint. For example, a report by economists at Bank of America/Merrill Lynch stated that:

while fiscal austerity could help the long-run outlook, near-term fiscal consolidation threatens the recovery in developed economies. . . . Interest rates are already quite low, signalling limited market pressure to reduce deficits. As a result, near-term fiscal austerity would do little to lower rates. Moreover, companies are flush with cash. Investment is low because of a lack of confidence in the recovery – not because government borrowing is crowding them out.¹

Is money supply exogenous or endogenous?

Money supply is *exogenous* (independently determined) if it can be fixed by the authorities and if it does not vary with aggregate demand and interest rates. The money supply ‘curve’ would be vertical, as in Figure 19.9(b). It would shift only if the government or central bank *chose* to alter the money supply.

Money supply is *endogenous* (determined within the model) if it is determined by aggregate demand and hence the demand for money: banks expanding or contracting credit in response to customer demand. In such a case, the money supply curve would be upward sloping or even horizontal. The more that money supply expands in response to

an increase in aggregate demand, the more gently upward sloping the money supply curve would be.

The more elastic the money supply curve, the less will money act as a constraint on expansion in the goods market, and the less will a rise in government expenditure crowd out private expenditure. In other words, the less will real interest rates rise in response to a rise in the demand for real money balances.

The extreme monetarist position is that money supply is wholly exogenous. The extreme Keynesian position is that money supply is wholly endogenous: money simply passively expands to meet the demand for money.

In reality, money supply is partly exogenous and partly endogenous. The authorities are able to influence money supply, but banks and other financial institutions have considerable scope for creating credit in response to rises in demand. If control of the money supply is adopted as the basis for policy, the authorities must reduce the endogenous element to a minimum.

The authorities in many countries recognise the difficulties in controlling the money supply directly. They therefore influence the supply of money indirectly by controlling interest rates and hence the demand for money.

Sometimes, however, in extreme circumstances, the authorities may attempt to control money supply directly. As we saw in Chapter 18, central banks in several countries, including the USA, the UK, Japan and eventually the eurozone, injected large amounts of liquidity into their financial systems in response to the financial crisis. The aim was to stabilise their economies and to stimulate bank lending. This use of ‘quantitative easing’ is examined in section 22.2 (Boxes 22.5 and 22.10).

Section summary

1. Changes in injections or withdrawals will have monetary implications. If there is a rise in investment with no change in the supply of real money balances, the increased demand for money will drive up real interest rates and reduce both investment and consumption. The resulting rise in real income will be smaller.
2. Similarly, if there is a fiscal expansion and no change in the money supply, the increased demand for money will again drive up the real interest rate. This will to some extent crowd out private expenditure and thus reduce the effectiveness of the fiscal policy.
3. The extent of crowding out will depend on the shape of the liquidity preference curve and the investment demand curve. The less elastic the demand for money, and the more elastic the investment demand, the more crowding out will take place, and the less effective will fiscal policy be.
4. If there is a rise in aggregate demand, money supply may rise in response to this. The more elastic the supply of money curve, the less crowding out will take place.
5. Money supply is not totally exogenous. This makes it hard for the authorities to control it precisely. Generally, therefore, central banks try to control *interest rates* and attempt to alter liquidity to back this up. Sometimes, however, they may take more deliberate steps to inject extra liquidity into the financial system.

19.3 MODELLING THE INTERACTION OF MONETARY POLICY AND THE GOODS MARKET

The goods and money markets

In this chapter, we have shown that there are two key markets in the economy at macroeconomic level, and that these two markets interact. The first is the goods market; the second is the money market. Each of these two markets has been analysed by using a model.

In the case of the goods market, the model is the Keynesian injections/withdrawals model. Any change in injections or withdrawals will cause national income to change. For example, a rise in government expenditure shifts the J line upwards and causes a rise in equilibrium real national income. In other words, an increase in the demand for goods and services causes a (multiplied) rise in the output of goods and services (assuming that there are sufficient idle resources).

In the case of the money market, the model is the one showing the real demand for money (L) and the real supply of money (M) and their effect on the rate of interest. A change in the supply or demand for money will cause the equilibrium rate of interest to change. Monetary policy operates directly in this market, either by affecting the supply of money or by operating on interest rates.

What we have shown in this chapter is that the two markets *interact*: that changes in one market cause changes in the other. Therefore, we need a model which allows us to *combine* the goods and money markets. The traditional approach has been through a model known as the IS/LM model. The IS curve is based on equilibrium in the goods market; the LM curve is based on equilibrium in the money market. By examining the interaction of both markets we can see the implication for interest rates *and* output.

In many countries, including the UK, interest rates have become the key tool of monetary policy, with money supply controlled directly only in extreme circumstances. A (nominal) interest rate is announced by the central bank and then it supplies a given level of reserves to banks (central bank money), taking into account the real demand for money, so that the announced interest rate is the equilibrium one. Central banks do this principally to affect aggregate demand so as to meet an inflation rate target (normally set by the government). In both the UK and the eurozone, the target inflation rate is 2 per cent.

Under inflation targeting the authorities use monetary policy to affect equilibrium in the goods market. Therefore, the modern approach to modelling the interaction between the goods and money markets retains the IS curve as the IS curve relates to equilibrium in the goods market. However, the LM curve is replaced with a 'monetary policy curve' – the MP curve. The MP curve captures the interest rate choices of central bank.

The traditional IS/LM model can be found in the Appendix to this chapter. We now develop the IS/MP model.

The IS curve

Deriving the IS curve

To explain how the IS curve is derived, let us examine Figure 19.11, which as you can see is in two parts. The top part shows the familiar Keynesian injections and withdrawals diagram, only in this case, for simplicity, we are assuming that saving is the only withdrawal from the circular flow of income, and investment the only injection. The levels of saving (S) and investment (I) are *real* levels and in equilibrium $I = S$ (i.e. $J = W$). The bottom part of Figure 19.11 shows the IS curve. This shows all the various combinations of real interest rates (r) and real national income (Y) at which $I = S$.

Assume initially that the real interest rate is r_1 . Both investment and saving are affected by the level of real interest rates, and thus, other things being equal, an interest rate of r_1 will give particular investment and saving schedules. Let us say that, in the top part of Figure 19.11, these are shown by the curves I_1 and S_1 . The equilibrium level of real national income will be where $I = S$, i.e. at Y_1 . Thus in the lower part of Figure 19.11, an interest rate of r_1 will give a level of output Y_1 . Thus point *a* is one point on the IS curve. At an interest rate of r_1 the goods market will be in equilibrium at output Y_1 .

Now what will happen if the real rate of interest changes? Let us assume that it falls to r_2 . This will cause a rise in investment and a fall in saving. A rise in investment is shown in the top part of Figure 19.11 by a shift in the investment line to I_2 . Likewise a fall in saving is shown by a shift in the saving curve to S_2 . This will lead to a multiplied rise in income to Y_2 (where $I_2 = S_2$). This corresponds to point *b* in the lower diagram, which therefore gives a second point on the IS curve.

Thus *lower* real interest rates are associated with *higher* real national income, if equilibrium is to be maintained in the goods market ($I = S$).

The elasticity of the IS curve

The elasticity of the IS curve (i.e. the responsiveness of real national income to changes in real interest rates) depends on two factors.²

The responsiveness of investment and saving to interest rate changes. The more investment and saving respond to a

² Note that, as with demand and supply curves, the elasticity of the IS curve will vary along its length. Therefore we should really talk about the elasticity at a particular point on the curve, or between two points.

change in the real rate of interest, the bigger will be the vertical shift in the I and S curves in the top part of Figure 19.11, and thus the bigger will be the effect on national income. The bigger the effect on national income, the more elastic will be the IS curve.

The size of the multiplier. This is given by $1/mps$ (i.e. $1/mpw$ in the full model). The mps is given by the slope of the S curve. The flatter the curve, the bigger the multiplier. The larger the value of the multiplier, the bigger will be the effect on real national income of any rise in investment and fall in saving, and the more elastic therefore will be the IS curve. Thus the flatter the S curve in the top part of Figure 19.11, the flatter the IS curve in the bottom part.

? In a complete model where there were three injections (I , G and X) and three withdrawals (S , T and M), what else would determine the shape of the 'JW' curve?

Keynesians argue that the IS curve is likely to be fairly inelastic. The reason they give is that investment is not very responsive to changes in real interest rates: the demand-for-investment curve in Figure 19.2(b) on page 589 is relatively inelastic. Saving also, claim Keynesians, is unresponsive to real interest rate changes. The effect of this is that there will only be a relatively small shift in the I and S curves in response to a change in interest rates, and thus only a relatively small change in national income.

Monetarists, by contrast, argue that investment and saving are relatively responsive to changes in real interest rates and that therefore the IS curve is relatively elastic.

Shifts in the IS curve

A change in real interest rates will cause a movement *along* the IS curve. As we saw in Figure 19.11, a reduction in interest rates from r_1 to r_2 causes a movement *along* the IS curve from point a to point b . Hence as real interest rates fall, real aggregate demand increases.

A change in any *other* determinant of investment or saving, however, will *shift* the whole curve. The reason is that it will change the equilibrium level of real national income at any given real rate of interest.

An increase in investment, other than as a result of a fall in real interest rates, will shift the IS curve to the *right*. This could happen, for example, if there were an increase in business confidence. A rise in business confidence *at the current real interest rate* will cause an upward shift of the I curve in the top part of Figure 19.11, which will cause a multiplied rise in real income. Thus in the lower part of Figure 19.11 a higher equilibrium real income is now associated with each level of the real interest rate: the IS curve has shifted to the right. Likewise, for any given real interest rate, a fall in saving, and hence a rise in consumption, would also shift the IS curve to the right.

In a complete model (with three injections and three withdrawals), where the IS curve was a ' $J = W$ ' curve rather than a simple ' $I = S$ ' curve, similar shifts would result from changes in other injections or withdrawals. Thus an expansionary fiscal policy that increased government expenditure on goods and services (G) or cut taxes (T) would shift the ' IS ' curve (i.e. the JW curve) to the right.

? In a complete JW model, what else would cause the JW curve (a) to shift to the right; (b) to shift to the left?

Figure 19.11 Goods market equilibrium: deriving the IS curve

Assume that a real interest rate of r_1 gives curves S_1 and I_1 and hence equilibrium national income of Y_1 . This gives point a on the IS curve.

Assume that a fall in the real interest rate to r_2 gives curves S_2 and I_2 . This gives point b on the IS curve.

The MP curve

Deriving the MP curve

To help analyse the monetary policy (MP) curve consider Figure 19.12. Unlike the *IS* curve, which was developed as part of the *IS/LM* model (see Appendix to this chapter) in the 1930s, the *MP* curve is a relatively new model, developed in the context of inflation targeting by central banks.³

In controlling inflation, the central bank adjusts the nominal policy rate. In simple terms, this is the rate of interest at which it is prepared to supply liquidity to financial institutions. Hence, this rate then affects other interest rates in the economy. For ease of exposition we begin our analysis by assuming a single representative interest rate. As we saw earlier (see page 589), it is the *real* rate of interest that is key in affecting aggregate demand.

Since, the *ex ante* real interest rate is the nominal interest rate (*i*) less the expected rate of inflation (π^e), the central bank needs to account for inflation rate expectations when deciding on the nominal interest rate. In the short term we assume an *inertia* in the adjustment of expectations. This means that the expected rate of inflation is constant or 'anchored' at any moment in time. Any adjustment to inflationary expectations in response to changes in actual inflation occurs with a lag.

The central bank is assumed to raise *real* interest rates when inflation rises above the target (π^*) and to lower them when inflation falls below the target. To raise the real rate of interest (*r*) the nominal rate of interest (*i*) must rise relative to the expected rate of inflation (π^e). Similarly, for the real rate of interest to fall the nominal interest rate must fall relative to the expected rate of inflation.

The *MP* curve is drawn as upward sloping. To understand why, assume that the economy represented in Figure 19.12 is at point *a* with real national income Y_1 and real interest rates r_1 . Assume too that inflation is currently at the target rate (π^*) and that Y_1 is the economy's potential output level, which in the short term is fixed.

Now assume that there is a positive 'shock' to aggregate demand because of a rise in consumer confidence that reduces saving by households. This (as we shall see later in Figure 19.14) is reflected in a rightward shift of the *IS* curve. The effect of this is to increase real national income, say to Y_2 . But, this pushes firms closer to full capacity and so results in the rate of inflation (π) rising above the target (π^*). The central bank will respond by raising the real rate of interest, say to r_2 . This gives a second point on the *MP* curve at point *b*.

The extent to which the inflation-targeting central bank raises real interest rates in response to the increase in real national income is determined by its forecasts of how the transmission mechanisms of monetary policy identified in

section 19.1 will affect inflation. Therefore, the *MP* curve represents the *short-term* response of the central bank. The adjustment process of the economy to economic shocks will determine subsequent monetary policy changes. We will consider these issues further in Chapters 20 and 21 when looking at the interaction between aggregate demand and supply both in the short and long run.

The short-term response of the central bank to a positive demand-side shock is to raise real interest rates: a move up the *MP* curve. But what if the economy had experienced a negative shock to aggregate demand? Because the fall in real national income causes the rate of inflation to fall below the target rate, the central bank responds by lowering the real rate of interest.

The relationship underpinning the *MP* curve can be summarised as follows:

$$Y \uparrow \rightarrow \pi > \pi^* \rightarrow r \uparrow$$

$$Y \downarrow \rightarrow \pi < \pi^* \rightarrow r \downarrow$$

The elasticity of the MP curve

The elasticity of the *MP* curve, i.e. the responsiveness of interest rates to changes in national income, will depend on the degree of slack in the economy.

If the economy is operating well below potential national income – a large negative output gap – a rise in national income (*Y*) will have little effect on inflation and hence little effect on the desired real rate of interest (*r*). The *MP* curve will be relatively flat. This means that the curve is relatively *inelastic* as interest rates (the dependent variable) are relatively unresponsive to changes in national income (the independent variable).

If, however, there is a positive output gap, with firms operating close to full capacity, a rise in income will be reflected largely in a rise in inflation, causing the central bank to make a relatively large change to interest rates. The *MP* curve will be relatively steep (*elastic*) as interest rates are relatively sensitive to changes in national income.

³ In fact, there are different versions of the *MP* curve. One version focuses on an interest rate target, rather than an inflation target. Another focuses on a complex target that is a combination of both inflation and national income or inflation and unemployment. The version we develop here is the most useful in the context of a specific inflation target and where the interest rate set by the central bank is only an intermediate variable determined by the actual rate of inflation relative to the target rate.

This means that the curve is likely to get steeper as national income rises, as in Figure 19.12. The closer the economy gets to full employment – i.e. the smaller the negative output gap or the bigger the positive output gap – the less slack there is in the economy. The less the slack, the more firms are likely to respond to a rise in demand by raising real prices (i.e. raising their prices above the rate of inflation) and the greater the resulting rise in inflation and the rise in central bank interest rates.

Shifts in the MP curve

A particular MP curve assumes a particular central bank target, a given expected rate of inflation and a particular level of potential income. If any one of these changes, a new MP curve will have to be drawn.

Change in the target rate of inflation. If the central bank chooses to raise the target rate of inflation, the MP curve will shift downwards. Any given level of national income and hence inflation will result in a lower central bank interest rate.

An inflationary shock. If there is a cost-push inflationary shock, such as a rise in inflationary expectations, an oil price increase or a substantial rise in the minimum wage, the MP curve will shift upwards. For any given level of national income (Y), there will be a higher rate of inflation and thus the central bank will choose a higher real rate of interest.

Change in central bank policy. If, instead of targeting just inflation, the central bank chooses to target national income or a combination of inflation and national income (known as a Taylor rule: we examine Taylor rules in section 22.4 on pages 705–706), then the MP curve will change shape. For example, putting a greater emphasis on targeting

a particular level of national income will make the MP curve steeper, as changes in national income will cause the central bank to make larger changes in interest rates than it would have done if it targeted inflation alone. In the extreme case of targeting just national income and not inflation at all, the curve would be vertical at the targeted level of national income.

Alternatively, the central bank may target unemployment alongside inflation. Again this will tend to make the curve steeper the more closely unemployment is aligned to national income. For example, the Fed in the USA has a dual mandate: it is required to target not only inflation but also increasing employment.

Change in potential national income. Potential national income is likely to rise over time. This rise in aggregate supply is the result of increased investment, new technology, greater labour efficiency, etc. A rise in potential national income will shift the MP curve to the right, as a given rate of inflation will be associated with a higher level of national income.

If the central bank targets real national income rather than inflation, what will be the shape of the MP curve?

Equilibrium

Equilibrium national income and the rate of interest are given by the intersection of the IS and MP curves. This is shown as point a in Figure 19.13, giving equilibrium national income of Y_e and an interest rate of r_e .

To demonstrate why this is an equilibrium, consider what would happen if national income were not at Y_e but at Y_1 . According to the MP curve (point b), the higher inflation associated with this higher level of national income would

Figure 19.13 Equilibrium in the goods and money markets

At Y_1 , the central bank will set a real rate of interest of r_1 . This will cause a fall in national income to Y_2 (a move along the IS curve). The central bank will then reduce the interest rate to r_e to achieve the target rate of inflation at Y_e .

* LOOKING AT THE MATHS

Equilibrium in the *IS/MP* model is where the two functions, *IS* and *MP*, are equal. The simplest mathematical representation of this is where both *IS* and *MP* are simple linear (i.e. straight-line) functions. The *IS* function could be expressed as

$$r = a - bY \quad (1)$$

In other words, the higher the real rate of interest (r), the lower will be the level of aggregate demand and hence real national income (Y).¹ This is consistent with a downward-sloping *IS* curve.

The *MP* function can be written as

$$r = c + dY \quad (2)$$

In other words, the higher the level of real national income (and hence the higher the rate of inflation), the higher will be the real rate of interest set by the central bank. This is consistent with an upward-sloping *MP* curve.

Equation (2) can be derived from the relationships between inflation (π) and national income and between inflation and the rate of interest. The relationship between inflation and national income is given by

$$\pi = e + f(Y - Y_p) \quad (3)$$

where Y_p is potential national income. The greater the excess of actual (short-run) income over potential income (i.e. the bigger the positive output gap), the higher will be the rate of inflation.

The relationship between inflation and the rate of interest is given by the central bank response function, which, in its simplest form, is given by

$$r = g + h(\pi - \pi^*) \quad (4)$$

where π^* is the target rate of inflation. The higher the actual inflation rate is relative to the target rate, the higher will be the rate of interest set by the central bank. Substituting equation (4) in equation (3) gives

$$r = g + h(e + f(Y - Y_p) - \pi^*) \quad (5)$$

Assuming that Y_p and π^* are constant, equation (5) can be simplified as equation (2):

$$r = c + dY \quad (2)$$

We can then solve for Y from equations (1) and (2) by setting the two equations equal. Thus

$$a - bY = c + dY$$

that is

$$bY + dY = a - c$$

giving

$$Y = \frac{a - c}{b + d}$$

Note that a change in any of the factors affecting Y , other than r , will shift the *IS* curve. Such factors include taxes, government expenditure, the exchange rate, expectations about income and prices, and so on.

Similarly, a change in any of the factors affecting r , other than Y , will shift the *MP* curve. Such factors include potential national income (Y_p), cost pressures, inflationary expectations and the inflation target (π^*).

The *IS* function can be written as

$$Y = IS(r, G, t, X, M, er, Y^e, \dots)$$

where G is government expenditure, t is the tax rate, X and M are the levels of exports and imports, er is the exchange rate, Y^e is the expected level of real national income and \dots represents other unspecified determinants.

Write an *MP* function in the form $r = MP(\dots)$ identifying each of the determinants.

¹ Note that although equation (1) shows r as a function of Y , the model in fact has Y as the dependent variable. In other words, r determines Y . We express equation (1) this way to make it consistent with equation (2), where r is the dependent variable.

lead the central bank to set an interest rate of r_1 . But this higher interest rate of r_1 will dampen aggregate demand. According to point c on the *IS* curve, the goods market will be in equilibrium at a level of national income of Y_2 . This will cause inflation to fall and hence the central bank to lower the rate of interest. As it does so, there will be a movement down along the *IS* curve and a rise in national income until equilibrium is reached at Y_c .

In practice, if the two markets are not in equilibrium, the central bank will attempt to move straight to r_c and Y_c by forecasting the likely movements in the economy and the results of its actions. The Bank of England, for example, at the meetings of the Monetary Policy Committee, examines forecasts of inflation and output contained in its quarterly *Inflation Report* and other models of the economy.

The next step in the analysis is to consider how shifts in either curve affect national income, inflation and interest rates.

Full effect of changes in the goods and money markets

Changes in goods market equilibrium resulting from changes to aggregate demand are illustrated by a shift in the *IS* curve. Changes to monetary policy or potential national income are illustrated by a shift in the *MP* curve.

Shifts in the *IS* curve

Assume in Figure 19.14(a) that equilibrium is at point a , at a level of national income of Y_1 . Now assume that a positive

demand shock occurs resulting in a rightward shift in the IS curve from IS_1 to IS_2 . This could arise, for example, because confidence rises and economic agents decide to increase spending or because of a loosening of fiscal policy (e.g. an increase in government purchases). This causes national income and inflation to rise. The central bank responds to the higher inflation by raising the rate of interest. There is a movement up along the MP curve. Equilibrium is reached at point b at a level of national income of Y_2 and a rate of interest of r_2 .

Shifts in the MP curve

As we noted earlier, many countries have adopted some form of inflation targeting. However, inflation targeting can take many different forms and the policy rule can be changed or adapted. For example, the Federal Reserve from 2008 and the Bank of England from 2013 supplemented their existing policy frameworks with forward guidance: statements about the likely path of future interest rates. The intention was to signal that interest rates were likely to remain low for some time given the fragile economic conditions following the financial crisis. The hope was that this would give economic agents confidence to bring forward spending.

To illustrate a change to the monetary policy rule using the IS/MP framework, consider the case where the central bank now sets a lower interest rate for any given level of output and rate of inflation. The effect of this looser monetary policy rule is to move the MP curve vertically downwards. This is illustrated by a move from MP_1 to MP_2 in Figure 19.14(b). The central bank reduces the nominal rate of interest so as to give a real rate of interest of r_3 . As a result there is a movement along the IS curve to point c and national income rises to Y_3 .

A positive supply-side shock would have a similar effect. An example is a rise in potential income. This again can be illustrated by a shift in the MP curve from MP_1 to MP_2 in Figure 19.14(b). With a rise in potential income, a higher level of actual income is now associated with any given rate of inflation and hence central bank interest rate.

What other examples of supply-side shocks would cause the MP curve to move vertically downwards?

Shifts in the both curves

If potential national income increases and also aggregate demand, actual income can rise without imposing extra inflationary pressures. This is illustrated in Figure 19.14(c). National income rises to Y_3 . The central bank does not need to raise interest rates as there is no upward movement in inflation.

Size of the effect on national income of shifts in either or both curves

The magnitude of a change in income resulting from a shift in one or both curves depends not only on the size of the shift, but in the shape of the curves.

- The effect of a shift in the IS curve will be bigger, the flatter is the MP curve and the steeper the IS curve. When MP is relatively flat (e.g. when there is plenty of slack in the economy), a rightward shift in IS will lead to only a small rise in the real rate of interest (r) by the central bank. If IS is steep (i.e. aggregate demand being relatively unresponsive to changes in interest rates), this rise in r will lead to only a small curtailing of investment. In these two circumstances, the dampening effect on investment and consumption is limited. There will be a large increase in national income (Y).
- The effect of a shift in the MP curve will be bigger when the MP curve is steep (e.g. when the economy is near full employment) and the IS curve is relatively flat. When the MP curve is steep, there will be a relatively large downward shift in the MP curve for any fall in the inflation target and hence a relatively large fall in r . When IS is relatively flat, this fall in r will lead to a relatively large increase in investment and hence Y .
- The effect of a shift in either curve will be bigger if matched by a similar shift in the other curve.

Figure 19.14 IS/MP analysis of changes in the goods and money markets

Section summary

1. The *IS/MP* model allows us to model the interaction between the goods and the money market. The model shows the relationship between national income and interest rates where central bankers set interest rates.
2. Equilibrium in the goods market is shown by the *IS* curve. This shows all the combinations of the real rate of interest and national income where investment (*I*) equals saving (*S*) (or, in a complete Keynesian model, where injections equal withdrawals). As the rate of interest rises, so investment will fall and saving will rise: therefore equilibrium national income will fall. The *IS* curve is thus downward sloping.
3. The *MP* curve shows the real rate of interest that the central bank would choose at any particular level of national income. We assume that the rate of inflation rises with the level of national income. The central bank will thus raise the real rate of interest (i.e. the nominal rate plus the rate of inflation) as national income rises. This gives an upward sloping *MP* curve. A higher potential national income, by putting downward pressure on inflation at any given level of actual national income, will shift the *MP* curve to the right. A lower inflation target will shift the curve downward.
4. Equilibrium occurs where $IS = MP$. At this point the goods market is in equilibrium at the real interest rate chosen by the central bank.
5. A shift in either curve will lead to a new equilibrium. The resulting size of the change in real national income and real interest rates will depend on the size of the shift and the shape of the other curve.

19.4 CREDIT CYCLES AND THE GOODS MARKET

Credit cycles

The flows of credit extended by financial institutions can vary considerably from period to period. This is shown in Figure 19.15, which plots annual flows of credit from monetary financial institutions (MFIs) to households and private non-financial corporations in the UK from 1965. The flows are measured relative to GDP, allowing us to make better comparisons of the magnitude of credit flows over time.

As you can see, there were heightened flows of credit in the late 1980s and the early-to-mid 2000s. In each case, this

was then followed by a period of significantly weaker credit growth and, for non-financial corporations, even net repayments of outstanding lending.

In analysing the interaction between the goods and money markets it is therefore important to understand how these cycles arise and what impact they have on aggregate demand and national output. We look at two theories of the instability of credit and the effect on the economy: the *financial accelerator* and the *financial instability hypothesis*.

Figure 19.15 Annual flows of credit from MFIs

Source: (i) *Statistical Interactive Database*, Bank of England, series LPQVWNV and LPQVWNQ (data published 29 September 2017) and (ii) *Quarterly National Accounts*, Office for National Statistics, series YBHA.

The financial accelerator

The *financial accelerator* explains how financial institutions can amplify the business cycle. They tend to lend more when macroeconomic conditions are improving or already strong, but less when they deteriorate.

The reason for this behaviour is that financial institutions use the macroeconomic environment as a basis for assessing the riskiness of their lending and the probability of default. A booming economy encourages banks to lend more; a recession makes them much more cautious.

This behaviour amplifies the effects of economic shocks. Positive economic shocks are magnified by increasing credit flows, while negative economic shocks are magnified by a weakening of credit flows.

Interest rate differentials

One way in which credit conditions can vary with macroeconomic conditions is through their impact on interest rate differentials. The financial system is characterised by a range of interest rates rather than a single interest rate. To simplify, we can assume that there is a representative real borrowing rate (r_b) and a representative real interest rate on savings (r_s). The differential between the two rates ($r_b - r_s$) reflects the risks attached to lending to economic agents and the costs incurred by financial institutions in screening clients and then in arranging and managing loans. The bigger the risk, the bigger the differential.

The interest rate differential can amplify economic fluctuations because the interest rate differential frequently varies across the course of business cycle. The differential tends to fall in a boom and rise in a slowdown or recession.

But why does the differential fall in a boom? As far as lending is concerned, banks and other financial institutions may see rising output levels as a signal that lending is becoming less risky. After all, the financial well-being of economic agents typically improves as national income rises. Consequently, banks tend to reduce the differential of borrowing rates over saving rates in periods of rapid economic growth. This is an example of the use of *heuristics* (see section 5.2, page 138) – banks using the macroeconomic situation to develop simple decision-making rules.

At the same time, with economic agents gaining more confidence, they may decide to spend more and reduce their level of savings. Banks may thus offer higher interest rates on savings, further reducing the differential between borrowing and saving rates.

Definition

Financial accelerator The amplification of effects on the macroeconomy from economic shocks because of changes in the pricing and supply of credit by financial institutions.

Availability of credit

A second way in which lending behaviour may vary across the business cycle is through changes in the volume of credit made available by financial institutions. Credit criteria are relaxed in a boom, as banks see rising output and incomes as a signal that lending is less risky. In a slowdown or recession, by contrast, lending is seen as more risky and hence credit criteria are tightened.

Taken together, varying interest rate differentials and varying credit constraints could therefore result in credit flows being strongly pro-cyclical.

The interaction between the multiplier and the financial accelerator

The effect of the financial accelerator is to *increase* the marginal propensity to consume domestically produced goods. To understand why, recall that the mpc_d is the proportion of the rise in output which is spent on domestic goods and services. As output rises, credit constraints weaken and the borrowing rate of interest (r_b) falls for a given saving interest rate (r_s). This means that investment (I) and consumption (C) rise as output rises. Hence, we have an *additional* channel by which increases in real national income cause aggregate expenditures to rise.

The financial accelerator has the effect of making the marginal propensity to consume domestically produced goods (mpc_d) bigger. Consequently, the measurable multiplier effect from increases in aggregate demand is bigger too. This is because the normal multiplier effects, whereby rising incomes increase spending, are supplemented by additional credit flows which facilitate further additional spending.

The financial accelerator and the IS/MP framework

Because the financial accelerator makes the overall multiplier bigger, the *IS* curve is more *elastic*. This is illustrated in Figure 19.16. When applying the *IS/MP* framework in the presence of interest rate differentials we need to identify

Figure 19.16 IS curve with financial accelerator effects

which interest rate is on the vertical axis. Since rates on saving typically track the central bank rate most closely, we now label the vertical axis the real interest rate on saving (r_s).

IS_1 shows the IS curve in the absence of financial accelerator effects, while IS_2 incorporates financial accelerator effects. This curve is flatter, as a given fall in saving rates will produce a bigger rise in national income as borrowing rates will have fallen more as the interest rate differential narrows and credit becomes more readily available.

The flatter curve, IS_2 , is shown as converging on IS_1 as output rises. This is because the interest rate differential declines and credit constraints weaken. Conversely, at lower levels of output credit constraints become tighter and the borrowing rate becomes relatively higher, so causing aggregate expenditure to be increasingly lower than it otherwise would be. In other words, we can think of financial market imperfections increasing as output falls (for a given level of potential output).

At each point on the IS curve the goods market is in equilibrium. As we illustrated in Figure 19.11 this means that injections (J) equal withdrawals (W). With the incorporation of an interest rate differential, we can think of our IS curve as showing the combination of the real interest rate on saving (r_s) and real national income (Y) that ensures that $J = W$.

The effects of consumer confidence. Consider now the effect of an increase in consumer confidence. In the presence of financial accelerator effects there is a larger rightward movement of the IS curve than would otherwise be the case. This is because as output rises (as the IS curves shifts rightwards) the financial market imperfections lessen. At each real interest rate on saving (r_s) there is a lower interest rate differential than before along with reduced credit constraints.

These additional effects further increase spending and, hence, output.

Another way of analysing the effect on output of an increase in consumer confidence is to consider upward shifts of the IS curve. The magnitude of the financial market imperfections grow smaller as the level of output rises. But, at any particular level of output, at any moment in time, they are fixed. Hence, these imperfections have no effect on the extent to which the IS curve moves upwards when consumer confidence rises. This is useful because we can now show more clearly how financial accelerator effects magnify the impact of demand shocks on output. We do this in Figure 19.17.

Assume the economy is at point a with the real interest on saving (and the real central bank policy rate) at r_1 and real national income at Y_1 . Curve IS_1 represents the economy in the presence of financial accelerator effects. It is flatter than IS'_1 , which illustrates the position with no financial accelerator effects.

The rise in consumer confidence causes an equivalent upward movement of both IS curves. This is represented by the vertical distance $b-a$ at the initial level of output, Y_1 . In the presence of financial accelerator effects the IS curve moves to IS_2 while in the absence of financial accelerator effects the IS curve moves to IS'_2 .

The new short-run equilibrium in the absence of the financial accelerator is at point c . From this we can see that output has increased from Y_1 to Y_2 . However, with financial accelerator effects the new equilibrium is at point d and this represents an increase in output from Y_1 to Y_3 . Therefore, the financial accelerator leads to an additional increase in output equivalent to $Y_3 - Y_2$. This captures the additional effects on aggregate demand as the interest rate differential falls and banks relax their lending criteria.

Figure 19.17 Financial accelerator: positive demand-side shock

The interest rate on saving increases by more following the rise in consumer confidence in the presence of the financial accelerator. Since the real interest rate on saving tracks the real policy rate, this reflects the larger increase in the real interest rate by the central bank. The financial accelerator causes a larger rise in output, which leads to a larger rise in the rate of inflation.

The increase in the saving (and central bank) interest rate is captured by the move up and along the MP curve. This will put upward pressure on the interest rate on borrowing (r_b). However, the fall in the interest rate differential ($r_b - r_s$) that occurs as output increases tends to decrease the interest rate on borrowing. We would tend to expect the borrowing rate to rise following the rise in confidence. But if it does rise, it will rise by less than otherwise in the presence of financial accelerator effects.

The financial instability hypothesis

The second theory of credit cycles is the *financial instability hypothesis (FIH)*. This theory argues that the volume of credit flows goes through stages which are ultimately destabilising for the economy. As flows of credit increase unsustainably as, it is argued, they inevitably do, they cause the health of the balance sheets of people and businesses to deteriorate. This then results in a period of consolidation during which spending growth is subdued.

The hypothesis argues that the financial system generates unsustainable growth in the goods market. Our appetite for goods and services is fed by increasing flows of credit which increasingly place greater strain on people's ability to meet their debt obligations. Eventually, the financial distress is too great and the growth in aggregate demand ends, perhaps very abruptly, as people take steps to improve their financial well-being.

The financial instability hypothesis is associated with American economist Hyman Minsky (1919–96). He argued that financial cycles are an inherent part of the economic cycle and are the primary source of fluctuations in real GDP. He argued that the accumulation of debt by people and

businesses is not only pro-cyclical, but destabilising. While Minsky himself focused on the accumulation of debt by businesses, the role of the mortgage market in generating unsustainable stocks of household debt during the 2000s (see Box 18.2) has meant that his ideas are now frequently applied across the whole of the private sector.

The extension of credit by financial institutions can be seen to go through three different stages: financial tranquility, financial fragility and financial bust. During each of these stages both the credit criteria of banks and the ability of borrowers to afford their debts vary.

Minsky argued that credit flows will tend to increase after a period of sustained growth. This causes banks and investors to develop a heightened euphoria and confidence in the economy and in the returns of assets. Economists refer to this as *irrational exuberance*, which results in people and businesses taking on bigger debts to acquire assets. These debts increasingly stretch their financial well-being. A point is reached, perhaps triggered by an economic shock or a tightening of economic policy, when the euphoria stops and confidence is replaced with pessimism. This moment is now commonly referred to as a *Minsky moment*.

The result of a Minsky moment is that lenders reduce their lending, and economic agents look to increase their net worth (i.e. reduce debts or increase savings) to ensure their financial well-being. However, the result of these individual actions causes a decline in spending and in national income. The collapse in aggregate demand from financial distress therefore leads to a *balance-sheet recession* or economic downturn. Furthermore, by selling assets to improve financial well-being, the value of assets falls. This paradoxical reduction of net worth is known as the paradox of debt (see Chapter 16, page 514).

Minsky believed that credit cycles are inevitable in a free-market economy. Hence, the authorities will need to take action to moderate credit cycles. The significance given to macro-prudential regulation by policy makers (see section 18.3) in the response to the financial crisis is recognition of the dangers posed to the economy by credit cycles.

Definitions

Financial instability hypothesis The theory that the economy goes through stages of credit accumulation which initially fuel aggregate demand but because of increasing financial distress eventually see a collapse in aggregate demand.

Irrational exuberance Where banks and other economic agents are over-confident about the economy and/or financial markets and expect economic growth to remain stronger and/or asset prices to rise further than warranted by evidence. The term is associated with the economist

Robert Shiller and his book *Irrational Exuberance* (2000) and with the former US Federal Reserve Chairman, Alan Greenspan.

Minsky moment A turning point in a credit cycle where a period of easy credit and rising debt is replaced by one of tight credit and debt consolidation.

Balance-sheet recession A recession or economic slowdown caused by a collapse in aggregate demand arising from the actions of financially distressed people and businesses.

BOX 19.5

THE FINANCIAL ACCELERATOR AND FLUCTUATIONS IN AGGREGATE DEMAND

EXPLORING
ECONOMICS

Illustrating financial accelerator effects using the Keynesian cross

Financial market imperfections

New Keynesians emphasise how market imperfections contribute to economic volatility (see pages 506–507). The financial accelerator shows how imperfections in the financial system can amplify the ups and downs associated with the business cycle.

According to the financial accelerator, the state of the economy affects the lending behaviour of financial institutions, which, in turn, affects aggregate demand and the real economy. Because of this feedback to the economy itself the business cycle is amplified. If we assume that financial institutions take rising levels of real GDP as a signal that lending is less risky and falling levels that it is more risky, then credit flows may become acutely pro-cyclical.

The financial accelerator and the 45° line diagram (Keynesian cross)

As national income rises, the financial accelerator effects are *additional* to the normal multiplier (and accelerator) effects which act to increase expenditures. The impact of the financial accelerator is to make the aggregate expenditure line in the Keynesian cross diagram *steeper*. This is illustrated in Figure (a). It shows a particular economy's aggregate expenditure. In the absence of financial accelerator effects the aggregate expenditure line is E_1 , while in the presence of financial accelerator effects it is E_2 . This reflects the idea that with financial accelerator effects the economy would have a bigger marginal propensity to consume domestically produced goods (mpc_d). The two lines grow closer as real

national income rises because credit constraints lessen and the interest rate differential narrows (see page 611).

We can use the Keynesian cross diagram to illustrate the amplification of fluctuations in output arising from fluctuations in aggregate demand. We do this in Figure (b). For ease of illustration we assume that, with or without financial accelerator effects, the economy is initially at income level Y_1 .

Consider now the effect of a given increase in autonomous expenditures: i.e. expenditures unrelated to real national income, such as investment (I) or government purchases (G). This results in both of the E lines moving vertically upwards by the same distance.

From the diagram we can see that, in the absence of the financial accelerator, output rises from Y_1 to Y_2 . However, in the presence of the financial accelerator, output rises from Y_1 to Y_3 . The financial accelerator effects lead to an additional increase in output equivalent to $Y_3 - Y_2$. This captures how the additional credit flows, which arise as the economy expands, generate additional expenditure.

The more significant the financial accelerator effects, the steeper is the E line and the more output fluctuates in response to shocks to aggregate demand.

1. Is it possible for the aggregate expenditure line to be steeper than the 45° line in the presence of financial accelerator effects?
2. What has happened to the interest rate on borrowing (r_b) and the interest rate on saving (r_s) in the two scenarios shown in Figure (b)?

(a) Financial accelerator and aggregate expenditure line

(b) Financial accelerator and output fluctuations

Section summary

1. The financial accelerator amplifies the impact on the economy of economic shocks. The lending behaviour of financial institutions is argued to be dependent on the state of the economy. Increasing output levels may weaken credit constraints and reduce the differential between interest rates on borrowing and on saving. Conversely, falling output levels increase credit constraints and the differential between interest rates on borrowing and saving.
2. The financial accelerator increases the size of the multiplier. The impact on real national income of demand-side shocks is amplified by changes in the pricing and supply of credit by financial institutions.
3. The financial instability hypothesis (FIH) characterises economies as progressing through stages. In the first stage people and businesses accumulate more debt. The accumulation of debt is driven by an over-confidence and euphoria and, hence, by an irrational exuberance.
4. The FIH predicts that debt accumulation will initially boost aggregate demand. However, as debt-servicing obligations progressively increase, the growth in aggregate demand will begin to weaken. A Minsky moment is reached when financial distress causes a collapse in aggregate demand. The result is a balance-sheet recession or slowdown.

APPENDIX: THE IS/LM MODEL

In Section 19.3 we applied a framework known as the *IS/MP* model to analyse the interaction between monetary policy and the goods market. This framework recognises that many central bankers today attempt to achieve a target rate of inflation. They do this by seeking to influence the structure of interest rates in the economy and thereby to affect aggregate demand. We look at central bank objectives and their evolution in greater detail in Chapter 22.

The predecessor to the *IS/MP* model was the *IS/LM model*. As with the *IS/MP* model, *IS/LM* model allows us to examine the effects of changes originating in the money or goods markets on *both* national income *and* interest rates: it shows what the equilibrium will be in both the goods and the money markets simultaneously. The difference with the *IS/MP* model is that there is no inflation target. Instead, interest rates are purely market determined. The central bank is assumed to conduct monetary policy through changes in money supply.

As we saw earlier, the *IS* curve is based on equilibrium in the goods market. The *LM* curve is concerned with equilibrium in the money market. It shows all the various combinations of interest rates and national income at which the demand for money (L) equals the supply (M). The *LM* curve is different from the *MP* curve in that it analyses how the interest rate adjusts to help bring money demand into equilibrium with money supply. In other words, the interest rate equilibrates the money market at any given level of national income.

In constructing the *IS/LM* model we assume, for simplicity, that prices are constant, i.e. there is an absence of

inflation. Therefore, there is no difference between the nominal interest rate (i) and real interest rate (r).

The *IS* curve

We analysed the *IS* curve in depth in section 19.3, so only a brief overview is provided here. The curve shows combinations of national income and interest rates at which planned expenditure equals national income. This occurs when the flow of injections (J) is matched by the flow of withdrawals (W). Hence, when we consider all injections (I , G and X) and withdrawals (S , T and M), rather than just investment and saving, we may think of the curve as a JW curve.

When the real rate of interest (r) rises, there is a fall in investment and a fall in saving. This will lead to a multiplied fall in income. Thus *higher* interest rates are associated with *lower* national income, if equilibrium is to be maintained in the goods market ($J = W$). The *IS* curve is therefore drawn as downward sloping, as illustrated in Figure 19.11 on page 605.

A change in *interest rates* causes movements *along* the *IS* curve. Changes in any *other* determinant of injections and withdrawals *shift* the whole curve. The reason is that it will change the equilibrium level of national income at any given rate of interest. For example, if, in response to a decline in their net worth, firms reduce their investment at *the current interest rate* (resulting in a downward shift of the I curve in the top part of Figure 19.11), there is a multiplied fall in national income. Thus a lower equilibrium income is now associated with each level of the interest rate. The *IS* curve has shifted to the left.

Definition

IS/LM model A model showing simultaneous equilibrium in the goods market ($I = S$) and the money market ($L = M$).

The *LM* curve

Deriving the LM curve

To explain how the *LM* curve is derived consider Figure 19.18. The left-hand part of the diagram is the

Figure 19.18 Money market equilibrium: deriving the *LM* curve

Assume that national income of Y_1 gives a demand for money of L' and hence an interest rate of r_1 . This gives point c on the LM curve.

Assume then that a rise in national income to Y_2 raises the demand for money to L'' and hence the interest rate to r_2 . This gives point d on the LM curve.

familiar money market diagram, showing a liquidity preference (demand for money) curve (L) and a supply of money curve (M).

At any given level of national income, there will be a particular level of transactions-plus-precautionary demand for money, and hence a given overall demand-for-money curve (L). Let us assume that, when national income is at a level of Y_1 in the right-hand part of Figure 19.18, the demand-for-money curve is L' . With the given money supply curve M_s , the equilibrium rate of interest will be r_1 . Thus point c is one point on the LM curve. At a level of national income Y_1 , the money market will be in equilibrium at a rate of interest of r_1 . (Note that we are assuming that the money supply curve is not totally exogenous; in other words, the curve is upward sloping. In simple IS/LM models, the money supply curve is (unrealistically) assumed to be vertical.)

Now what will happen if the level of national income changes? Let us assume that national income rises to Y_2 . The effect is to increase the transactions-plus-precautionary demand for money. The L curve shifts to the right: to, say, L'' . This will cause the rate of interest to rise to the new equilibrium level of r_2 . This therefore gives us a second point on the LM curve (point d).

Thus *higher* national income leads to a greater demand for money and hence *higher* interest rates if equilibrium is to be maintained in the money market. The LM curve is therefore upward sloping.

The elasticity of the LM curve

The elasticity of the LM curve (i.e. the responsiveness of interest rate changes to a change in national income) depends on two factors.⁴

The responsiveness of the demand for money to changes in national income. The greater the marginal propensity to consume, the more will the transactions demand for money rise as national income rises, and thus the more the L curve will shift to the right. Hence the more the equilibrium interest rate will rise, and the steeper will be the LM curve.

The endogeneity of money will lessen this effect. In the case of an upward-sloping money supply curve (as in Figure 19.18), the less steep it is, the more will money supply expand in response to a rise in the demand for money and the less will interest rates rise. Hence the flatter will be the LM curve. Where money supply simply expands passively to meet any rise in demand, the LM curve will be horizontal.

The responsiveness of the demand for money to changes in interest rates. The more the demand for money responds to a change in interest rates, the flatter will be the liquidity preference curve in the left-hand part of Figure 19.18. The flatter the L curve, the less will the equilibrium interest rate change for any given horizontal shift in the L curve (arising from a change in Y). The less the equilibrium interest rate changes, the flatter will be the LM curve.

The Keynesian and monetarist views on the shape of the LM curve reflect their respective views on the elasticity of the L curve. Keynesians argue that the L curve is likely to be relatively flat given the responsiveness of the speculative demand for money to changes in interest rates and the endogeneity of money. They thus argue that the LM curve is correspondingly relatively flat (depending, of course, on the scales of the axes). Monetarists, on the other hand, argue that the LM curve is relatively steep. This is because they see the demand for money as insensitive to changes in interest rates and the supply of money as being exogenous.

⁴ Note that the rate of interest is the dependent variable and the level of national income is the independent variable. Thus the more elastic is the LM curve (i.e. the more responsive interest rates are to changes in national income), the *steeper* it will be.

Shifts in the LM curve

A change in *national income* will cause a movement *along* the LM curve to a new equilibrating interest rate. Thus in Figure 19.18 a rise in national income from Y_1 to Y_2 leads to a movement along the L curve from point *c* to point *d* and hence a rise in the rate of interest from r_1 to r_2 .

A change in any *other* determinant of the demand and supply of money will *shift* the whole curve. The reason is that it will change the equilibrium level of interest associated with any given level of national income.

An increase in the demand for money, other than as a result of a rise in income, will shift the L curve to the *right*. This could be due to people being paid less frequently, or a greater use of cash, or increased speculation that the price of securities will fall. This increased demand for money will raise the equilibrium rate of interest at the current level of national income. The LM curve will shift upwards.

An increased supply of money by the authorities will shift the M_s curve to the right. This will lower the rate of interest (in the left-hand part of Figure 19.18). This will shift the LM curve downwards: a lower rate of interest will be associated with any given level of national income.

? Draw a diagram like Figure 19.18, only with just one L curve. Assume that the current level of national income is Y_1 . Now assume that the supply of money decreases. Show the effect on
(a) the rate of interest;
(b) the position of the LM curve.

Equilibrium

The IS curve shows all the combinations of the rate of interest (r) and national income (Y) at which the *goods* market is

in equilibrium. The LM curve shows all the combinations of r and Y at which the *money* market is in equilibrium. *Both* markets will be in equilibrium where the curves intersect. This is at r_e and Y_e in Figure 19.19.

But what would happen if both markets were not simultaneously in equilibrium? How would equilibrium be achieved?

Let us suppose that the current level of real national income is Y_1 . This will create a demand for money that will lead to an equilibrium real interest rate of r_1 (point *a* on the LM curve). But at this low interest rate, the desired level of investment and saving would generate an income of Y_2 (point *b* on the IS curve). Thus national income will rise. But as national income rises, there will be a movement up along the LM curve from point *a*, since the higher income will generate a higher demand for money and hence push up interest rates. And as interest rates rise, so the desired level of investment will fall and the desired level of saving will rise so as to reduce the equilibrium level of national income below Y_2 . There will be a movement back up along the IS curve from point *b*. Once the interest rate has risen to r_e , the actual level of income will be at the equilibrium level (i.e. on the IS curve). Both markets will now be in equilibrium.

? Assume that national income is initially at Y_2 in Figure 19.19. Describe the process whereby equilibrium in both markets will be achieved.

Full effects of changes in the goods and money markets

IS/LM analysis can be used to examine the full effects of changes in the goods market. Such changes are illustrated

Figure 19.19 Equilibrium in both the goods and money markets

* LOOKING AT THE MATHS

Equilibrium in the *IS/LM* model is where the two functions, *IS* and *LM*, are equal. The simplest mathematical representation of this is where both *IS* and *LM* are simple linear (i.e. straight-line) functions. The *IS* function could be expressed as

$$r = a - bY \quad (1)$$

In other words, the higher the rate of interest (*r*), the lower will be the level of aggregate demand and hence national income (*Y*).¹ This is consistent with a downward-sloping *IS* curve.

The *LM* function can be written as

$$r = g + hY \quad (2)$$

In other words, the higher the level of real national income (and hence the higher the demand for money), the higher will be the real rate of interest. This is consistent with an upward-sloping *LM* curve.

We can then solve for *Y* by setting the two equations equal.

Thus

$$a - bY = g + hY$$

that is

$$bY + hY = a - g$$

giving

$$Y = \frac{a - g}{h + b}$$

More complex *IS* and *LM* functions

In practice, neither function is likely to be linear. Both *IS* and *LM* are likely to be curves rather than straight lines. To understand why, we need to look at the other determinants of *Y* in the case of the *IS* curve and of *r* in the case of the *LM* curve. Let us first examine the *IS* function.

Real national income consists of five elements:

$$Y = C + I + G + X - M \quad (3)$$

or

$$Y = C(Y, T, r, \pi^e) + I(r, \pi^e, \Delta Y) + G + X(er) - M(Y, T, r, \pi^e, er) \quad (3a)$$

Equation (3a) is simply an expansion of equation (3) listing the key determinants of each of the variables in equation (3), where *T* is taxes, π^e is expected inflation and *er* is the exchange rate. Investment being a function of changes in national income (ΔY) is the accelerator effect. Thus an *IS* function could be expressed as

$$Y = IS(r, T, \pi^e, \Delta Y, G, er) \quad (4)$$

- - + + + -

All the variables in this function are contained in equation (3a). It is highly likely that the relationship between *Y* and most, if not all, these variables is non-linear (i.e. contains squared or higher power terms).

The sign under each of the variables indicates the direction in which *Y* changes when the variable changes. For example, the negative sign under the *T* term means that a rise in taxes would lead to a *fall* in *Y*. Put another way, the sign indicates the sign of the partial derivative of *Y* with respect to each variable. For example, the positive sign under the expected inflation term (π^e) means that when you differentiate *Y* with respect to π^e , you end up with a positive number. This simply means that a rise in π^e leads to a *rise* in *Y*.

Note that a change in *r* would lead to a movement along the *IS* curve. A change in any of the other determinants in equation (4) would shift the curve. A rise in any of the determinants with a positive sign would result in a rightward shift in the curve; a rise in any of the determinants with a negative sign would result in a leftward shift.

Turning to the *LM* function, this can be expressed as

$$r = LM\left(Y, \frac{M_s}{P}, \pi^e, er^e, f\right) \quad (5)$$

+ - + + -

where M_s/P is the real money supply, π^e is the expected rate of inflation, er^e is the expected exchange rate and *f* is the frequency with which people are paid. The *LM* curve assumes equilibrium in the money market. It therefore represents all the combinations of *r* and *Y* where the real demand for money is equal to the real supply. The real supply of money is given by the term M_s/P and the real demand for money depends on the other terms in equation (5) (see page 583).

A rise in *Y* would cause a movement up along the *LM* curve. A rise in any of the other determinants would shift the curve: upwards in the case of the determinants with a positive sign; downwards in the case of those with a negative sign.

As with the *IS* function, it is highly likely that the relationship between *r* and most, if not all, the variables in the *LM* function is likely to be non-linear.

Maths Case 19.1 on the student website shows how equilibrium in the *ISLM* model can be derived from specific *IS* and *LM* functions.

¹ Note that although equation (1) shows *r* as a function of *Y*, the model in fact has *Y* as the dependent variable. In other words, *r* determines *Y*. We express equation (1) this way to make it consistent with equation (2), where *r* is the dependent variable.

by a shift in the *IS* curve. Likewise, the full effects of changes in the money market can be illustrated by a shift in the *LM* curve.

Changes in the goods market

Consider a positive demand-side shock where the confidence of economic agents begins to rise. Assume that this leads firms to increase their investment and consumers to reduce their precautionary saving. The resulting increase in

aggregate expenditure leads to a rightward shift in the *IS* curve. This is illustrated in Figure 19.20(a). It is assumed that there is no exogenous increase in the money supply and that, therefore, the *LM* curve does not shift. Income rises to Y_2 , but interest rates also rise (to r_2).

The rise in the rate of interest to r_2 restricts the rise in real national income, since the higher real interest rate dampens both investment and consumption. The net rise in aggregate expenditure is less than the original increase. The steeper the

LM curve, the less national income rises. The equilibrating effect of interest rates in the money market therefore 'chokes off' some of the increase in national income originating from the positive demand-side shock.

The IS/LM framework allows us to see how monetary policy could accommodate the positive demand-side shock. If money supply is expanded to meet the extra demand for money, then interest rates will not have to rise. This is illustrated in Figure 19.20(c). The rightward shift in the IS curve is matched by a downward shift in the LM curve. The rate of interest remains at r_1 and there is a full multiplied rise in national income to Y_4 .

In the context of the early 2010s, central banks like the Federal Reserve and the Bank of England were keen that monetary policy should stimulate economic recovery. While remaining watchful of inflation, monetary policy was predominantly geared to supporting the still fragile economic recovery. This saw the authorities boost the money supply through asset purchases (see Box 22.10). One effect of this was to put downward pressure on the general structure of interest rates. As we saw in section 18.5, there is not a single interest rate. Rather, there is a myriad of interest rates on a range of financial instruments.

The IS/LM framework demonstrates nicely the policy dilemma that faced the authorities in the early 2010s as aggregate demand recovered: how quickly to put the brakes on quantitative easing. To do so too quickly ran the risk of stalling the recovery as general interest rates rose, even if the authorities maintained a low policy rate. As our analysis in section 19.4 showed, interest rate differentials tend to be greatest when output levels are relatively low. The authorities therefore looked to apply the monetary policy handbrake gently.

Changes in the money market

Now consider an increase in money supply. The LM curve shifts downwards. This is illustrated in Figure 19.20(b). Interest rates fall and this encourages an increase in borrowing and hence an increase in investment and consumption. This is shown by a movement down along the IS curve. National income rises. Equilibrium is reached at a rate of interest of r_3 and a national income of Y_3 .

The fall in the rate of interest means that some of the extra money is absorbed in idle balances and is not all used to finance additional expenditure and this reduces the resulting increased national income. The effect on national income also depends on the elasticity of the IS curve. The steeper the IS curve, the less will national income rise. This will be the case when investment is relatively insensitive to cuts in interest rates.

If, however, the rise in money supply is accompanied by an autonomous rise in injections (for example, a rise in government expenditure), then the effect can be much bigger. If the downward shift in the LM curve is matched by a rightward shift in the IS curve, then the effect is once more illustrated in Figure 19.20(c).

To summarise: the effect on national income of a change in either market depends on the slope of the IS and LM curves.

- The flatter the LM curve and the steeper the IS curve, the bigger will be the effect of a shift in the IS curve. When LM is relatively flat, a rightward shift in IS will lead to only a small rise in the rate of interest (r). If IS is steep, this rise in r will lead to only a small curtailing of investment. In these two circumstances, the dampening effect on investment and consumption is limited. There will be a large increase in real national income (Y).
- The effect of a shift in the LM curve will be bigger when the liquidity preference curve (L) (e.g. in Figure 19.18(a)) is steep and the IS curve is relatively flat. When L is steep, there will be a relatively large downward shift in the LM curve for any given increase in the money supply and hence a relatively large fall in r . When IS is relatively flat, this fall in r will lead to a relatively large increase in investment and hence Y .
- The effect of a shift in either curve will be bigger if matched by a similar shift in the other curve.

On a diagram similar to Figure 19.19, trace through the effects of (a) a fall in investment and (b) a fall in the money supply. On what does the size of the fall in national income depend?

Figure 19.20 IS/LM analysis of changes in the goods and money markets

Appendix summary

1. The *IS/LM* model allows equilibrium to be shown in both goods and money markets simultaneously. The model shows the relationship between national income and interest rates.
2. Equilibrium in the goods market is shown by the *IS* curve. As the rate of interest rises, so investment will fall and saving will rise: thus equilibrium national income will fall. The *IS* curve is thus downward sloping.
3. A change in interest rates will cause a movement along the *IS* curve. A change in anything else that affects national income causes a shift in the *IS* curve.
4. Equilibrium in the money market is shown by the *LM* curve. This shows all the combinations of national income and the rate of interest where the demand for money (*L*) equals the supply (*M*). As national income rises, so the demand for money will rise: thus the equilibrium rate of interest in the money market will rise. The *LM* curve is therefore upward sloping.
5. A change in national income will cause a movement along the *LM* curve. A change in anything else that affects interest rates (i.e. a change in the demand or supply of money other than as a result of a change in national income) will shift the *LM* curve.
6. Simultaneous equilibrium in both goods and money markets (i.e. the equilibrium national income *and* the equilibrium rate of interest) is where $IS = LM$.
7. A change in injections or withdrawals will shift the *IS* curve. A rise in injections will shift it to the right. This will cause a rise in both national income and the rate of interest. The steeper the *IS* curve and the flatter the *LM* curve, the bigger will be the rise in income and the smaller the rise in the rate of interest.
8. A rise in money supply will shift the *LM* curve downwards. This will cause a fall in interest rates and a rise in national income. The rise in national income will be larger, the flatter is the the *IS* curve and the steeper the liquidity preference curve (*L*) and hence the bigger the downward shift in the *LM* curve for any given increase in the money supply.

END OF CHAPTER QUESTIONS

1. Using one or more diagrams like Figures 19.2, 19.7, 19.8, 19.9 and 19.10, illustrate the following:
 - (a) The effect of a contraction in the money supply on national income. Refer to both the interest rate and exchange rate transmission mechanisms and show how the shapes of the curves affect the outcome.
 - (b) The effect of a fall in investment on national income. Again show how the shapes of the curves affect the outcome. Specify your assumptions about the effects on the supply of money.
2. Controlling the money supply is sometimes advocated as an appropriate policy for controlling inflation. What implications do different assumptions about the relationships between *M* and *V*, and *M* and *Y*, in the equation $MV = PY$ have for the effectiveness of this policy?
3. Why may an expansion of the money supply have a relatively small effect on national income? Why may any effect be hard to predict?
4. What impact might the balance sheets of economic agents have on the influence of interest rates in affecting aggregate expenditure?
5. Why does the exchange rate transmission mechanism strengthen the interest rate transmission mechanism?
6. Explain how the holding of a range of assets in people's portfolios may help to create a more direct link between changes in money supply and changes in aggregate demand.
7. Explain how financial crowding out can reduce the effectiveness of fiscal policy. What determines the magnitude of crowding out?
8. What determines the shape and position of the *IS* curve?
9. What determines the shape and position of the *MP* curve?
10. Using the *IS/MP* model analyse the possible effect of an increase in aggregate expenditure on output, the real interest rate and inflation.
11. Using the *IS/MP* model analyse how a lower bound on real interest rates might cause the economy to enter a deflationary spiral following a significant decrease in aggregate expenditure.
12. What impact does the financial accelerator have on the marginal propensity to consume domestically produced goods (mpc_d)? How does this affect the *IS* curve?
13. Illustrate the impact on the *IS* curve of a general increase in interest rate differentials following a credit market disruption like that experienced during the financial crisis of the late 2000s.
14. Using the *IS/MP* framework illustrate how the financial accelerator affects the extent of the fall in output following a negative demand-side shock.
15. What implication does the financial instability hypothesis have for the balance sheets of different sectors of the economy?
- *16. Using the *IS/LM* model analyse under what circumstances will (a) a rise in investment and (b) a rise in money supply cause a large rise in national income?

Controversy 2: the flexibility of aggregate supply	640
Controversy 3: the role of expectations in the working of the market	642

The focus so far of Part F has been to develop a better understanding of aggregate demand. We have looked at a variety of influences on aggregate demand and its components, including the effects of financial institutions and money markets. Now we consider in more detail the interaction of aggregate demand and aggregate supply. We will see that the effects of changes in aggregate demand on output, employment and prices depend crucially on the responsiveness of aggregate supply.

We begin this chapter by constructing the aggregate demand and supply (*AD/AS*) model. We then apply the model to analyse demand-pull and cost-push inflation, including the subsequent effects on prices and output that can result from these sources of inflation. In the next section (section 20.3) we extend this model to the modern context of inflation targeting by central banks. The model highlights the dynamic nature of economies and, hence, the importance of considering the subsequent effects that can arise from economic shocks.

The adjustment of economies to shocks is a theme we pursue further in the final two sections of the chapter. First, we focus on the role the labour market plays in determining the interaction between aggregate demand and supply. In doing so, we distinguish between classical and Keynesian perspectives on the labour market. Finally, we take a broader look at debates around output determination. We analyse the contrasting views of different macroeconomic schools on the behaviour of markets, the flexibility of aggregate supply and the role of expectations.

20.1 THE AD/AS MODEL

Our focus to this point has been on developing an understanding of aggregate demand. This is a sensible starting point since fluctuations in aggregate demand are generally argued to be the primary source of fluctuations in the economy's output path. However, to understand economic fluctuations more fully we need to analyse the interaction between aggregate demand and aggregate supply.

The problem with the circular flow model and the Keynesian multiplier model is that they take no account of just how firms make supply decisions: they assume that firms simply respond to demand. But supply decisions, as well as being influenced by current levels of demand, are also influenced by prices and costs. To be able to analyse the impact of changes in aggregate demand on national income *and* prices we make use of the aggregate demand–aggregate supply (AD/AS) model. This is illustrated in Figure 20.1. Note that the aggregate supply curve we shall be examining is the short-run curve (SRAS), as explained below.

As with demand and supply curves for individual goods, we plot quantity on the horizontal axis, except that now it is the *total quantity of national output*, (real) GDP; and we plot price on the vertical axis, except that now it is the *general price level*. Because the general price level relates to the prices of all domestically produced goods and services it is also known as the *GDP deflator*.

We now examine each curve in turn.

The aggregate demand curve

In Chapter 15 we saw how aggregate demand consists of four elements: consumer spending (C), private investment (I), government expenditure on goods and services (G) and

expenditure on exports (X) less expenditure on imports (M). Thus:

$$AD = C + I + G + X - M$$

The aggregate demand curve shows how much national output (GDP) will be demanded at each level of prices. But why does the AD curve slope downwards? Why will people demand less as prices rise? There are two effects that can cause this: income effects and substitution effects.

Income effects

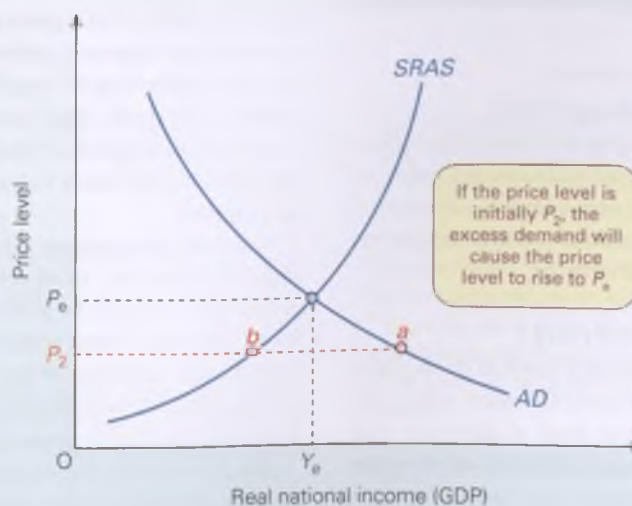

For many people, when prices rise, their wages will not rise in line, at least not in the short run. There will therefore tend to be a redistribution of income away from wage earners (and hence consumers) to those charging the higher prices – namely, firms. Thus for consumers there has been an *income effect* of the higher prices. The rise in prices leads to a cut in real incomes and therefore people will spend less. Aggregate demand will fall. The AD curve will be downward sloping, as in Figure 20.1.

To some extent this will be offset by a rise in profits, but it is unlikely that much of the additional profits will be spent by firms on investment, especially if they see consumer expenditure falling; and any increase in dividends to

Definition

GDP deflator The price index of all final domestically produced goods and services: i.e. all those items that contribute towards GDP.

Figure 20.1 Aggregate demand and aggregate supply

shareholders will take a time before it is paid, and then may simply be saved rather than spent. To summarise: if prices rise more than wages, the redistribution from wages to profits is likely to lead to a fall in aggregate demand.

Clearly, this income effect will not operate if wages rise in line with prices. Real incomes of wage earners will be unaffected. In practice, as we shall see at several places in this book, in the short run wages do lag behind prices.

An income effect is also likely to occur as a result of progressive taxes. As prices and incomes rise, so people will find that they are paying a larger proportion of their incomes in taxes. As a result, they cannot afford to buy so much.

Substitution effects

In the *microeconomic* situation, if the price of one good rises, people will switch to alternative goods. This is the substitution effect of that price rise and helps to explain why the demand curve for a particular good will be downward sloping. At a *macroeconomic* level we can identify three main reasons why people will demand fewer products as prices.

- **An international substitution effect.** If prices rise, people will be encouraged to buy fewer of the country's products and more imports instead (which are now relatively cheaper); the country will also sell fewer exports (which are now less competitive). Thus imports (a withdrawal) will rise and exports (an injection) will fall. Aggregate demand, therefore, will be lower.
- **An inter-temporal substitution effect.** As prices rise, people will need more money to pay for their purchases. With a given supply of money in the economy, this will have the effect of driving up interest rates (see section 19.1). The effect of higher interest rates will be to discourage borrowing and encourage saving, with individuals postponing current consumption in favour of future consumption. The effect will be a reduction in spending and hence in aggregate demand.
- **Real balance effect.** If prices rise, the value of people's savings will be eroded. They may thus save more (and spend less) to compensate.

The shape of the aggregate demand curve

We have seen that both the income and substitution effects of a rise in the general price level will cause the aggregate demand for goods and services to fall. Thus the *AD* curve is downward sloping. The bigger the income and substitution effects, the more elastic will the curve be.

Shifts in the aggregate demand curve

The aggregate demand curve can shift inwards (to the right) or outwards (to the left), in exactly the same way as the demand curve for an individual good. A rightward shift represents an increase in aggregate demand, whatever the price level; a leftward shift represents a decrease in aggregate demand, whatever the price level.

Definitions

International substitution effect As prices rise, people at home and abroad buy less of this country's products and more of products from abroad.

Inter-temporal substitution effect Higher prices may lead to higher interest rates and thus less borrowing and more saving. Current consumption falls; future consumption (from the higher savings) rises.

Real balance effect As the price level rises, so the value of people's money balances will fall. They will therefore spend less in order to increase their money balances and go some way to protecting their real value.

A shift in the aggregate demand curve will occur if, for any given price level, there is a change in any of its components – consumption, investment, government expenditure or exports minus imports. Thus if the government decides to spend more, or if consumers spend more as a result of lower taxes, or if business confidence increases so that firms decide to invest more, the *AD* curve will shift to the right.

The aggregate supply curve

The aggregate supply (*AS*) curve shows the amount of goods and services that firms are willing to supply at each level of prices. We focus here on the *short-run AS* curve (*SRAS* curve). When constructing this curve, we assume that various other things remain constant. These include wage rates and other input prices, technology and the total supply of factors of production (labour, land and capital).

Why do we assume that wage rates and other input prices are constant? Wage rates are frequently determined by a process of collective bargaining and, once agreed, will typically be set for a whole year, if not two. Even if they are not determined by collective bargaining, wage rates often change relatively infrequently. So too with the price of other inputs: except in perfect, or near perfect markets (such as the market for various raw materials), firms supplying capital equipment and other inputs tend to change their prices relatively infrequently. They do not immediately raise them when there is an increase in demand or lower them when demand falls. Thus there is a 'stickiness' in both wage rates and the price of many inputs.

The short-run aggregate supply curve slopes upwards, as shown in Figure 20.1. In other words, the higher the level of prices, the more will be produced. The reason is simple. Because we are holding wages and other input prices constant, then as the prices of their products rise, firms' profitability at each level of output will be higher than before. This will encourage them to produce more.

But what *limits* the increase in aggregate supply in response to an increase in prices? In other words, why is the *SRAS* curve not horizontal? There are two main reasons:

- **Diminishing returns.** With some factors of production fixed in supply, notably capital equipment, firms experience a diminishing marginal physical product from their other factors, and hence have an upward-sloping marginal cost curve. In microeconomic analysis the upward-sloping cost curves of firms explain why the supply curves of individual goods and services slope upwards. Here in macroeconomics we are adding (horizontally) the supply curves of all goods and services and thus the aggregate supply curve also slopes upwards.
- **Growing shortages of certain variable factors.** As firms collectively produce more, even inputs that can be varied

may increasingly become in short supply. Skilled labour may be harder to find, and certain raw materials may be harder to obtain.

Thus rising costs explain the upward-sloping short-run aggregate supply curve. The more steeply costs rise as production increases, the less elastic will the aggregate supply curve be. It is likely that, as the level of national output (i.e. national income) increases and firms reach full-capacity working, so marginal costs will rise faster. The SRAS curve will thus tend to get steeper (as shown in Figure 20.1).

Box 20.1 considers further the microeconomic foundations of the SRAS curve.

BOX 20.1 SHORT-RUN AGGREGATE SUPPLY

EXPLORING ECONOMICS

The importance of microeconomic foundations

To understand the shape of the short-run AS curve, it is necessary to look at its microeconomic foundations. How will individual firms and industries respond to a rise in demand? What shape will their individual supply curves be?

In the short run, we assume that firms respond to the rise in demand for their product *without* considering the effects of a general rise in demand on their suppliers or on the economy as a whole. We also assume that the prices of inputs, including wage rates, are constant.

In the case of a profit-maximising firm under monopoly or monopolistic competition, there will be a rise in price and a rise in output. In diagram (a), profit-maximising output rises from where $MC = MR_1$ to where $MC = MR_2$. Just how much price changes compared with output depends on the slope of the marginal cost (MC) curve.

The nearer the firm is to full capacity, the steeper the MC curve is likely to be. Here the firm is likely to find diminishing returns setting in rapidly, and it is also likely to have to use more overtime with correspondingly higher unit labour costs. If, however, the firm is operating well below capacity, it can

probably supply more with little or no increase in price. Its MC curve may thus be horizontal at lower levels of output.

Under oligopoly, where there is a tendency for prices to be more stable, firms may respond to an increase in demand without raising prices, even if their costs rise somewhat.

When there is a general rise in demand in the economy, the aggregate supply response in the short run can be seen as simply the sum of the responses of all the individual firms. The short-run AS curve will look something like that in diagram (b).

If there is generally plenty of spare capacity, a rise in aggregate demand (e.g. from AD_1 to AD_2) will have a big effect on output and only a small effect on prices. However, as more and more firms find their costs rising as they get nearer to full capacity, so the AS curve becomes steeper. Further increases in aggregate demand (e.g. from AD_2 to AD_3) will have bigger effects on prices and smaller effects on output (GDP).

A general rise in prices, of course, means that individual firms were mistaken in assuming that a rise in price from P_1 to P_2 in diagram (b) was a *real* price rise (i.e. relative to prices elsewhere).

What is happening to real wage rates as we move up the SRAS curve?

Shifts in the short-run aggregate supply curve

The SRAS curve will shift if there is a change in any of the variables that are held constant when we plot the curve. Several of these variables, notably technology, the labour force and the stock of capital, change only slowly – normally shifting the curve gradually to the right. This represents an increase in potential output.

By contrast, wage rates and other input prices can change significantly in the short run, and are thus the major causes of shifts in the short-run supply curve. For example, a general rise in wage rates throughout the economy reduces the amount that firms wish to produce at any level of prices. The aggregate supply curve shifts to the left. A similar effect will occur if other costs, such as oil prices or indirect taxes, increase.

Equilibrium

Equilibrium in the macroeconomy occurs when aggregate demand and aggregate supply are equal. In Figure 20.1, this is at the price level P_e and national income (GDP) of Y_e . To

demonstrate this, consider what would happen if aggregate demand exceeded aggregate supply: for example, at P_2 in Figure 20.1. The resulting shortages throughout the economy would drive up prices. This would encourage firms to produce more: there would be a movement up *along* the AS curve. At the same time, the increase in prices would reduce the level of aggregate demand: that is, there would also be a movement back up *along* the AD curve. The shortage would be eliminated when price had risen to P_e .

Shifts in the AD or SRAS curves

If the AD or SRAS curve shifts, there will be a movement along the other curve to the new point of equilibrium. For example, if there is a cut in income taxes and a corresponding increase in consumer demand, the AD curve will shift to the right. This will result in a movement up along the SRAS curve to the new equilibrium point: in other words, to a new higher level of national income and a higher price level. The more elastic the SRAS curve, the more will output rise relative to prices.

Section summary

1. An aggregate demand curve shows the relationship between aggregate demand ($C + I + G + X - M$) and the price level. The curve is downward sloping because of income and substitution effects.
2. If a rise in the price level causes wage rises to lag behind or causes a rise in the proportion of income paid in income tax, then consumers will respond to the resulting fall in their real incomes by cutting consumption. This is the income effect.
3. If a rise in the price level causes (a) imports to rise and exports to fall, (b) people to spend less and save more because of a rise in interest rates and possibly (c) people to spend less in order to maintain the value of their bank balances, these effects too will result in a fall in the level of aggregate demand. These are all substitution effects.
4. If the determinant of any component of aggregate demand (other than the price level) changes, the aggregate demand will shift.
5. The short-run aggregate supply (SRAS) curve is upward sloping. This reflects the fact that at higher prices, firms will find it profitable to supply more. The curve will be more elastic, the less rapidly diminishing returns set in and the more elastic the supply of variable factors.
6. The SRAS curve will shift to the left (upwards) if wage rates or other costs rise independently of a rise in aggregate demand.
7. Equilibrium in the economy occurs when aggregate demand equals aggregate supply. A rise in the price level will occur if there is a rightward shift in the aggregate demand curve or a leftward shift in the short-run aggregate supply curve.

20.2 AD/AS AND INFLATION

We first analysed inflation in section 15.6. There we identified two principal types of inflation: demand-pull and cost-push inflation. Demand-pull inflation is caused by continuing rises in aggregate demand while cost-push inflation is caused by continuing rises in costs, which occur *independently* of aggregate demand.

We can use our aggregate demand and supply framework to further our understanding of demand-pull and cost-push inflation. In particular, we can think about the possible subsequent effects on output and prices that might arise from these types of inflation. This illustrates the dynamic nature

of economies: macroeconomic fluctuations or shocks frequently set in motion a chain of events.

Demand-pull inflation

Demand-pull inflation can be represented by *continuous* shifts of the AD curve to the right. In Figure 20.2, the AD curve shifts to the right and continues doing so. A single increase in AD caused by a *positive* demand shock only causes inflation in short run. Once the price level has settled at its new higher level, the inflation rate falls back to zero.

Figure 20.2 Demand-pull inflation

For demand-pull inflation to continue, the rightward shifts of the AD curve must also continue; for demand-pull inflation to rise, the rightward shifts must get faster.

Subsequent effects

In illustrating demand-pull inflation in Figure 20.2, we have analysed the short-term effects on output and the price level. Crucially, we have assumed that the factors taken as given in constructing the short-run aggregate supply curve remain constant. But eventually the $SRAS$ curve will start shifting. In Figure 20.3 we analyse how this might happen and what this could mean subsequently for the economy's price level and output.

As before, assume that aggregate demand rises. In Figure 20.3(a), there is some increase in output, and the price level rises from P_0 to P_1 . If demand goes on rising, so that the

AD curve goes on shifting to the right, the price level will go on rising and there will be demand-pull inflation. There will be a movement from point a to b to c in Figure 20.3(b).

An important part of the subsequent adjustment process comes from the *interdependence of firms*. Rising aggregate demand will lead firms throughout the economy to raise their prices (in accordance with the short-run AS curve). But as raw material and intermediate good producers raise their prices, this will raise the costs of production further up the line. A rise in the price of steel will raise the costs of producing cars and washing machines. At the same time, workers, experiencing a rise in demand for labour, and seeing the prices of goods rising, will demand higher wages. Firms will be relatively willing to grant these wage demands, since they are experiencing buoyant demand.

The effect of all this is to raise firms' costs, and hence their prices. As prices rise for any given level of output, the short-run AS curve shifts upwards.

All other things being equal, this will lead to a falling back of output but a further rise in prices as the economy moves to point d .

If there was to be a further rise in demand, we might perhaps observe a further outward movement of the AD curve, say to point e , but a further rise in prices. Then the $SRAS$ curve will probably continue shifting upwards and the economy will move to point f .

If the source of the increase in demand was to cease or government now makes the control of inflation its main policy objective, then this may stop further increases in aggregate demand. Aggregate supply may continue shifting upwards for a while as cost increases and expectations feed through. The economy moves to point g . In the extreme case, point g may be vertically above point a . The only effect of the shift in AD to AD_3 has been inflation.

Figure 20.3 Demand-pull inflation: initial and subsequent effects

Note that, although costs in Figure 20.3(b) have increased and hence the AS curves have shifted upwards, this is not *cost-push* inflation because the rise in costs is the result of the rise in *demand*.

Whatever the output and price paths that result from rising (or falling) demand, the analysis illustrates the dynamic nature of economies. The responses of economic agents, the interdependencies that exist between them and the workings of markets are important in determining the adjustment processes that take place following economic shocks. This is crucial too when thinking about cumulative causation: i.e. the ideas that economic effects can snowball. Multiple changes can result from an initial economic shock or set of events. In section 20.4 we focus on the role of the labour market in determining adjustment processes.

TC 15
p535

? How would the shifts in the SRAS curve be affected if, in response to rising output levels, firms increased their investment expenditures?

Cost-push inflation

Cost-push inflation can be represented by *continuous* shifts of the SRAS curve upwards to the left. This is illustrated in Figure 20.4. As with our analysis of demand-pull inflation, we need to distinguish between single shifts and continuous shifts of the SRAS curve when looking at cost-push inflation. A single *negative* supply shock will cause only temporary inflation. If cost-push inflation is to continue, the SRAS curve must keep shifting upwards to the left. Similarly, for the rate of cost-push inflation to rise, these shifts of the SRAS curve must get faster.

If we compare Figures 20.2 and 20.4, we can see that demand-pull and cost-push inflation have the opposite effect on output. This is because it is *positive* demand shocks

but *negative* supply shocks that cause price levels to rise. Therefore, with demand-pull inflation output and hence employment tend to rise. On the other hand, with cost-push inflation output and employment tend to fall.

Subsequent effects

In illustrating cost-push inflation to this point, the aggregate demand curve has been unaffected by the shifts in the SRAS curve. After a time, this is unlikely to remain the case. We use Figure 20.5 to consider how the AD curve might be affected subsequently.

Assume that there is some exogenous increase in costs: a sharp increase in world oil prices, or an increase in wages due to increased trade union activity, or firms raising prices to cover the costs of a rise in interest rates. In Figure 20.5(a), the SRAS curve shifts to SRAS₁. Prices rise to P₁ and there is a fall in national output.

If these increases in costs continue for some time, the *SRAS* curve will go on shifting upwards. Price rises will continue and there is cost-push inflation. The economy will move from point *a* to *b* to *c* in Figure 20.5(b). Continuous upward shifts in the *SRAS* curve are particularly likely if there is a continuing struggle between different groups (e.g. unions and employers' organisations) for a larger share of national income.

After a time, aggregate demand is likely to rise. This may be due to the government using expansionary fiscal and monetary policies to halt the falling output and employment. Or it may be due to money supply expanding

endogenously as workers and firms need larger money balances to allow for increasingly costly transactions. Aggregate demand shifts to AD_1 and there is a movement to point *d*.

There may be a further increase in costs and a movement to point *e*, and then a further increase in aggregate demand and so on. Again, the dynamics of the adjustment process following the initial effect in Figure 20.5(a) will shape the actual path that prices and national output take in Figure 20.5(b).

Note this time that, although demand has increased, this is not *demand-pull* inflation because the rise in demand is the result of the upward pressure on *costs*.

BOX 20.2

COST-PUSH INFLATION AND SUPPLY SHOCKS

EXPLORING ECONOMICS

It is important to distinguish a *single* supply shock, such as a rise in oil prices or an increase in VAT or excise duties, from a continuing upward pressure on costs, such as workers continually demanding increases in real wages above the level of labour productivity, or firms continually using their monopoly power to increase the real value of profits.

A single supply shock will give a *single* upward movement in the *SRAS* curve. Prices will move to a new higher equilibrium. An example occurred in the UK in January 2011, with the rise in VAT from 17.5 to 20 per cent. Cost-push inflation in this case is a *temporary* phenomenon. Once the new higher price level has been reached, the cost-push inflation disappears.

Sometimes these supply-side shocks can themselves be the result – at least partially – of an increase in demand elsewhere in the world. An example of this occurred during 2008 when the prices of materials and fuels used by industry began rising sharply, partly in response to the rapid growth in developing countries, such as China and India. As we can see from the chart, this caused the rate of input price inflation amongst manufacturers to rise to 35 per cent. This spike in

prices was temporary, however, as the global downturn acted to depress the demand for inputs and led to a fall in their prices – at least for a while.

But what if there is continuous upward pressure on costs? In this case, cost-push inflation is likely to continue, resulting in repeated shifts of the *SRAS* curve. During 2010, as the global economy began to recover, the prices of materials and fuels began to rise sharply once again. This raised concerns that the global slowdown had only acted as a temporary brake on rising input prices.

This created a dilemma for central banks, like the Bank of England, which are charged with meeting inflation rate targets. Should they raise interest rates to slow the growth in aggregate demand, even if much of the cause of consumer price inflation was emanating from the supply side?

? Give some examples of single shocks and continuing changes on the demand side. Does the existence of multiplier and accelerator effects make the distinction between single shocks and continuing effects more difficult to make on the demand side than on the supply side?

Annual change in manufacturers' input costs

Note: Manufacturers' inputs costs include materials, fuels and climate levy.

Source: Based on data from *Producer Price Index - Statistical bulletin time series dataset*, series K646 (National Statistics).

Section summary

1. Demand-pull inflation occurs where there are continuous rightward shifts in the *AD* curve. Subsequently we would expect the *SRAS* curve to start shifting. This might occur as rising costs are passed from firm to firm, which then acts to shift the *SRAS* curve upwards.
2. Cost-push inflation occurs where there are continuous upward shifts in the *AS* curve. Subsequently we may expect to see *AD* start shifting rightwards. This might occur if the supply of money increases to meet the demand for more liquidity as transactions become increasingly costly.

20.3 AGGREGATE DEMAND AND SUPPLY WITH INFLATION TARGETING: THE *DAD/DAS* MODEL

A more modern version of the aggregate demand and supply model plots aggregate demand and supply, not against the level of prices, but against the rate of inflation. This model has become known as the *DAD/DAS* model, where *DAD* stands for 'dynamic aggregate demand' and *DAS* stands for 'dynamic aggregate supply'.¹

As with the *IS/MP* model, which we looked at in section 19.3, the *DAD/DAS* model has been developed to incorporate an important feature of contemporary monetary policy: central banks setting interest rates to meet an inflation target (or a more complex target). We will explore in more detail developments in monetary policy and the objectives of central bankers in Chapter 22.

Together, we can use both models to analyse the interaction of the goods and money markets for national income, real interest rates and inflation.

Aggregate demand and supply plotted against inflation

The *DAD/DAS* model is illustrated in Figures 20.6 and 20.7.

In this version of aggregate demand and supply, the horizontal axis, as before, measures real national income (*Y*). The vertical axis, however, measures the *rate of inflation*, not the *level of prices*. The aggregate demand and supply curves are labelled *DAD* and *DAS* to distinguish them from the curves in the normal aggregate demand and supply diagram. We also add a line showing the target rate of inflation (π_{target}).

Before we look at the properties of the model, let us examine each of the three lines in turn. The first two are illustrated in Figure 20.6.

The inflation target line

This is simply a horizontal line at the target rate of inflation (π_{target}). If inflation is above target, real interest rates will be raised by the central bank. If it is below target, real interest rates will be cut.²

Figure 20.6 Aggregate demand plotted against inflation

Figure 20.7 Aggregate demand and supply plotted against inflation

If the government or central bank changes the target, the line will shift to the new target rate.

² Note that, in practice, although it is the nominal rate of interest (*i*) that the central bank changes, the objective is to affect the real rate of interest (*r*) in order to meet the inflation target.

¹ As the model has developed over recent years, different names have been given to the two curves. In earlier editions of this book, we used the terms *ADI* and *ASI*, meaning aggregate demand and aggregate supply plotted against inflation. We have switched to *DAD* and *DAS* for this edition as this has now become the more common terminology. The model, however, is exactly the same as in previous editions.

The dynamic aggregate demand curve

As with the normal *AD* curve, the *DAD* curve is downward sloping. In other words, a higher rate of inflation leads to a lower level of (real) aggregate demand. But why?

The reason is simple. It consists of a two-stage process.

1. If the rate of inflation (π) goes above the target level, the central bank will raise the *real* rate of interest (r). In other words it will raise the nominal rate *more* than the rise in the inflation rate. Thus if the rate of inflation goes up from a targeted 2 per cent to 3 per cent, the nominal interest rate (i) must rise by more than 1 percentage point in order to achieve a rise in the real interest rate.
2. The higher real rate of interest will then reduce (real) aggregate demand (*AD*), through both the interest rate and exchange rate mechanisms (see pages 589–93). In terms of the *IS/MP* framework, there is a movement leftward along the *IS* curve.

To summarise:

$$\pi \uparrow \rightarrow r \uparrow \rightarrow AD \downarrow$$

Similarly, a fall in the rate of inflation will cause the central bank to lower the real rate of interest. This will then lead to an increase in aggregate demand.

The slope of the *DAD* curve. The slope of the *DAD* curve depends on the strength of the two stages. The curve will be flatter:

- the more the central bank adjusts real interest rates in response to a change in inflation. The faster the central bank wants to get inflation back to its target level and the less concerned it is about cutting back on aggregate demand and hence output and employment, the larger will interest rate changes be;
- the more responsive investment, consumption and exports (i.e. the components of aggregate demand) are to a change in interest rates.

A movement along the *DAD* curve. This will be caused by a change in the rate of inflation. If inflation rises, there will be a movement up the curve as the central bank raises the real rate of interest and this causes real income to fall. When inflation begins to fall in response to the higher rate of interest, there will be a movement back down the curve again.

The position of the *DAD* curve. A given *DAD* curve represents a given monetary policy (the vertical position of the *MP* curve for a given inflation target). The particular *DAD* curve in Figure 20.6 intersects with the inflation target line at a real income of Y_1 . This means that if inflation is on target, real national income will be Y_1 . The central bank will need to consider whether this is consistent with long-term equilibrium in the economy: in other words, whether Y_1 is the *potential* level of national output: i.e. the level of real national income with a zero output gap (see Box 15.3 on page 460). If it is, then the monetary policy it has chosen is appropriate.

A shift in the *DAD* curve. Any factor that causes aggregate demand to change, other than the central bank responding

to inflation being off-target, will cause the *DAD* curve to shift. A rightward shift represents an increase in aggregate demand. A leftward shift represents a decrease.

Examples of a rightward shift include cuts in tax rates, an increase in government expenditure and a rise in consumer or business confidence. These also cause the *IS* curve to shift rightwards in the *IS/MP* model (see page 605).

The *DAD* curve will also shift to the right if the government or central bank sets a higher target rate of inflation. The reason is that this will lead to lower interest rates at every level of inflation. This causes the *MP* curve to move vertically downwards.

The curve will also shift if the central bank *changes* its monetary policy, such that it no longer wants Y_1 to be the equilibrium level of national income. For example, if Y_1 in Figure 20.6 were below the potential level, and there was therefore demand-deficient unemployment, the central bank would want to reduce real interest rates in order to achieve a higher level of aggregate demand at the target rate of inflation. This will shift the *DAD* curve to the right. In other words, each rate of inflation along this new *DAD* curve would correspond to a lower real rate of interest (r) and hence a higher level of aggregate demand.

But what determines the level of Y ? This is determined by the interaction of aggregate demand and aggregate supply. To show this we introduce a third line: the *DAS* curve.

The dynamic aggregate supply curve

The *DAS* curve, like the normal *AS* curve, is upward sloping. In the short run it will be relatively flat. In the long run it will be relatively steep, if not vertical at the potential level of national income. The curve illustrated in Figure 20.7 is the short-run *DAS* curve. But why is it shaped this way? Why will a higher rate of inflation lead to higher real national income?

Assume that the economy is currently generating a real national income of Y_1 and that inflation is on target (π_{target}). Equilibrium is at point *a*. Assume also that Y_1 represents the long-run potential level of output.

Now assume that consumer confidence rises, and that, as a result, the *DAD* curve shifts to *DAD*₂. Firms will respond to the higher aggregate demand partly by raising prices more than the current (i.e. target) rate of inflation and partly by increasing output: there is a movement along the *DAS* curve. Equilibrium moves to point *b*, where *DAD* = *DAS*.

But why will firms raise output as well as prices? The reason is that wage rises lag behind price rises. This is because of the time it takes to negotiate new wage rates and the fact that people were probably anticipating that inflation would stay at its target level. The higher prices now charged by firms will generate bigger profit margins for them, and thus they will be willing to supply more.

Over time, however, if the higher demand persists, wage rises would get higher. This would be the result of firms trying to obtain more labour to meet the higher demand and of unions seeking wage increases to compensate for the higher

rate of inflation. Thus, assuming no increase in productivity, the *DAS* curve would shift upwards and continue doing so until real national income returned to the potential level Y_1 . The long-run *DAS* curve would be vertical through point a .

Response to changes in aggregate demand and supply

A rise in aggregate demand

Assume, in Figure 20.7, that there has been a rise in real aggregate demand and that the *DAD* curve has shifted to *DAD*₂. Assume also that Y_1 is the potential level of national output. If inflation remained at its target level, the economy would move to point c , with national income increasing to Y_3 . But as firms respond partly by increasing prices more rapidly, equilibrium is reached at point b . In other words, there has been a movement up along the (short-run) *DAS* curve from point a to point b and back up along the new *DAD* curve from point c to point b . This movement along curve *DAD*₂ is the result of the higher interest rates imposed by the central bank in response to inflation rising to π_2 .

But equilibrium at point b is above the target rate. This is unsustainable, even in the short run. One of two things must happen. The first option is for the central bank (or government) to accept a higher target rate of inflation: i.e. π_2 . But if it does this, real income can only remain above its potential level in the short run. Soon, higher prices will feed through into higher wages and back into higher prices, and so on. The *DAS* curve will shift upwards.

The second option – the only effective option in the long run – is for the central bank to reduce aggregate demand back to *DAD*₁. This will mean changing monetary policy, such that a higher real rate of interest is chosen for each rate of inflation. This tighter monetary policy shifts the *DAD* curve to the left.

In other words, if the central bank is adhering strictly to an inflation target, any rise in real aggregate demand can have only a temporary effect, since the higher inflation that results will force the central bank to bring aggregate demand back down again.

The one exception to this would be if the higher aggregate demand encouraged firms to invest more. When the effects of this on aggregate supply began to be felt in terms of higher output, the short-term *DAS* curve itself would shift to the right, leading to a new equilibrium to the right of point a . In such a case, there would have been a long-term increase in output, even though the central bank was sticking to an inflation target.

 Using a graph similar to Figure 20.7, trace through the effect of a reduction in aggregate demand.

A rise in aggregate supply

Assume now that aggregate supply rises. This could be a temporary ‘supply shock’, such as a cut in oil prices or a good harvest, or it could be a permanent increase caused, say, by technical progress. Let us take each in turn.

A temporary supply shock. In Figure 20.8, initial equilibrium is at point a , with curves *DAD*₁ and *DAS*₁ intersecting at point a , at the target rate of inflation. The rise in aggregate supply causes the *DAS* curve temporarily to shift from *DAS*₁ to *DAS*₂. Inflation thus falls below the target rate. As a result, the central bank reduces the real rate of interest (r). The effect is to increase aggregate demand. This is shown by a movement along curve *DAD*₁ from point a to point d . Inflation falls to π_3 and real national income rises to Y_4 . Since this is only a temporary increase in aggregate supply, the central bank will not change its monetary policy. The *DAD* curve, therefore, will not shift.

As the supply shock subsides, aggregate supply will fall again. The *DAS* curve will shift back from *DAS*₂ to *DAS*₁, causing inflation to rise again. The result is a move back up the *DAD*₁ curve from point d to point a .

1. Trace through the effect of an adverse supply shock, such as a rise in oil prices.
2. What determines the amount that national income fluctuates when there is a temporary shift in the *DAS* curve?

A permanent increase in aggregate supply. Now assume that *DAS*₂ represents a permanent shift. As before, the reduction in inflation causes the central bank to reduce interest rates. If there is no change in monetary policy, there would be, once more, a movement from point a to point d with inflation now at π_3 .

Once the central bank realises that the rise in aggregate supply is permanent, it will want to move to equilibrium at point e . To do this it will have to *change* its monetary policy and adopt a lower real interest rate at each rate of inflation (a shift downwards of the *MP* curve, as in Figure 19.14(b) on page 609)). This will shift the *DAD* curve to *DAD*₂. If it does this, equilibrium will be restored at the target rate of inflation. Y_5 will be the new sustainable level of real national income.

In other words, the central bank, by maintaining an inflation target, will allow aggregate demand to expand sufficiently to accommodate the full rise in aggregate supply.

Figure 20.8 The effects of an increase in aggregate supply

In Chapter 22 we explore policies to control aggregate demand. In section 22.4, we look at whether it is best for a central bank to target inflation or whether it should adopt an alternative target. We also look at the more general issue of whether governments ought to set targets and stick to them, or whether they should allow themselves more discretion in managing the economy.

In the next chapter we expand our analysis of aggregate demand and supply to take account of unemployment and also the role of expectations. We look at how the various schools of thought model the macroeconomy in this more complete framework.

BOX 20.3

ANALYSING DEMAND-PULL AND COST-PUSH INFLATION USING THE DAD/DAS MODEL

EXPLORING ECONOMICS

Types of inflation under a policy of inflation targeting

We can use the DAD/DAS model to analyse the implications of demand-pull and cost-push pressures under a policy of inflation targeting.

The diagram below is similar to Figure 20.8. Assume that the central bank operates with an inflation target of π_{target} and that the economy is currently in equilibrium at point *a* with dynamic aggregate demand and supply given by DAD_1 and DAS_1 respectively. Real national income is at the potential (or 'natural') level of Y_1 .

Demand-pull inflation

If there is a rise in aggregate demand to DAD_2 , this will result in demand-pull pressures on inflation. The government or central bank could respond in either of two ways.

- Fiscal or monetary policy could be tightened to shift the DAD curve back to DAD_1 , thereby maintaining inflation at the target level.
- A new higher inflation target could be adopted (e.g. π_2), allowing an equilibrium at point *b*. Note, however, that if the potential level of income remains at Y_1 , Y_2 will not be sustainable. In the long run, the DAS curve will drift upwards, pushing inflation above the new higher target level. A tighter monetary policy (DAD_3) would then be needed to bring national income back down to the potential level, Y_1 .

Cost-push inflation

If costs now rise faster than the rate of inflation (a *real* rise in costs), the DAS line will shift upwards (e.g. to DAS_2). Again, the government or central bank could respond in either of two ways.

- The central bank could stick to its target and adopt a tighter monetary policy. In this case the DAD curve will shift to the left to give an equilibrium at point *c* at the target rate of inflation. The potential level of output is now at the lower level of Y_3 .
- The central bank could be given a higher target rate of inflation (π_2) to prevent real income falling. It will thus expand aggregate demand and the DAD line will shift to DAD_3 . Equilibrium would now be at point *d*. The problem with this second approach is that if there has been a long-term reduction in potential output to Y_3 (as opposed to a one-off supply-side shock that is later reversed), there will be further upward pressure on inflation: the DAS curve will continue shifting upwards as long as real national income remains above Y_3 . It will only be possible to keep to the target rate of inflation, at any level, if DAD is allowed to fall so that it intersects with DAS at Y_3 .

? If cost-push pressures reduce the potential level of real national income (e.g. from Y_1 to Y_3 in the diagram), why do demand-pull pressures not increase the potential level of real national income (e.g. from Y_1 to Y_2 in the diagram)?

Section summary

1. The effects of adhering to an inflation target can be illustrated in a modified version of the aggregate demand and supply diagram. Inflation, rather than the price level, is plotted on the vertical axis. The aggregate demand curve in this diagram (labelled *DAD*) is downward sloping. This is because higher inflation encourages the central bank to raise interest rates and this leads to a fall in real national income.
2. The aggregate supply (*DAS*) curve in the short run is upward sloping. This is because wage rises lag behind price rises and thus firms are encouraged to supply more in response to a rise in demand knowing that their profits will increase.
3. If aggregate demand rises, the *DAD* curve will shift to the right. The rate of inflation will rise above its target level. This is shown by a movement up the *DAS* curve and back up the new *DAD* curve to the new intersection point (as in Figure 20.7). The movement up the new *DAD* curve is in response to the higher interest rate now set by the central bank as it attempts to bring inflation back down to its target level.
4. Since the new equilibrium is above the target rate of inflation, the central bank must change to a tighter monetary policy and raise the real rate of interest. This shifts the *DAD* curve back to the left, and equilibrium is restored back at its original level. The rise in aggregate demand (unless accompanied by a rightward shift in aggregate supply) has had only a temporary effect on real national income.
5. A rise in aggregate supply (unless merely a temporary supply shock) will have a permanent effect on real national income. A rightward shift in aggregate supply will lead to an initial equilibrium at a rate of inflation below target and some rise in real national income as the rate of interest is reduced (as in Figure 20.8). The equilibrium is now below the target rate of inflation. The central bank must therefore change to a looser monetary policy and reduce the real rate of interest. This will shift the *DAD* curve to the right, causing a further rise in real national income that now fully reflects the rise in aggregate supply.

20.4 THE LABOUR MARKET AND AGGREGATE SUPPLY

Labour is a vital factor of production and so an important element of the aggregate supply relation we have considered in the previous sections of this chapter. The wage rate, quantity and quality of labour all, in one way or another, affect aggregate supply.

But the demand for labour is a derived demand: firms demand labour because of the goods and services it helps to produce. The level of aggregate demand for goods and services (*AD*) therefore affects the aggregate demand for labour in the economy (*AD_L*). Yet the aggregate demand for goods and services is itself affected by the price paid by firms for the labour it employs.

All of this illustrates the importance of the labour market to the behaviour of the economy. Therefore, we now take a closer look at how the labour market works.

Modelling the labour market

Figure 20.9 shows the *aggregate demand* for labour and *aggregate supply* of labour: that is, the total demand and supply of labour in the whole economy. The *real* average wage rate is plotted on the vertical axis. As we saw in section 15.5, this is the average wage rate expressed in terms of its purchasing power to workers and the purchasing cost to employers. Therefore, the real wage is the nominal wage corrected for inflation.

Definitions

Aggregate demand for labour curve A curve showing the total demand for labour in the economy at different average real wage rates.

Aggregate supply of labour curve A curve showing the total number of people willing and able to work at different average real wage rates.

Figure 20.9 Disequilibrium unemployment

The aggregate supply of labour curve (AS_L) shows the number of workers *willing to accept jobs* at each real wage rate. This curve is relatively inelastic, since the size of the labour force at any one time cannot change significantly. Nevertheless it is not totally inelastic because (a) a higher wage rate will encourage some people to enter the labour market (e.g. parents raising children), and (b) the unemployed will be more willing to accept job offers rather than continuing to search for a better-paid job.

The aggregate demand for labour curve (AD_L) slopes downwards. This is an extension of the microeconomic demand for labour curve (see section 10.1) and is based on the assumption of diminishing returns to labour. For a given capital stock, the more people are employed, the lower their marginal productivity. Thus firms take on more labour only if there is a fall in the real wage rate to compensate them for the lower output produced by the additional workers. On the other hand, the higher the real wage rate, the more will firms attempt to economise on labour and to substitute other factors of production for labour.

The labour market is in equilibrium at a real wage of W_e – where the demand for labour equals the supply.

If the wage rate were above W_e , the labour market would be in a state of disequilibrium. At a wage rate of W_1 , there is an excess supply of labour of $a - b$. This is called **disequilibrium unemployment**.

For disequilibrium unemployment to occur, two conditions must hold:

- The aggregate supply of labour must exceed the aggregate demand for labour.
- There must be a 'stickiness' in wages. In other words, the wage rate must not immediately fall to W_e , the market-clearing wage.

Even when the labour market is in equilibrium, however, not everyone looking for work will be employed. Some people will hold out, hoping to find a better job. This is illustrated in Figure 20.10.

Figure 20.10 Equilibrium unemployment

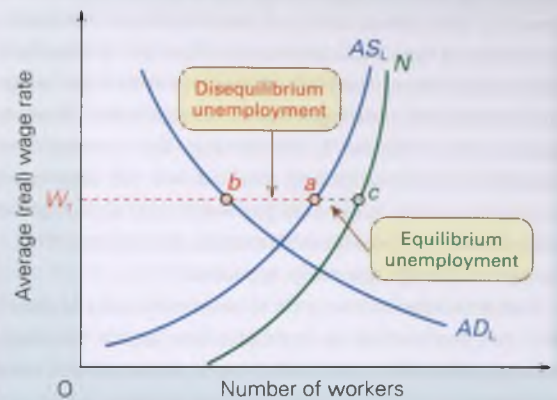

Figure 20.11 Disequilibrium and disequilibrium unemployment

The curve N shows the total number in the labour force. The horizontal difference between it and the aggregate supply of labour curve (AS_L) represents the excess of people looking for work over those actually willing to accept jobs. Q_e represents the equilibrium level of employment and the distance $d - e$ represents the **equilibrium level of unemployment**. This is sometimes known as the **natural level of unemployment**.

Note that the AS_L curve gets closer to the N curve at higher wages. The reason for this is that the higher the wages that are offered to the unemployed, the more willing they will be to accept jobs.

Figure 20.11 shows both equilibrium *and* disequilibrium unemployment. At a wage of W_1 , disequilibrium unemployment is $a - b$; equilibrium unemployment is $c - a$; thus total unemployment is $c - b$.

We are now able to relate the concepts of equilibrium and disequilibrium unemployment to our discussion of the causes of unemployment in Chapter 15 (see pages 469–72). Real wage unemployment and demand-deficient unemployment are types of disequilibrium unemployment while structural, frictional and seasonal unemployment are types of equilibrium unemployment.

Definitions

Disequilibrium unemployment Unemployment resulting from real wage rates in the economy being above the equilibrium level.

Equilibrium ('natural') unemployment The difference between those who would like employment at the current wage rate and those willing and able to take a job.

Disequilibrium unemployment

Real-wage unemployment is disequilibrium unemployment caused by real wages being driven up above the market-clearing level. In Figure 20.9, the wage rate is driven up above W_e . There are a variety of possible reasons for this, as we saw in section 15.5. Some argue that it is the result of trade unions using their monopoly power to drive wages above the market-clearing level or, more generally, those in employment ('insiders') preventing the unemployed ('outsiders') from competing wages down. An alternative perspective is that firms may pay wage rates above market levels in order to provide an incentive for workers. This is the basis of the *efficiency wage hypothesis*.

Demand-deficient or cyclical unemployment is associated with fluctuations in aggregate demand. In the recessionary phase of a business cycle demand-deficient unemployment is likely to rise; as the economy expands it is likely to fall.

Demand-deficient unemployment is illustrated in Figure 20.12. Assume initially that the economy is at the peak of the business cycle. The aggregate demand for and supply of labour are equal at the current wage rate of W_1 . There is no disequilibrium unemployment. Now assume that the economy moves into recession. Consumer demand falls and as a result firms demand less labour. The demand for labour shifts to $AD_{1,2}$. If there is a resistance to wage cuts, such that the real wage rate remains fixed at W_1 , there will now be disequilibrium unemployment of $Q_1 - Q_2$.

Some Keynesians focus on the reluctance of real wage rates to fall from W_1 to W_2 . Others, as we saw in Chapter 15, argue that the focus should be on the low level of aggregate demand. This, they argue, causes an equilibrium in the goods market at an output level that is too low to generate full employment. The disequilibrium in the labour market is the result of the low equilibrium output level in the goods market.

Equilibrium (or natural) unemployment

Although there may be overall macroeconomic equilibrium, with the aggregate demand for labour equal to the aggregate supply, and thus no disequilibrium unemployment, at a microeconomic level supply and demand may not match. There may be excess demand for labour (vacancies) in some markets and excess supply (unemployment) in others.

Two commonly identified sources for these mismatches are skills and geography. There may be vacancies for computer technicians and unemployment in the steel industry, but unemployed steel workers cannot immediately become computer technicians. Even if the working population were relatively adaptable and therefore mobile between different sectors of the economy, there is still the potential problem that those unemployed may be in different geographical locations from where vacancies are located.

Then there is the problem of *imperfect information*. There is considerable turnover or churn in the labour market, with some individuals being made redundant or quitting their jobs while others are finding work. But employers are not fully informed about the labour available, while workers are not fully informed about what jobs are available and what they entail. The result is a process of search which sees employers searching for the right labour and workers for the right jobs.

The longer people search for a job, the better the wage offers they are likely to be made. This is illustrated in Figure 20.13 by the curve W_0 . It shows the highest wage offer that the typical worker will have received since being unemployed.

When they first start looking for a job, people may have high expectations of getting a good wage. The longer they are unemployed, however, the more anxious they are likely to be to get a job, and therefore the lower will be the wage they are prepared to accept. The curve W_a shows the wage that is acceptable to the typical worker.

Figure 20.12 Demand-deficient unemployment

Figure 20.13 Average duration of unemployment

Why are W_o and W_a drawn as curves rather than straight lines?

The average duration of unemployment will be T_e . That is, workers will remain unemployed until they find a job at an acceptable wage.

By improving the flow of job information, for example through government spending on job centres, the intention is to make the curve W_o reach its peak earlier. This has the effect of shifting the intersection of W_o and W_a to the left.

Other economists advocate reducing levels of unemployment benefit. The argument here is that this incentivises the unemployed to take work by making them more prepared to accept a lower wage. It will therefore have the effect of shifting the W_a curve downwards and again of shifting the intersection of W_o and W_a to the left.

The classical model of labour markets and aggregate supply

The classical model is based on the 'classical' assumptions that real wage rates are flexible in the long run and that people are fully aware of price and wage changes, and hence do not believe that a given percentage pay increase will make them better off when prices are rising by the same percentage. In other words, people do not suffer from *money illusion*.

Figure 20.14(a) shows again our aggregate demand and supply of labour diagram. The equilibrium real wage is W_e , where $AD_L = AS_L$, with Q_e workers employed. There is no disequilibrium unemployment at this real wage rate, but there is some equilibrium or natural unemployment. As we saw above, this is largely made up of frictional and structural unemployment. It is represented by the distance $(b - a)$.

With flexible prices and wage rates in the long run, real wage rates will also be flexible in the long run. This ensures that long-run employment is kept at Q_e .

The equilibrium in the labour market is matched by a corresponding equilibrium in the goods market, which is shown in Figure 20.14(b). The level of real national income corresponding to the natural level of employment is known as the *natural level of income (or output)*. This is just another name for the *potential level of output* (Y_p): i.e. where there is a zero output gap (see Box 15.3, on page 460). The natural level of income is shown in the diagram as Y_p .

Now assume that aggregate demand for goods rises. This is shown by a rightward move of the aggregate demand curve from AD_1 to AD_2 . It causes a movement up the short-run aggregate supply curve, $SRAS_1$, from point e to point f . The price level rises from P_1 to P_2 . This causes the real wage to fall below W_e , say to W_1 in Figure 20.14(a). But at this real wage rate there is an excess demand for labour of $d - c$. This drives up the money (nominal) wage rate until the *real* wage rate has returned to W_e . Thus equilibrium employment is at Q_e and output is at its natural level irrespective of changes in aggregate demand.

Q_e would change only if there were some *exogenous* shift in the AD_L or AS_L curve (e.g. a growth in the working population would cause N and AS_L to shift to the right; a growth in labour productivity would cause AD_L to shift to the right). In turn, this would affect the economy's natural level of output.

Assume that there is a fall in aggregate demand (for goods). Trace through the short-run and long-run effect on employment.

The time taken for national output and employment to return to their natural levels will depend on the speed with

Figure 20.14 Classical analysis of the labour market and output determination

which money wages adjust. However, any disequilibrium experienced in the labour market will be temporary. Indeed, a group of economists known as new classical economists (see section 16.4) argue that wage and price flexibility is very great, especially with increased numbers of part-time and short-term jobs. This flexibility is so great that both goods and labour markets clear virtually instantaneously. This is the assumption of *continuous market clearing* (see page 504).

Consequently, the speed of adjustment in the labour market to changes in aggregate demand means that there will be very little in the way of fluctuations in employment and output around their natural levels. Only if the change in aggregate demand was *unexpected* might there be any more significant effect on output and employment (see section 16.4, pages 504–505). For this reason some economists refer to the short-run aggregate supply curve as the ‘surprise aggregate supply curve’.

It is argued that once people recognise the impact that demand shocks have had on the prices of goods and services and, in turn, on their real wages, the labour market will readily adjust to equilibrium. As it does, the short-run (or surprise) aggregate supply curve moves readily to intersect the aggregate demand curve at the natural level of output.

Definitions

Money illusion The belief that a *money* change in wages or prices represents a *real* change.

Natural level of real income (or output) The level of output consistent with the equilibrium or ‘natural’ level of employment.

Keynesian models of labour markets and aggregate supply

Keynesians take a very different view of labour markets, arguing that they are characterised by imperfections and frictions. In particular, they point to labour markets exhibiting considerable wage inflexibility. Employers bargain with unions and usually set wage rates for a whole year. Even in non-unionised firms, wage rates are still often set for a year.

A negative output gap. The inflexibility of wages and of prices in goods markets is a concern when an economy experiences a fall in aggregate demand. This is because it can lead to significant falls in the *quantities* of output and employment. Compare this with the classical model, where the adjustment occurs through *prices*. In the classical model a fall in aggregate demand for goods (a leftward shift of the *AD* curve) causes prices in the goods market to fall. This eliminates the excess supply of goods in the goods market. Meanwhile, in the labour market money wages fall. This is driven by an excess supply of labour from real wages being higher because of lower goods prices. The proportionate fall in money wages matches the fall in goods prices so that the real wage rate is restored at its equilibrium level.

Keynesians argue that if there is a fall in consumer demand, firms usually respond *not* by cutting wages. Instead they lay off workers, cut hours, institute early retirement or do not replace workers when they leave. In the short run, therefore, wages in many sectors of the economy are insensitive to a fall in demand.

Consider an economy characterised by equilibrium in the labour and goods market. In Figure 20.15(a), employment is Q_e and the only unemployment is equilibrium unemployment of $b - a$. Meanwhile, real national income (output) is the natural level Y_1 and the economy’s price level is P_1 .

Assume now the case of a fall in aggregate demand, represented by a leftward shift of the aggregate demand curve

Figure 20.15 Keynesian analysis of the labour market and output determination

from AD_1 to AD_2 in Figure 20.15(b). However, the aggregate price level does not adjust following the fall in aggregate demand. Firms find that they cannot sell all the goods they previously did. Hence, the adjustment to the fall in aggregate demand occurs solely through a fall in the quantity of output. The SRAS curve becomes a horizontal line at price level P_1 in Figure 20.15(b) and output falls from Y_1 to Y_2 .

In the labour market, the stickiness of nominal wages means that, with nominal wages and prices not affected by the fall in demand, real wages are unaffected too. Hence, with a lower aggregate demand for goods but real wages still at their full-employment real wage rate, firms reduce their effective demand for labour. This is represented in Figure 20.15(a) by a fall in the aggregate demand for labour from AD_{L1} to AD_{L2} . Firms thus reduce employment from Q_e to Q_2 . There is now demand-deficient unemployment of $a - c$. Total unemployment is $b - c$.

But what about the long run? Clearly it depends on how long the long run is. Many Keynesians argue that prices and especially wages exhibit a degree of inflexibility over quite a

long period of time, and over this period of time, therefore, the aggregate supply curve would not be vertical. In other words, it could take some considerable time for the economy to move from point f in Figure 12.15(b) to point g . The result could be an economy stuck at an output level below its potential. In such a scenario, Keynesians argue, governments can play a important role by helping to stimulate aggregate demand.

The possibility of a low-output equilibrium is a significant insight. But, can the current analysis explain positive output gaps: i.e. output levels above potential output?

A positive output gap. Again, assume that the economy is characterised by equilibrium in both the goods and labour market. In the presence of sticky prices in the goods market the increase in aggregate demand (a rightward shift of the AD curve) is reflected in full by an increase in output. There is no effect on the real wage. Hence, in the labour market, firms' effective demand for labour rises (a rightward shift of the AD_L curve). If we assume that workers choose to supply this additional demand, despite being off their AS_L curve, then employment rises to produce the additional goods.

Section summary

1. The goods and labour markets are interdependent. A rise in aggregate demand in the goods market will lead to a rise in the aggregate demand for labour.
2. Equilibrium in the labour market is where the aggregate demand and supply of labour are equal. However, even in equilibrium, there is likely to be some unemployment. This 'equilibrium unemployment' occurs when there are people unable or unwilling to fill job vacancies. This could be frictional or structural unemployment.
3. Disequilibrium unemployment occurs when real wage rates are above the level that will equate the aggregate demand and supply of labour. In the case of demand-deficient unemployment, the disequilibrium in the labour market may correspond to a low-output equilibrium in the goods market. A fall in real wage rates may be insufficient to remove the deficiency of demand in the labour market.
4. Classical economists argue that prices and wages respond quickly to changes in aggregate demand and supply. A fall in aggregate demand will quickly result in a fall in prices, with equilibrium remaining at the natural level of output. Likewise, nominal wages will quickly fall and there will be no disequilibrium unemployment.
5. Keynesian economists argue that, because of sticky prices and wages, a fall in demand in the goods market will lead to a fall in output and a fall in employment; disequilibrium unemployment will occur. The slower prices and wages are to adjust, the longer it is likely to persist.

20.5 AD/AS AND MACROECONOMIC CONTROVERSIES

In this chapter we have introduced the AD/AS, DAD/DAS and AD_L/AS_L models. These models allow us to analyse the interaction of aggregate demand and aggregate supply in determining the economy's output, price and employment levels. The nature of this interaction and, in particular, the way in which the economy adjusts to economic shocks highlights important differences between economists. In this final section of the chapter we discuss some of these differences and the implications they have for policy.

Most of the debate in macroeconomics has centred on the working of the market mechanism: just how well or how badly it achieves various macroeconomic objectives. We

focus here on three major areas of disagreement: (a) how flexible are wages and prices, (b) how flexible is aggregate supply; (c) what is the role of expectations? We examine each in turn.

Controversy 1: the flexibility of prices and wages

Generally, the political right has tended to ally with those economists who argue that prices and wages are relatively flexible. Markets tend to clear, they say, and clear fairly quickly.

Disequilibrium unemployment is likely to be fairly small, according to their view, and normally only a temporary, short-run phenomenon. Any long-term unemployment, therefore, will be equilibrium (or 'natural') unemployment. To cure this, they argue, encouragement must be given to the free play of market forces: to a rapid response of both firms and labour to changes in market demand and supply, to a more rapid dissemination of information on job vacancies, and generally to greater labour mobility, both geographical and occupational.

There are some on the political right, however, who argue that in the short run wages may not be perfectly flexible. This occurs when unions attempt to keep wages above the equilibrium. In this case, disequilibrium unemployment may continue for a while. The solution here, they argue, is to curb the power of unions so that wage flexibility can be restored and disequilibrium unemployment cured.

The political centre and left have tended to ally with economists who reject the assumption of highly flexible wages and prices. There exists, they argue, frictions and market imperfections. If there is a deficiency of demand for labour in the economy, for example during a recession, there will be a resistance from unions to cuts in real wages and certainly to cuts in money wages. Any cuts that do occur will be insufficient to eliminate the disequilibrium, and will anyway serve only to reduce aggregate demand further, so that workers have less money to spend. The aggregate demand for labour curve in Figure 20.15 (see page 638) would shift further to the left.

The prices of goods may also be inflexible in response to changes in demand. As industry became more concentrated and more monopolistic over the years, firms, it is argued, became less likely to respond to a general fall in demand by cutting prices. Instead, they were likely to build up stocks if they thought the recession was temporary, or cut production and hence employment if they thought the recession would persist. It is also argued that many firms use cost-plus methods of pricing. If wages are inflexible downwards, and if they form a major element of costs, prices will also be inflexible downwards.

Thus, according to those who criticise the right, markets cannot be relied upon automatically to correct disequilibria and hence cure disequilibrium unemployment.

Why are real wages likely to be more flexible downwards than money wages?

The process of globalisation has helped to offset the growth in market power in many industries in recent years. Competition from China and India, for example, has made prices in many markets more flexible. In other markets, however, particularly in the service sector, international competition is less relevant and in others, global giants, such as Apple, Monsanto, Boeing and GlaxoSmithKline, have considerable price-setting power.

Controversy 2: the flexibility of aggregate supply

The question here is, how responsive is national output (i.e. aggregate supply), and hence also employment, to a change in aggregate demand?

The arguments centre on the nature of the aggregate supply curve (*AS*). Three different *AS* curves are shown in Figure 20.16. In each of the three cases, it is assumed that the government raises aggregate demand through the use of fiscal and/or monetary policy. Aggregate demand shifts from AD_1 to AD_2 . The effect on prices and output will depend on the shape of the *AS* curve.

Some economists, generally supported by the political right, argue that output is not determined by aggregate demand, except perhaps in the very short run. Instead, the rise in aggregate demand will simply lead to a rise in prices. They therefore envisage an *AS* curve like that in Figure 20.16(a).

If the government wants to expand aggregate supply and get more rapid economic growth, it is no good, they argue, concentrating on demand. Instead, governments should concentrate directly on supply by encouraging enterprise and competition, and generally by encouraging markets to operate more freely. For this reason, this approach is often labelled *supply-side economics*.

Their critics, however, argue that a rise in aggregate demand will lead to a rise in output. In the extreme case where actual output is well below potential output, prices will not rise at all. In this case, the *AS* curve is like that in Figure 20.16(b). Output will rise to Y_2 with the price level remaining at P .

Others argue that both prices and output will rise. In this case, the short-term curve will be like that in Figure 20.16(c). If there is plenty of slack in the economy – idle machines, unemployed labour, etc. – output will rise a lot and prices only a little. But as slack is taken up, the *AS* curve becomes steeper. Firms, finding it increasingly difficult to raise output in the short run, simply respond to a rise in demand by raising prices.

As we discussed in Chapter 16, a new macroeconomic consensus has emerged in recent times. It is generally agreed that the short-run *AS* curve is similar to that in Figure 20.16(c), but that in the long run, given time for prices and wages to adjust, the curve is much steeper, if not vertical. Any increase in aggregate demand will simply result in higher prices.

Definition

Supply-side economics An approach which focuses directly on aggregate supply and how to shift the aggregate supply curve outwards.

Figure 20.16 Contrasting views on the aggregate supply curve

Aggregate demand and investment

There is not total agreement, however, that changes in aggregate demand have no long-term effect on output. One way in which changes in aggregate demand can have a lasting impact on output is if these affect firms' investment plans.

Assume there is a rise in aggregate demand. As a result, firms may be encouraged to invest in new plant and machinery (the accelerator effect). In so doing, they may well be able to increase output significantly in the long run with little or no increase in their prices. This would make their long-run MC curves much flatter than their short-run MC curves.

In Figure 20.17, the short-run AS curve (SRAS) shifts to the right. Equilibrium moves from point *a* to *b* to *d*. In this case, the long-run AS curve (LRAS) joining points *a* and *d* becomes more elastic. There is a relatively large increase in output and a relatively small increase in price.

**Figure 20.17** Effect of investment on the long-run aggregate supply curve

The LRAS curve will be flatter and possibly even downward sloping if the investment involves the introduction of new cost-reducing technology, or if firms generally experience economies of scale. It will be steeper if the extra investment causes significant shortages of materials, machinery or labour. This is more likely when the economy is already operating near its full-capacity output.

1. Will the shape of the LRAS curve here depend on just how the 'long' run is defined?
2. If a shift in the aggregate demand curve from AD to AD_1 in Figure 20.17 causes a movement from point *a* to point *d* in the long run, would a shift in aggregate demand from AD_1 to AD cause a movement from point *d* back to point *a* in the long run?

The possibility that increases in aggregate demand can stimulate higher levels of investment, and so bring about higher capacity and a higher aggregate supply, has clear policy implications. For example, Keynesian economists argued for a package of measures to expand aggregate demand following the banking crisis of 2008. An expansion in aggregate demand, through fiscal and monetary policies, would, they argue, result in higher investment and hence an increase in capacity of the economy, which would allow economic recovery to be sustained.

Hysteresis

The possibility of economic *hysteresis* provides another means by which fluctuations in aggregate demand may generate long-term real effects on the economy. As you may have seen in section 16.5, page 509, hysteresis refers to the lagging or persistence of an effect, even when the initial cause has been removed. In other words, an equilibrium position depends on the path taken to arrive there. In this context, hysteresis would be where long-run aggregate

Figure 20.18 The effect on wages and employment of a recovery from recession

supply depends on what has been happening to aggregate demand and supply in the short run.

To illustrate this, we apply a Keynesian view of goods and labour markets, assuming that both prices and wages are sticky. Now assume that the economy goes into recession, with a corresponding rise in demand-deficient unemployment and a fall in output. In Figure 20.18, the effective aggregate demand for labour curve has fallen from AD_{1_1} to AD_{1_2} . Demand-deficient unemployment is $a - b$ (the short-run effect).

As the recession persists, those previously laid off may not be readily re-employable, especially if they have been out of work for some time and have become deskilled and demoralised. The aggregate supply of labour curve shifts to the left, perhaps as far as AS_{1_2} . In such a case, there would now no longer be an excess supply of labour that firms regard as 'employable' ($AD_{1_2} = AS_{1_2}$). There is no downward pressure on real wages: a long-run equilibrium has been reached. The implication of this is that the long-run aggregate supply (of goods) curve is *not* vertical. A leftward shift in aggregate demand has led to a long-run fall in output.

Assume now that the government pursues a reflationary policy, and that the aggregate demand for labour shifts back to AD_{1_1} . There will be a move up along AS_{1_2} to point d . Unemployment is now $e - d$, higher than the original level of $c - a$.

Controversy 3: the role of expectations in the working of the market

How quickly and how fully will individuals and firms anticipate changes in prices and changes in output? How are their expectations formed, and how accurate are they? What effect do these expectations have? This has been the third major controversial topic.

The political right tended to ally with those economists who argue that people's expectations adjust rapidly and fully to changing economic circumstances. They emphasise the role of expectations of *price* changes.

If aggregate demand expands, they argue, people will expect higher prices. Workers will realise that the apparently higher wages they are offered are an illusion. The higher wages are 'eaten up' by higher prices. Thus workers are not encouraged to work longer hours, and unemployed workers are not encouraged to take on employment more readily. Likewise the higher prices that firms can charge are necessary to cover higher wages and other costs, and are not a reflection of higher real demand. Firms thus soon realise that any apparent increased demand for their products is an illusion. Their price rises will fully absorb the extra spending in money terms. There will be no increase in sales, and hence no increase in output and employment.

Therefore, they argue, increased aggregate demand merely fuels inflation and can do no more than give a very temporary boost to output and employment. If anything, the higher inflation could damage business confidence and thus worsen long-term output and employment growth by discouraging investment.

Those who criticise this view argue that the formation of expectations is more complex than this. Whether people expect an increase in demand to be fully matched by inflation depends on the current state of the economy and how any increase in demand is introduced.

If there is a lot of slack in the economy (if unemployment is very high and there are many idle resources) and if an increase in demand is in the form, say, of direct government spending on production (on roads, hospitals, sewers and other infrastructure) then output and employment may quickly rise. Here the effect of expectations may be beneficial. Rather than expecting inflation from the increased demand, firms may expect faster growth and an expansion of markets. As a result, they may choose to invest, and this in turn will produce further growth in output and employment.

Views on expectations, therefore, tend to parallel views on aggregate supply. The right argues that a boost to demand will not produce extra output and employment: aggregate supply is inelastic (as in Figure 20.16(a)) and therefore the higher demand will merely fuel expectations of inflation. Their critics argue that a boost to demand can increase aggregate supply and employment. If firms expect this, they will produce more.

? *If firms believe the aggregate supply curve to be moderately elastic, what effect will this belief have on the outcome of an increase in aggregate demand?*

We examine the role of expectations in determining output and employment in the next chapter.

BOX 20.4

COMMON GROUND BETWEEN ECONOMISTS?

EXPLORING
ECONOMICS**Identifying areas of agreement**

The financial crisis of the late 2000s helped to reignite long-standing debates amongst macroeconomists. Up to that point a new macroeconomic consensus was developing. This brought under one large tent a group of macroeconomists modelling the interaction of representative forward-looking economic agents in markets characterised by varying degrees of imperfections where shocks regularly hit economies.

The models were a fusion of new Keynesian and new classical ideas (see Chapter 16 for more on 'macroeconomic schools of thought'). The models were argued to provide insights into how economies adjust to new equilibria in the face of economic shocks. The focus would be on the paths taken by key macroeconomic variables such as output, employment and inflation.

The financial crisis raised several concerns about the new mainstream macroeconomic approach. Had the approach to modelling become too mathematical? Did it, therefore, not sufficiently account for the effects, for instance, of human behaviour and the way in which humans interact? Had it placed too much faith in the ability of markets to deliver socially desirable outcomes? Had it taken too little account of the financial system and the financial well-being of economic agents?

These and many other questions continue to be debated. Nonetheless, we can still identify areas of common ground between many economists over many issues. Hence, some degree of macroeconomic consensus may be argued to have survived the financial crisis. We summarise here three general areas of agreement first introduced in section 16.6 (see pages 514–16).

1. Fluctuations in aggregate demand can have significant effects on output and employment in the short term

With the exception of extreme new classical economists, most economists would accept that the short-run aggregate supply (SRAS) curve is *upward sloping*, albeit getting steeper as potential output is approached. There are two major implications of this analysis.

- Reductions in aggregate demand can cause reductions in output and increases in unemployment. In other words, too little spending will cause a recession.
- An expansion of aggregate demand by the government (whether achieved by fiscal or monetary policy, or both) will help to pull an economy out of a recession. There may be considerable time lags, however, before the economy fully responds to such expansionary policies.

2. Changes in aggregate demand will have much less effect on output and employment and much more effect on prices in the longer term

As we have seen, new classical economists and others argue that the long-run aggregate supply (LRAS) curve is vertical.

Some Keynesian economists agree, but argue that the long run might be quite a long time. Others, while arguing that the LRAS curve is not vertical, would still see it as less elastic than the short-run aggregate supply curve. Nevertheless, some Keynesians argue that changes in aggregate demand *will* have substantial effects on long-term output and employment via changes in investment and hence in potential ('full-employment') output.

3. Expectations have important effects on the economy

Virtually all economists argue that expectations are crucial in determining the success of government policy on unemployment and inflation. Whatever people expect to happen, their actions will tend to make it happen.

If people believe that an expansion of money supply will merely lead to inflation (the monetarist and new classical position), then it will. Firms and workers will adjust their prices and wage rates upwards. Firms will make no plans to expand output and will not take on any more labour. If, however, people believe that an expansion of demand will lead to higher output and employment (the Keynesian position), then, via the accelerator mechanism, it will.

Similarly, just how successful a deflationary policy is in curing inflation depends in large measure on people's expectations. If people believe that a deflationary policy will cause a recession, then firms will stop investing and will cut their workforce. If they believe that it will cure inflation and restore firms' competitiveness abroad, firms may increase investment.

To manage the economy successfully, therefore, the government must convince people that its policies will work. This is as much a job of public relations as of pulling the right economic levers. It is one of the reasons for making central banks independent. If people believe that the central bank will not be swayed from its task of keeping inflation on target, either by public opinion or by political pressure, then people will come to expect low inflation.

In Chapter 21 we will look further at the importance of expectations, particularly inflationary expectations. We will also consider the process by which people's expectations are formed.

1. *If constant criticism of governments in the media makes people highly cynical about any government's ability to manage the economy, what effect will this have on the performance of the economy?*
2. *Suppose that, as part of the national curriculum, everyone in the country had to study economics up to the age of 16. Suppose also that the reporting of economic events by the media became more thorough (and interesting!). What effects would these developments have on the government's ability to manage the economy? How would your answer differ if you were a Keynesian from if you were a new classicist?*

Section summary

- Over the years there has been considerable debate among economists and politicians about how the market mechanism works at a macroeconomic level.
- The right has tended to argue (a) that prices and wages are relatively flexible, (b) that aggregate supply is determined independently of aggregate demand and (c) that people's price and wage expectations adjust rapidly to shifts in aggregate demand so as to wipe out any output effect.
- The centre and left to varying degrees have argued (a) that prices and wages are inflexible downwards, (b) that aggregate supply is relatively elastic when there is slack in the economy and (c) aggregate supply can be responsive to changes in aggregate demand in the longer term because of, for example, economic hysteresis or positive expectations of output and employment.

END OF CHAPTER QUESTIONS

- For what reasons might the long-run aggregate supply curve be (a) vertical; (b) upward sloping; (c) downward sloping?
- How would you attempt to assess whether a particular period of inflation was the result of cost-push or demand-pull pressures?
- Repeat the analysis undertaken in Figure 20.5 to consider the possible subsequent effects following a period of demand-pull deflation.
- What implications would a vertical short-run aggregate supply curve have for the effects of demand management policy?
- What would cause (a) a steep *DAD* curve; (b) a gently sloping *DAD* curve? Compare the short-run and long-run effects of (i) a temporary adverse supply shock and (ii) a permanent supply reduction under each of (a) and (b).
- Under what circumstances would a rightward shift in the *DAD* curve lead to a *permanent* increase in real national income?
- For what reasons may the natural level of unemployment increase?
- Assume that there is a positive technological shock. How would this impact on the equilibrium level of employment and the economy's potential output? Illustrate using diagrams of both the labour and goods markets.
- How might fluctuations in aggregate demand lead to changes in output even under the assumption of continuous market clearing?
- Given the Keynesian explanation for the persistence of high levels of unemployment after the recessions of the early 1980s and early 1990s, what policies would you advocate to reduce unemployment in the years following a recession?

The <i>EAPC</i> and <i>DAD/DAS</i> frameworks	661

In this chapter we turn to the relationship between inflation and unemployment. We examine a range of alternative perspectives. Once more we shall see that a crucial element here is the response of aggregate supply to a change in aggregate demand, in this case reflected in the shape of the Phillips curve. If aggregate supply responds to changes in aggregate demand, then a rise in aggregate demand should lead to a fall in unemployment, but will probably lead to a rise in inflation.

We shall see that the behaviour of markets and the formation of expectations are especially important in affecting the unemployment/inflation relationship, both in the short run and in the long run.

Around the world many central banks target inflation, often supplemented by other macroeconomic objectives. We look at how the analysis of the inflation/unemployment relationship has led many government to delegate monetary policy to their central banks. Finally, by integrating the Phillips curve framework with the *DAD/DAS* framework introduced in Chapter 20, we begin to consider how central banks can affect the adjustment paths of economies that face frequent economic shocks.

21.1 THE EAPC AND THE INFLATION-UNEMPLOYMENT RELATIONSHIP

The expectations-augmented Phillips curve (EAPC)

In Chapter 20 we discussed the interaction of aggregate demand and supply and the impact on output and prices from the frequent shocks that affect the economy. We saw how the adjustment process is affected, among other things, by the behaviour of product and labour markets and by expectations. In this section we look at the importance of inflationary expectations in affecting macroeconomic outcomes. To do so, we introduce an alternative way of looking at the macroeconomy: the *expectations-augmented Phillips curve (EAPC)*.

The EAPC was a major contribution to our understanding of the relationship between unemployment and inflation made by Milton Friedman (see Case Study 16.8 on the student website) and others in the late 1960s. They incorporated people's expectations about the future level of prices into the Phillips curve.

The original Phillips curve stems from the inverse relationship identified by Bill Phillips between wage inflation and unemployment for the UK from 1861 to 1957 (see Box 15.6). It appeared to offer a trade-off between inflation against unemployment. Lower unemployment could be bought at the cost of higher inflation, and vice versa, through changes in aggregate demand (relative to potential output).

Friedman argued that the theoretical trade-off implied by the simple Phillips curve relationship relied on permanent changes in the *real* wage. For the rate of unemployment to remain below its natural rate, i.e. the equilibrium rate, workers would need to supply labour at below the equilibrium real wage rate (e.g. W_e in Figure 20.10 on page 635). Friedman argued that this was implausible other than in the short term and that wage inflation would surely catch up with consumer price inflation to restore the real wage equilibrium.

Hence, Friedman believed that the theory underpinning the original Phillips curve relationship had failed to incorporate people's expectations of inflation.

In its simplest form, this expectations-augmented Phillips curve may be expressed as

$$\pi = f(1/U) + \pi^e + k \quad (1)$$

This states that the rate of price inflation (π) depends on three things.

- First, it is a function (f) of the inverse of unemployment ($1/U$). This is simply the original Phillips curve relationship. A rise in aggregate demand will lead to a fall in unemployment (a rise in $1/U$) and a rise in inflation: e.g. a movement from point a to point b in Figure 21.1.
- Second, the expected rate of inflation π^e must be added to the inflation that would result simply from the level of excess demand represented by $(1/U)$.

- Third, if there are any exogenous cost pressures on inflation (k) (such as increases in international commodity prices), this must be added too.

Thus if people expected a 3 per cent inflation rate ($\pi^e = 3\%$) and if excess demand were causing demand-pull inflation of 2 per cent ($f(1/U) = 2\%$) and exogenous increases in costs were adding another 1 per cent to inflation ($k = 1\%$), actual inflation would be $3 + 2 + 1 = 6$ per cent.

By augmenting the Phillips curve with expectations, we move from a single curve to a family of Phillips curves. The vertical position of each curve is determined by inflationary expectations (π^e) and any exogenous costs pressures (k). If we assume that on average $k = 0$, then we can simplify the EAPC framework so that each expectations-augmented Phillips curve is associated with a particular rate of inflationary expectations.

In Figure 21.1, points a and c both represent a hypothetical economy with unemployment at its natural rate, U_n . However, in the case of point a it is assumed that people's inflationary expectations are π_1 , while at point c they are π_2 . If we start at point a and aggregate demand expands so that, in the short run, inflation rises and unemployment falls but expected inflation stays at π_1 , there will be a movement up along curve $EAPC_1$ to, say, point b . But this is not the end of the story; inflationary expectations will adjust. Once they do, the EAPC will shift upwards to $EAPC_2$. Unless there is a further rise in aggregate demand, the original rise in aggregate demand will simply

Definition

Expectations-augmented Phillips curve A (short-run) Phillips curve whose position depends on the expected rate of inflation.

Figure 21.1 More than one EAPC

result in higher inflation and the economy moves to point c , with unemployment rising back to the natural rate, U_n .

But by what process do people form their inflationary expectations? We can identify two principal forms of expectations: adaptive and rational expectations. We examine each in turn. We will see that the response of inflation and unemployment to a rise in aggregate demand differs according to how expectations are formed.

Assume the economy is represented by EAPC₁ in Figure 21.1. Illustrate the effects of positive and negative inflation shocks on the curve.

Adaptive expectations

If we assume that people base their expectations of inflation on past inflation rates, then they form what are called **adaptive expectations**. If, for example, last year people underpredicted the rate of inflation, then this year they will adapt by revising their expectations of inflation upwards.

The simplest form of adaptive expectations is to assume that people use last year's actual inflation rate (π_{t-1}) as their prediction for the expected rate of inflation this year (π_t^e):

$$\pi_t^e = \pi_{t-1}$$

Box 21.1 considers more sophisticated versions of adaptive expectations.

Rational expectations

The adaptive expectations hypothesis, it is argued, suffers from a serious flaw: it assumes that people base their expectations on the past. So if inflation is on an upward trend, the future of inflation will always be underestimated. Similarly, inflation will always be overestimated if it is on a downward trend. Thus people will normally be wrong.

But people will soon realise that it is not rational to base their expectations blindly on the past. They will look at the *current* situation and what is likely to affect inflation. Thus, it is argued, adaptive expectations cannot be a rational basis of behaviour.

Rational expectations are not based on past rates of inflation. Instead they are based on the current state of the economy and the current policies being pursued by the government. Workers and firms look at the information available to them – at the various forecasts that are published, at various economic indicators and the assessments of them by various commentators, at government pronouncements, and so on. From this information they predict the rate of inflation as well as they can. It is in this sense that the expectations are 'rational': people use their reason to assess the future on the basis of current information.

But forecasters frequently get it wrong, and so do economic commentators! And the government does not always do what it says it will. Thus workers and firms base their expectations on *imperfect information*. Other versions assume that they may make very poor use of information. But either way, people frequently forecast incorrectly. The crucial point about the rational expectations theory, however, is that these errors in prediction are *random*. People's predictions of inflation are just as likely to be too high as too low.¹

p129

Definition

Adaptive expectations Where people adjust their expectations of inflation in the light of what has happened to inflation in the past.

* BOX 21.1 BASING EXPECTATIONS ON THE PAST

EXPLORING
ECONOMICS

More sophisticated adaptive expectations models

More complex adaptive expectations models assume that π_t^e is a weighted average of past rates of inflation:

$$\pi_t^e = a\pi_{t-1} + b\pi_{t-2} + c\pi_{t-3} \dots + m\pi_{t-n} \quad (1)$$

where $a + b + c \dots + m = 1$, and where $a > b > c$, etc.

In other words, people will base their expectations of inflation on the actual inflation rates over the last few time periods (e.g. months, quarters or years), but with the last

period's inflation having a bigger influence on people's expectations than the previous period's and so on.

In times of rapidly *accelerating* inflation, people may adjust their expectations of inflation upward by the amount that inflation *rose* last period ($\Delta\pi_{t-1}$). This gives:

$$\Delta\pi_t^e = \Delta\pi_{t-1} \quad (2)$$

Under what circumstances will term a in equation (1) be large relative to terms b , c etc.?

¹ The rational expectations hypothesis can be stated as:

$$\pi_t = \pi_{t-1} + \left(\sum_{i=0}^{\infty} \alpha^i e_{t-i}\right) \quad (\alpha = 0)$$

In other words, the rate of inflation for any time period (π_t) will be the rate that people expected in that time period (π_{t-1}) plus an error term (e_t). This error term may be quite large but is equally likely to be positive or negative. Thus when you sum (\sum) the error terms over the years (strictly speaking, to infinity), the positive and negative values will cancel each other out and the sum will therefore be zero.

Short-run and long-run perspectives

As we saw in Chapter 16, Friedman and other monetarists argued that there exists a long-run Phillips curve (*LRPC*) which is vertical at the natural (equilibrium) rate of unemployment. Only in the *short run* would higher aggregate demand reduce the unemployment rate below the natural rate (and raise output above its potential level). In the long run there would be no *real* increase in aggregate demand.

The idea that unemployment will return to its natural rate (and output to its potential level) following fluctuations in aggregate demand is commonly referred to as the **natural rate hypothesis**. Although initially associated with monetarists, the hypothesis has become more widely incorporated into macroeconomic models.

However, not all economists accept that the natural rate of unemployment is unaffected by fluctuations in aggregate demand. As discussed in section 20.5, Keynesian economists, for example, have developed theories exploring how changes in aggregate demand can have effects on physical and human capital. These effects, they argue, can result in a non-vertical *LRPC* (and *LRAS* curve).

In understanding the long-run relationship between inflation and unemployment, it is important to analyse the adjustment of economies to economic shocks. Short-run adjustments to fluctuations in aggregate demand involve movements along expectation-augmented Phillips curves. Hence, the *EAPC* provides us with a framework to analyse the implications for inflation and the labour market from the frequent fluctuations in aggregate demand.

The way in which people form expectations is an important factor in determining how economies adjust to shocks. We have already seen that people may form adaptive or rational expectations. This is the case for their expectations of inflation and also other macroeconomic variables, such as output.

Another important factor affecting the adjustment processes of economies is the speed with which markets clear

through the adjustment of prices to equate demand and supply.

Market clearing

In models which assume market clearing, prices are deemed to be flexible and so adjust to bring about equilibrium between demand and supply. In the labour market, for example, wages are not sticky downwards, at least not in the long run. There can be no long-run disequilibrium unemployment: no long-run deficiency of demand.

However, within the modern fusion of macroeconomic ideas (see section 16.6 and Box 20.4) models vary according to the speed with which markets are assumed to adjust. The more rapid is the process of market clearing the more quickly unemployment will, other things being equal, adjust to its natural rate.

The assumption made by new classical economists (see section 16.4) is that of *continuous* market clearing. This means that markets experience a very rapid adjustment of prices resulting in them clearing continuously. On the other hand, New Keynesian economists (see section 16.5) argue that there are frictions which impede and slow the adjustment of markets to economic shocks.

We now consider the effect of a range of views about both expectations and the degree of market clearing on the inflation/unemployment trade-off. We begin in section 21.2 with original monetarist thinking which combines adaptive expectations of inflation with the assumption that markets are relatively flexible.

Definition

Natural rate hypothesis The theory that, following fluctuations in aggregate demand, unemployment will return to a natural rate. This rate is determined by supply-side factors, such as labour mobility.

Section summary

1. A refinement of the simple Phillips curve involves the incorporation of people's expectations about the rate of inflation. This gives an expectations-augmented Phillips curve.
2. One explanation of how people form these expectations is given by the adaptive expectations hypothesis. In its simplest form, the hypothesis states that the expected rate of inflation this year is what it actually was last year: $\pi_t^e = \pi_{t-1}$.
3. An alternative process by which expectations are formed is known as rational expectations. This assumes that people base their expectations of inflation on a rational assessment of the current situation. People may predict wrongly, but they are equally likely to underpredict or to overpredict. On average, over the years, it is assumed that they will predict correctly.
4. Those who support the natural rate hypothesis argue that fluctuations in aggregate demand have no long-term effect on unemployment, which will adjust to its natural rate. Hence, the economy is characterised by an *LRPC* which is vertical at the natural rate of unemployment. The natural rate is determined by supply-side factors.
5. Though the natural rate hypothesis has become increasingly accepted by economists other than just monetarists, it is not universally accepted. The *EAPC* provides a framework to study the adjustment of economies to shocks and their longer-term impact on the inflation–unemployment relationship.
6. The formation of expectations and the flexibility of markets are two important factors in determining the long-term inflation–unemployment relationship.

21.2

INFLATION AND UNEMPLOYMENT: THE MONETARIST PERSPECTIVE

The short-run trade-off

As we have seen in the previous section, monetarists argued that the natural rate of unemployment is determined independently of aggregate demand. Consequently, the long-run Phillips curve is vertical. In the long run it is supply-side policies that affect levels of structural and frictional unemployment. However, in the short run unemployment may deviate from its natural rate. To understand why, we develop a simple model of the economy.

The model is based on two key assumptions. First, prices adjust relatively quickly to ensure equilibrium between demand and supply in goods and labour markets. Second, people form adaptive expectations of inflation.

To make the analysis more straightforward, we assume that they use last year's actual inflation rate year (π_{t-1}) as their prediction for the expected rate of inflation this year (π_t^e):

$$\pi_t^e = \pi_{t-1} \quad (2)$$

Also we assume that the economy's inflation rate last year was zero, no inflation is expected and there are no exogenous cost pressures on inflation ($k = 0$ in equation (1) on page 646).

In Figure 21.2 the economy is initially at point *a* with both actual and expected inflation of zero. The goods and labour markets are in equilibrium: $AD = AS$ and unemployment is at its natural rate, U_n .

Increase in aggregate demand. Assume that there is an increase in real aggregate demand. The economy moves to, say, point *b* along the expectations-augmented Phillips curve, $EAPC_0$. The rate of inflation rises from zero to π_1 .

But, with people still expecting zero inflation, the labour market sees a fall in the average real wage rate, leading to a rise in the demand for labour. Assuming that workers are fooled into supplying the additional labour despite the fall in real wages, unemployment falls below its natural rate to U_1 .

If we now move ahead a year, people will have revised their expectations of inflation upwards to π_1 . The result is that the Phillips curve has shifted up vertically by π_1 to $EAPC_1$. If *nominal* aggregate demand (i.e. demand purely in monetary terms, irrespective of the level of prices) continues to rise at the same rate, the whole of the increase will now be absorbed in higher prices. *Real* aggregate demand will fall back to its previous level and the economy will move to point *c* on the long-run Phillips curve. Unemployment will return to its natural rate, U_n , consistent with the natural rate hypothesis. There is no *demand-pull* inflation now ($f(1/U) = 0$), but inflation is π_1 per cent due to inflationary expectations.

Decrease in aggregate demand. Assume that the economy is at point *c* in Figure 21.2. It now experiences a decrease in the growth of nominal demand. Real aggregate demand falls. Let us assume that there is downward pressure on inflation such that the inflation rate falls to zero. The economy moves down $EAPC_1$ to point *d*. In the labour market the expected average real wage rate increases because the expected inflation rate is π_1 . The demand for labour falls and unemployment rises above its natural rate, U_n to U_2 .

The following year the expected rate of inflation will fall to zero. The $EAPC$ moves vertically down to $EAPC_0$. If the growth in nominal aggregate demand remains at its new lower rate, with inflation now at zero, the economy will again be at point *a* on the long-run Phillips curve. Unemployment is again at its natural rate.

Figure 21.2 $EAPC$ and the natural rate hypothesis

The accelerationist hypothesis

The preceding analysis helps to show that when people form adaptive expectations of inflation, unemployment can deviate from its natural rate following changes in aggregate demand even if markets clear fairly quickly. This raises the theoretical possibility that governments could keep unemployment below the natural rate. But this would come at a cost, since to do so it must raise nominal aggregate demand at ever-increasing rates.

Each time government is able to raise the nominal growth in aggregate demand there is a transitory period when real aggregate demand rises too. But inflationary expectations then rise to reflect higher inflation rates. This is mirrored in the labour market by real wages being driven

back up to their equilibrium level. Hence, for the government to keep unemployment below its natural rate it needs to keep raising the growth in nominal aggregate demand – in other words, it must increase nominal aggregate demand faster and faster. This, of course, means that nominal aggregate demand needs to grow at more than the rate of inflation. However, the rate of inflation is itself getting progressively higher as people are continually raising their inflationary expectations.

The theory that unemployment can be reduced below the natural rate only at the cost of accelerating inflation is known as the **accelerationist hypothesis**. Box 21.2 considers a numerical example of the hypothesis.

Stagflation and Phillips loops

In the 1970s, many countries experienced ‘stagflation’ – a simultaneous rise in unemployment and inflation. Monetarists used the adaptive expectations model to explain why this occurred. The explanation involved clockwise Phillips loops and rightward shifts in the long-run Phillips curve.

Clockwise Phillips loops

Consider a 10-year cycle. This is illustrated in Figure 21.3. The economy starts at position *a* in year 0. There is no inflation and the economy is at the natural rate of unemployment. The government pursues an expansionary policy over the next three years in order to reduce unemployment. The economy moves up through points *b*, *c* and *d*.

The government then starts worrying about inflation. It allows unemployment to rise somewhat, but as it is still below U_n there is still demand-pull inflation. The economy moves to point *e*. The government now allows unemployment to rise to U_n , but the Phillips curve still shifts up as expectations catch up with last year’s inflation. The economy moves from point *e* to point *f*.

Thereafter the government allows unemployment to rise further, and the economy eventually returns to point *a*, via points *g*, *h*, *i* and *j*. The economy has thus moved through a clockwise loop.

Stagflation is easy to see. From points *d* to *f*, both unemployment *and* inflation are rising. What is more, several points are to the ‘north-east’ of other earlier points. For example, point *g* is north-east of point *c*. In other words, inflation *and* unemployment in year 6 (point *g*) are higher than in year 2 (point *c*).

Under what circumstances would a Phillips loop be (a) tall and thin; (b) short and wide?

Rightward shifts in the long-run Phillips curve

If frictional or structural unemployment rises (due, say, to increased unemployment benefits), U_n will increase. The long-run Phillips curve will shift to the right.

Assume that the economy was initially on the long-run Phillips curve with $U_n = 8$ per cent and a stable inflation rate of 5 per cent. U_n now rises to 12 per cent. The government uses demand-management policy to keep the rise in unemployment to only 10 per cent. But this is now *below* U_n and thus inflation will increase. Thus both inflation *and* unemployment have risen.

Phillips loops and the political business cycle

The monetarist adaptive expectations model can also be applied to illustrate how the path of unemployment and inflation can follow a cycle mirroring the election cycle. In other words, policy makers may attempt to engineer a path for the macroeconomy that increases its probability of election. This path is known as the **political business cycle**.

The theory suggests that the discretionary policy choices of government can purposefully destabilise the economy. Therefore, it is argued, governments should be made to adopt policy rules.

Imagine that a politically naïve government has been fulfilling election promises to reduce unemployment, cut taxes and increase welfare spending. In Figure 21.3 this is shown by a move from points *a* to *b* to *c*. However, by the time the next election comes, inflation is accelerating and unemployment is rising again. The economy is moving from point *d* to *e* to *f*. This is unlikely to be a successful strategy for a vote-maximising government.

What the political business cycle model suggests is that at the start of their electoral terms, governments will engineer a recession and begin to squeeze down inflationary expectations. Assuming the economy is already at point *f* as a result of previous political business cycles, it will look to move the economy from point *f* to *g* to *h*.

But people are assumed to have short memories. Therefore, the government looks to engineer a pre-election boom and be rewarded for its economic management over the latter part of the election period. Unemployment falls, but inflation continues falling because of expectations adjusting downwards. The economy moves from point *h* to *i* to *j* to *a*.

How would the political business cycle be affected if governments were able to choose when to hold elections?

Definitions

Accelerationist hypothesis The theory that unemployment can be reduced below the natural rate only at the cost of accelerating inflation.

Political business cycle The theory that governments, after being elected, will engineer an economic contraction, designed to squeeze out inflation. They will then later engineer a pre-election boom to appeal to the electorate.

BOX 21.2 THE ACCELERATIONIST HYPOTHESIS

EXPLORING
ECONOMICS

The race to outpace inflationary expectations

Let us trace the course of inflation and expectations over a number of years in an imaginary economy. To keep the analysis simple, assume there is no growth in the economy and no exogenous cost pressures on inflation ($k = 0$ in equation (1) on page 646).

Year 1. Assume that at the outset, in year 1, there is no inflation of any sort; that none is expected; that $AD = AS$; and that equilibrium unemployment is 8 per cent. The economy is at point *a* in the diagram.

Year 2. Now assume that the government expands aggregate demand in order to reduce unemployment. Unemployment falls to 6 per cent. The economy moves to point *b* along $EAPC_1$. Inflation has risen to 4 per cent, but people, basing their expectations of inflation on year 1, still expect zero inflation. There is therefore no shift as yet in the Phillips curve. $EAPC_1$ corresponds to an expected rate of inflation of zero. (See Case Study 21.1 on the student website for an explanation of why the short-run Phillips curve slopes downwards.)

Year 3. People now revise their expectations of inflation to the level of year 2. The Phillips curve shifts up by 4 percentage points to $EAPC_2$. If nominal aggregate demand (i.e. demand purely in monetary terms, irrespective of the level of prices) continues to rise at the same rate, the whole of the increase will now be absorbed in higher prices. Real aggregate demand will fall back to its previous level and the economy will move to point *c*. Unemployment will return to 8 per cent. There is no demand-pull inflation now ($f(1/U) = 0$), but inflation is still 4 per cent due to expectations ($\pi^e = 4$ per cent).

Year 4. Assume now that the government expands real aggregate demand again so as to reduce unemployment once more to 6 per cent. This time it must expand nominal aggregate demand by more than it did in year 2, because this time, as well as reducing unemployment, it also has to validate the 4 per cent expected inflation. The economy moves to point *d* along $EAPC_2$. Inflation is now 8 per cent.

Year 5. Expected inflation is now 8 per cent (the level of actual inflation in year 4). The Phillips curve shifts up to $EAPC_3$. If at the same time the government tries to keep unemployment at 6 per cent, it must expand nominal aggregate demand 4 per cent faster in order to validate the 8 per cent expected inflation. The economy moves to point *e* along $EAPC_3$. Inflation is now 12 per cent.

Year 6 onwards. To keep unemployment at 6 per cent, the government must continue to increase nominal aggregate demand by 4 per cent more than the previous year. As the expected inflation rate goes on rising, the Phillips curve will go on shifting up each year.

Construct a table like the one in the diagram, only this time assume that the government wishes to reduce unemployment to 5 per cent. Assume that every year from year 1 onwards the government is prepared to expand aggregate demand by whatever it takes to do this. If this expansion of demand gives $f(1/U) = 7$ per cent, fill in the table for the first six years. Do you think that after a couple of years people might begin to base their expectations differently?

The accelerationist theory of inflation

Figure 21.3 Clockwise Phillips loops

Policy implications

The implications of the monetarist application of the expectations-augmented Phillips curve are that monetary

or fiscal policy can have no *long-run* effect on unemployment. They can only be used to influence the inflation rate.

Ultimately, monetary and fiscal policies merely move the economy up or down the vertical long-run Phillips curve. An expansionary policy, for example, could only ever bring a *temporary* reduction in unemployment below U_n . Moreover, demand-side policy can be destabilising, especially if used by governments to court electoral popularity.

To reduce unemployment permanently, *supply-side* policies should be used. These could either be market-orientated policies of removing impediments to the working of the market (see section 23.5) or interventionist policies, such as improving education and training or the country's transport and communications infrastructure (see section 23.6). By reducing frictional and/or structural unemployment, such policies will shift the long-run Phillips curve back to the left.

Section summary

1. The monetarist model assumes that markets are relatively flexible. But the assumption of adaptive expectations allows unemployment to deviate from the natural rate in the short term. People can be fooled, allowing unemployment and output to fluctuate.
2. If there is excess demand in the economy, producing upward pressure on wages and prices, initially unemployment will fall. The reason is that workers and firms will believe that wage and price increases represent *real* wage and price increases respectively. Thus workers are prepared to take jobs more readily and firms choose to produce more. But as people's expectations adapt upwards to these higher wages and prices, so

ever-increasing rises in nominal aggregate demand will be necessary to maintain unemployment below the natural rate. Price and wage rises will accelerate: i.e. inflation will rise.

3. The long-run Phillips curve, according to this analysis, is thus vertical at the natural rate of unemployment.
4. Stagflation can be explained in this model either by a movement from 9 o'clock to 12 o'clock round a clockwise Phillips loop, or by a rightward shift in the vertical Phillips curve combined with a mild expansionary policy.
5. The model also illustrates how governments can benefit electorally by generating a political business cycle.

21.3 INFLATION AND UNEMPLOYMENT: THE NEW CLASSICAL POSITION

New classical assumptions

Economists of the *new classical school* (see section 16.4) go further than the traditional monetarist theory described above. They argue that unless there are unexpected or 'surprise' events, there is no short-run trade-off between inflation and unemployment. The *EAPC* therefore represents a short-run trade-off between inflation and unemployment only in the presence of surprise events. It mirrors the *SRAS* curve which, as we saw in section 20.4, some refer to as the 'surprise aggregate supply curve'.

The argument that there is normally *no* trade-off between unemployment and inflation, even in the short run, is based on two key assumptions:

- Prices and wages are flexible so that markets clear continuously.
- Expectations are 'rational', but are based on imperfect information.

Continuous market clearing. The new classical position is that markets clearly continuously. This is likely, they argue, in modern economies with flexible labour markets (see Box 10.8 on pages 296–7) and facing global competition. There is thus no disequilibrium unemployment, even in the short run. All unemployment, therefore, is *equilibrium* unemployment, or 'voluntary unemployment' as new classical economists tend to call it. Increases in unemployment are therefore due to an increase in the natural level of

TC 5
p50

unemployment, as people choose not to take jobs because of a lack of incentives to do so.

Rational expectations. The monetarist analysis of the previous section was based on *adaptive* expectations. New classical analysis, by contrast, is based on *rational* expectations. As we saw above, these are assumed to diverge only randomly from the actual rate of inflation. On average they are assumed to be correct.

K3 30
p20

Anticipated fluctuations in aggregate demand

If markets continuously clear and if people are correct in their expectations, then fluctuations in aggregate demand will have no impact on unemployment either in the short run or long run. The only effect is on the rate of inflation.

In the new classical (rational expectations) model, unlike the adaptive expectations model, there is *no* lag in expectations. If their information is correct, people will rationally predict that output and employment will stay at the natural level. They predict that any change in *nominal* aggregate demand will be reflected purely in terms of changes in prices,

and that real aggregate demand will remain the same. If real aggregate demand remains the same, so will the demand for and supply of labour and the demand for and supply of goods. Thus, even in the *short run*, output and employment will stay at the natural level.

TC 13
p453

Is the assumption of rational expectations on its own sufficient for anticipated demand shocks to have no impact on economic activity even in the short run?

We can use Figure 21.4 to illustrate the adjustment of the economy under continuous market clearing, rational expectations and anticipated demand shocks. Assume that the economy is at point *a* with unemployment at its natural rate, U_n , and an actual and expected inflation rate of zero. Now assume that government increases aggregate demand. With rational expectations and no surprises, people fully anticipate that the inflation rate will rise to π_1 . $EAPC_0$, which is based on expectations of zero inflation, cannot be moved along. The moment that aggregate demand rises people correctly anticipate an inflation rate of π_1 . Thus the whole $EAPC$ moves vertically upwards to $EAPC_1$. As a result, the economy moves *directly* from point *a* to point *c*.

BOX 21.3

THE RATIONAL EXPECTATIONS REVOLUTION

EXPLORING
ECONOMICS

Trying to 'unfool' the economics profession

The rational expectations revolution swept through the economics profession in the 1970s in a way that no other set of ideas had done since Keynes. Although largely associated with the free-market, non-interventionist wing of economics, the rational expectations revolution has been far more wide-reaching. Even economists implacably opposed to the free market nevertheless incorporated rational expectations into their models. Hence, rational expectations became part of the mainstream consensus that emerged up to the financial crisis of the late 2000s (see section 16.6).

The rational expectations revolution is founded on a very simple idea. People base their expectations of the future on the information they have available. They don't just look at the past, they also look at current information, including what the government is saying and doing and what various commentators have to say.

The new classical economists use rational expectations in the following context. If the *long-run* Phillips curve is vertical, so that an expansionary policy will in the end merely lead to inflation, it will be difficult for the government to fool people that this will not happen. If employers, unions, city financiers, economic advisers, journalists, etc., all expect this to happen, then it will: and it will happen in the *short run*. Why should firms produce more in response to a rise in demand if their costs are going to rise by just as much? Why should higher wages attract workers to move jobs, if wages everywhere are going up? Why should firms and unions not seek price and wage rises fully in line with the expected inflation?

But can the government not surprise people? The point here is that 'surprising' people really only means 'fooling' them – making them believe that an expansionary policy really *will* reduce unemployment. But why should the public be fooled? Why should people believe smooth-talking government ministers rather than the whole host of critics of the government, from the opposition, to economic commentators, to the next-door neighbour?

The rational expectations school revised the old saying 'You can't fool all the people all the time' to 'You can hardly fool the people at all'. And if that is so, argue the new classical economists, unemployment can only momentarily be brought below its natural level.

Two of the most famous rational expectations economists are Robert Lucas and Thomas Sargent. Robert Lucas, like Milton Friedman and many other famous conservative economists, has his academic base in the University of Chicago, where he has been a professor since 1974. In 1995, like Milton Friedman in 1976, Lucas was awarded the Nobel prize in economics. Tom Sargent is Professor of Economics at New York University and senior fellow at the Hoover Institution of Stanford University. He was Professor of Economics at Chicago in the 1990s.

In recent years, rational expectations have been incorporated into models characterised by market imperfections and frictions, such as those developed by new Keynesians (see section 16.5). In this context, government policy *can* be effective. For example, supply-side policies can be directed to removing market distortions.

Figure 21.4 Anticipated and unanticipated changes in aggregate demand

Surprise fluctuations in aggregate demand

Although over time people's expectations are assumed to be correct on average, it is more than likely that in any one period they will be wrong. Economic shocks, which for instance lead to unexpected changes in aggregate demand, mean that households and businesses are subject to 'surprises' (see section 16.5).

To illustrate the economic effects of unexpected fluctuations in aggregate demand, assume again that the economy is point *a* in Figure 21.4 above. The government now increases aggregate demand, but the size of the increase is unexpected. Prices and wages thus also rise more than people expect.

Consider first the potential impact in the labour market. If workers believe that they are getting a higher *real* wage

BOX 21.4 FORECASTING THE WEATHER

CASE STUDIES AND APPLICATIONS

An example of rational expectations

'What's the weather going to be like tomorrow?' If you are thinking of having a picnic, you will want to know the answer before deciding.

So what do you do? You could base your assessment on past information. Yesterday was fine; so was the previous day. Today is glorious. So, you think to yourself, it's a good bet that tomorrow will be fine too. If, on the other hand, the weather has been very changeable recently, you may feel that it's wiser not to take the risk. These 'forecasts' are examples of *adaptive* expectations: your forecasts are based on the actual weather over the past few days.

But would you really base such a crucial decision as to whether or not to have a picnic on something so unreliable? Wouldn't you rather take on board more information to help you make up your mind?

The first thing that might come to mind is the old saying that a British summer is three fine days and a thunderstorm. We've just had the three fine days, you think to yourself, so perhaps we'd better stay at home tomorrow.

Or, being a bit more scientific about it, you look at the weather forecast. Seeing loads of sunshine symbols all over the map, you decide to take a chance.

Basing your expectations in this way on current information (including even seeing whether there is a red sky that night) is an example of *rational* expectations.

So you go on your picnic and, guess what, it rains! 'I bet if we had decided to stay at home, it would have been fine', you grumble, as you eat your soggy sandwiches.

What you are acknowledging is that your decision was made on *imperfect* information. But the decision was still rational. It was still the best decision you could have made on the information available to you.

Weather forecasters make mistakes. But they are probably just as likely to get it wrong in predicting a sunny day as in predicting a wet day. It is still rational to base your decisions on their forecasts provided they are reasonably accurate.

? *Under what circumstances might weather forecasters have a tendency to err on the side of pessimism or optimism? If you knew this tendency, how would this affect your decisions about picnics, hanging out the washing or watering the garden?*

Figure 21.5 Effects in the labour market of an underprediction of inflation

(W/P) than they really are, such that $(W/P)^e > W/P$, they will supply more labour. In Figure 21.5, the labour supply curve shifts from AS_1 to AS_2 . Employment rises above the natural level Q_1 (where expectations are correct), to Q_2 . If only labour (and not firms) had underpredicted the rate of inflation, this rise in employment to Q_2 would be the only short-run effect.

But with firms underpredicting the rate of inflation too, the effect on employment is more complicated. On the one hand, with a rise in prices firms will want to produce more; their demand for labour will, therefore, tend to increase. For example, it might shift to AD_2 in Figure 21.5, and thus employment would rise to Q_3 . On the other hand, given that they are underpredicting the rate of inflation, they will believe that any given level of money wages (W) represents a higher level of real wages $(W/P)^e$ than it really does (W/P) . They will tend, therefore, to employ fewer people at each wage rate, and the demand-for-labour curve will shift to the left. Thus, depending on which way the AD_1 curve shifts, firms could employ more or less labour than Q_2 .

The result of the surprise increase in aggregate demand is that workers or firms or both experience money illusion. This increases the employment of labour and output of goods. If we return to Figure 21.4, the surprise causes a move along an *EAPC*. If for simplicity we assume that the surprise occurred with people's expectations of inflation remaining at zero then the increase in demand would cause unemployment to fall below the natural rate, say to U_1 . Once the surprise becomes apparent then the *EAPC* shifts upwards, eventually reaching $EAPC_2$. If the growth of demand then remains at the same rate, long-run equilibrium is represented by point *c*.

BOX 21.5 THE BOY WHO CRIED 'WOLF'

CASE STUDIES AND APPLICATIONS

A government had better mean what it says

Do you remember the parable of the boy who cried 'Wolf!'?

There was once this little village on the edge of the forest. The villagers used to keep chickens, but when no one was around wolves would come out of the forest and carry off the chickens. So one of the boys in the village was given the job of keeping a lookout for wolves.

One day for a joke the boy called out 'Wolf, wolf! I see a wolf!' even though there was none. All the villagers came rushing out of their houses or back from the fields to catch the wolf. As you might expect, they were very angry to find that it was a false alarm.

The next day, thinking that this was great fun, the boy played the same trick again. Everyone came rushing out, and they were even more angry to find that they had been fooled again. But the boy just grinned.

The next day, when everyone was away in the fields, a wolf stalked into the village. The boy, spotting the animal, cried out 'Wolf, wolf! I see a wolf!' But the people in the fields said to each other 'We're not going to be fooled this time. We've had enough of his practical jokes.' And so they carried on working. Meanwhile, back in the village, the wolf was killing all the chickens.

You can probably guess what the villagers said when they returned in the evening to find just a large pile of feathers.

A government says 'We will take tough action to bring the rate of inflation down to 2 per cent.' Now of course this might be a 'joke' in the sense that the government doesn't really expect to succeed or even seriously to try, but is merely attempting to persuade unions to curb their wage demands. But if unions *believe* in both the government's intentions and its ability to succeed, the 'joke' may pay off. Some unions may well moderate their pay demands.

But some may not. What is more, the government may decide to give tax cuts to boost its popularity and stimulate growth, knowing that union pay demands are generally quite moderate. As a result, inflation soars.

But can the government get away with it a second or third time? It's like the boy who cried 'Wolf!' After a time, people will simply not believe the government. If they see the government boosting aggregate demand, they will say to themselves, 'Here comes inflation. We'd better demand higher wages to compensate.'

Does this parable support the adaptive or the rational expectations hypothesis?

What would the process of adjustment to the unanticipated size of the increase in aggregate demand look like if people had adjusted their inflationary expectation upwards from zero but to a rate less than π_1 ?

Policy implications

If the new classical 'surprise model' is correct, anticipated changes in aggregate demand will have no effect on output and employment. *Unanticipated* changes in aggregate demand will have some effect, but only for as long as it takes people to realise their mistake and for their wages and prices to be corrected. Given rational expectations, people can be fooled in this way only by luck. There is no way that a government can *systematically* use demand management policy to keep output and employment above the natural level.

The new classical economists therefore totally reject Keynesian demand management policy, even in the short run. Monetary policy should be used to control inflation, but neither fiscal nor monetary policy can be used systematically to increase output and employment. Similarly, there is no fear of a deflationary monetary policy reducing output and employment and leading to a recession. The reduction in

aggregate demand will simply lead to lower inflation. Output and unemployment will remain at the natural level.

Thus for new classicists, the problems of inflation and unemployment are totally separate. Inflation is caused by excessive growth in the money supply and should be controlled by monetary policy. Unemployment will be at the natural rate and should be reduced by supply-side policies designed to increase the incentives to work. In this respect, their views echo monetarist sentiments too.

To prevent unanticipated changes in aggregate demand and thus to prevent unemployment deviating from its natural level, new classical economists advocate the announcement of clear monetary rules and then sticking to them. The delegation of monetary policy to independent central banks with clear remits, such as inflation rate targets, can form part of this approach.

1. *If the government announced that it would, come what may, reduce the growth of money supply to zero next year, what (according to new classical economists) would happen? How might their answer be criticised?*
2. *For what reasons would a new classical economist support the policy of the Bank of England publishing its inflation forecasts and the minutes of the deliberations of the Monetary Policy Committee?*

Section summary

1. New classical theories assume continuous market clearing with flexible prices and wages in the short run as well as in the long run. It also assumes that people base their expectations of inflation on a rational assessment of the *current* situation.
2. People may predict wrongly, but they are equally likely to underpredict or to overpredict. On average, over the years, they will predict correctly.
3. The assumptions of continuous market clearing and rational expectations imply that only unexpected fluctuations in aggregate demand will cause unemployment to deviate from its natural rate. There can be no short-run trade-off between inflation and unemployment when changes in aggregate demand are anticipated.
4. If people correctly predict the rate of inflation, they will correctly predict that any increase in nominal aggregate demand will simply be reflected in higher prices. Total output and employment will remain the same: at the natural level.
5. If people underpredict the rate of inflation, they will believe that there has been a *real* increase in aggregate demand, and thus output and employment will increase. But they are just as likely to overpredict the rate of inflation, in which case they will believe that real aggregate demand has fallen. The result is that output and employment will fall.
6. When the government adopts fiscal and monetary policies, people will rationally predict their effects. Given that people's predictions are equally likely to err on either side, fiscal and monetary policies are useless as means of controlling output and employment.

21.4 INFLATION AND UNEMPLOYMENT: THE MODERN KEYNESIAN POSITION

Keynesians in the 1950s and early 1960s looked to aggregate demand to explain inflation and unemployment. Their approach was typically that of the inflationary/deflationary gap model (see pages 538–9). Although they recognised the

existence of some cost-push inflation and some equilibrium unemployment, these factors were seen as relatively constant. As a result, there was thought to be a relatively stable inverse relationship between inflation and unemployment,

as depicted by the Phillips curve. Governments could trade off inflation against unemployment by manipulating aggregate demand.

Modern developments of the Keynesian model

Keynesians still see aggregate demand as playing the crucial role in determining the rate of inflation and the levels of output and employment. They still argue that the free market works inefficiently: it frequently fails to clear; price signals are distorted by economic power; most wages and many prices are 'sticky'; and, most important, the free market is unlikely to settle at full employment.

They still argue, therefore, that it is vital for governments to intervene actively to prevent either a slump in demand or an overexpansion of demand.

Nevertheless, the Keynesian position has undergone some major modifications in recent years (see section 16.5). This has been in response to apparent shifts in the Phillips curve and the inability of the traditional Keynesian model to explain it.

The breakdown of the Phillips curve in the 1970s and the growing problem of 'stagflation' (see page 680) led many Keynesians to focus on cost-push causes of inflation. These causes included increased power and militancy of trade unions, a growing concentration of monopoly power in industry, and rising oil and other commodity prices. The effect was to push the short-run Phillips curve outwards.

Later, with a decline in industrial unrest in the 1990s and a growth of international competition keeping prices down, the Phillips curve apparently shifted inwards again. Keynesians attributed this partly to a *decline* in cost-push inflation. (These cost-push explanations are examined in Case Study 21.3 on the student website.)

More recently, Keynesian analysis has incorporated three major modifications:

- An increased importance attached to equilibrium unemployment.
- A rationale for the persistence of demand-deficient unemployment.
- The incorporation of the theory of expectations: either adaptive or rational.

Changes in equilibrium unemployment

Changes in structural unemployment

Most Keynesians include growth in equilibrium unemployment as part of the explanation of the apparent rightward shift in the Phillips curve in the 1970s and 1980s. As we noted in Chapter 16, rather than the natural rate, some Keynesians prefer to speak of the *non-accelerating-inflation rate of unemployment*, which is known more simply as the NAIRU. This acknowledges that there exist market imperfections. The NAIRU can be thought of as the rate of

unemployment that is consistent with steady inflation in the near term.

Keynesians highlight the considerable structural rigidities that existed in the economy in a period of rapid industrial change. The changes include the following:

- Dramatic changes in technology. The microchip revolution, for example, made many traditional jobs obsolete.
- Competition from abroad. The introduction of new products from abroad, often of superior quality to domestic goods, or produced at lower costs, had led to the decline of many older industries: e.g. the textile industry.
- Shifts in demand away from the products of older labour-intensive industries to new 'high-tech' capital-intensive products.

Keynesians argue that the free market simply could not cope with these changes without a large rise in structural/technological unemployment. Labour was not sufficiently mobile – either geographically or occupationally – to move to areas where there were labour shortages or into jobs where there were skill shortages. A particular problem here was the lack of investment in education and training, with the result that the labour force was not sufficiently flexible to respond to changes in demand for labour.

1. What effect did these developments have on (a) the Phillips curve; (b) the aggregate supply curve?
2. What policy implications follow from these arguments?

From the mid-1980s up to the financial crisis of the late 2000s, structural unemployment was thought to have fallen as labour markets become more flexible and as various government supply-side policies took effect (see Chapter 24).

Hysteresis

If a recession causes a rise in unemployment which is not then fully reversed when the economy recovers, there is a problem of hysteresis (see page 509). Recessions can lead to a growing number of people becoming both deskilled and demotivated. What is more, many firms, in an attempt to cut costs, cut down on training programmes. In these circumstances, a rise in aggregate demand would not simply enable the long-term unemployed to be employed again. The effect is a rightward shift in the Phillips curve: a rise in the NAIRU. To reverse this, argue Keynesians, the government should embark on a radical programme of retraining.

Recessions also cause a lack of investment. The reduction in their capital stock means that many firms cannot respond to a recovery in demand by making significant increases in output and taking on many more workers. Instead they are more likely to raise prices. Unemployment may thus fall only modestly and yet inflation may rise substantially. The NAIRU increases: the Phillips curve shifts to the right.

These arguments hold in reverse. A period of sustained growth can reduce the NAIRU: the Phillips curve shifts to the left.

? Are hysteresis effects likely to be asymmetrical (i.e. of different magnitude) following an economic boom rather than an economic slowdown?

The persistence of demand-deficient unemployment

Monetarists and new classical economists argue that markets, including the labour market, clear quickly, if not continuously. Keynesians point to frictions in the labour market which may prevent real wages from falling and helping to eliminate demand-deficient unemployment. Two major explanations for the persistence of real wage rates above equilibrium are efficiency wages and insider power. While we first came across these in Chapter 16 (see pages 506–509), we revisit them here in the context of the inflation–unemployment relationship.

- **Efficiency wages.** Wage rates work not only to balance the demand and supply of labour but also to motivate workers. If real wage rates are reduced when there is a surplus of labour (demand-deficient unemployment), then those workers already in employment may become dispirited and work less hard. If, on the other hand, firms keep wage rates up, then by maintaining a well-motivated workforce, by cutting down on labour turnover and by finding it easier to attract well-qualified labour, firms may find that their costs are reduced: a higher real wage rate is thus more profitable for them. The maximum-profit real wage rate (the *efficiency wage rate*: see pages 291) is likely to be above the market-clearing real wage rate. Demand-deficient unemployment is likely to persist.
- **Insider power.** If those still in employment (the insiders) are members of unions while those out of work (the outsiders) are not, or if the insiders have special skills or knowledge that give them bargaining power with employers while the outsiders have no influence, then there is no mechanism whereby the surplus labour – the outsiders – can drive down the real wage rate and eliminate the demand-deficient unemployment.

These two features help to explain why real wage rates did not fall during the recessions of the early 1980s and early 1990s. With the more flexible labour markets of more recent years, however, real wages did fall consistently in the period following the financial crisis (see Figure 15.13 on page 474). Over the period 2009–13, the annual rate of consumer price inflation typically exceeded annual earnings growth by 1.6 percentage points.

? How might the possibility of labour shirking affect the real wage firms are willing to pay?

The incorporation of expectations

Some Keynesians incorporate adaptive expectations into their models. Others incorporate rational expectations.

Either way, their models differ from monetarist and new classical models in two important respects:

- Prices and wages are not perfectly flexible. Markets are characterised by various frictions and imperfections.
- Expectations influence *output* and *employment* decisions, not just pricing decisions.

Price and wage rigidities are likely to be greater *downwards* than upwards. It is thus necessary to separate the analysis of a decrease in aggregate demand from that of an increase.

Expansion of aggregate demand

Unless the economy is at full employment or very close to it, Keynesians argue that an expansion of demand *will* lead to an increase in output and employment, even in the long run after expectations have fully adjusted.

In Figure 21.6, assume that the economy has a fairly high level of unemployment (U_1) but at the same time some cost inflation. Inflation is constant at π_1 , with expectations of inflation at π_1 also. The economy is at point *a*.

Now assume that the economy begins to recover. Aggregate demand rises. As there is plenty of slack in the economy, output can rise and unemployment fall. The economy moves to point *b* on short-run Phillips curve I. The rise in inflation will feed through into expectations. The short-run Phillips curve will shift upwards. With adaptive expectations, it will initially shift up, say, to curve II.

But will the short-run Phillips curve not go on shifting upwards as long as there is any upward pressure on inflation? Keynesians reject this argument for two reasons:

- If there is a gradual but sustained expansion of aggregate demand, firms, seeing the economy expanding and seeing their orders growing, will start to invest more and make longer-term plans for expanding their labour force. People will generally *expect* a higher level of output, and this optimism will cause that higher level of output to be produced. In other words, expectations will affect output

Figure 21.6 The Keynesian analysis of reflationary policies

and employment as well as prices. The Phillips curve will shift downwards to the left, offsetting (partially, wholly or more than wholly) the upward shift from higher inflationary expectations. The NAIRU has fallen.

- If U_1 includes a considerable number of long-term unemployed, then the expansion of demand may be *initially* inflationary, since many of the newly employed will require some retraining (a costly exercise). But as these newly employed workers become more productive, their lower labour costs may offset any further upward pressure on wages from the expansion of demand. At the same time, the higher investment may embody new, more productive, techniques that will also help to prevent further acceleration in costs. These factors occurred in the 1990s as the economy recovered from recession.

It is quite likely that these effects can prevent any further rises in inflation. Inflation can become stable at, say, π_2 , with the economy operating at point *c*. The short-run Phillips curve settles at position *Z*. There is thus a long-run downward-sloping Phillips curve passing through points *a* and *c*. What this analysis is assuming is that, in the medium to long run, the NAIRU itself is responsive to changes in real aggregate demand.

? *Would it in theory be possible for this long-run Phillips curve to be horizontal or even upward sloping over part of its length?*

If expectations are formed rationally rather than adaptively, there will merely be a quicker movement to this long-run equilibrium. If people rationally predict that the effect of government policy will be to move the economy to point *c*, then their predictions will bring this about. All rational expectations do is to bring the long run about much sooner! The theory of rational expectations on its own does not provide support specifically for either the new classical or the Keynesian position.

The lesson here for governments, however expectations are formed, is that a sustained, but moderate, increase in aggregate demand can lead to a sustained growth in aggregate supply. What should be avoided is an excessive and unsustainable expansion of aggregate demand, as occurred in the late 1980s in the UK and in the late 1990s in the USA. This will lead to a boom, only to be followed by a 'bust' and a consequent recession.

Contraction of aggregate demand

Many Keynesians argue that the short-run Phillips curve is kinked at the current level of real aggregate demand. A reduction in real aggregate demand will have only a slight effect on inflation, since real wages are sticky downwards. Unions may well prefer to negotiate a reduction in employment levels, preferably by natural wastage (i.e. not replacing people when they leave), rather than accept a reduction in real wages. Thus in Figure 21.7, to the right of point *a*, the short-run Phillips curve is very shallow.

Figure 21.7 The Keynesian analysis of deflationary policies

As long as this curve is not totally horizontal to the right of *a*, the introduction of expectations into the analysis will cause the short-run curve to shift downwards over time (if unemployment is kept above U_1) as people come to expect a lower rate of inflation.

With *adaptive* expectations, however, the curve could shift downwards very slowly indeed. If a movement from point *a* to point *d* represents only a 1 per cent reduction in inflation, and if it takes, say, two years for this to be fully reflected in expectations, then if unemployment is kept at U_2 , inflation will reduce (i.e. the curve shift downwards) by only 0.5 per cent a year. This may be totally unacceptable politically if inflation is already at very high levels, and if U_2 is also very high.

Even with *rational* expectations the response may be too slow. If there is a resistance from unions to receiving increases in wages below the current rate of inflation, or if they are attempting to 'catch up' with other workers, then even if they rationally predict the correct amount by which inflation will fall, inflation will fall only slowly. People will rationally predict the *resistance* to wage restraint, and sure enough, therefore, inflation will fall only slowly.

The worst scenario is when the government, in its attempt to eliminate inflation, keeps unemployment high for a number of years. As the core of long-term unemployed workers grows, an increasing number of workers become deskilled and therefore effectively unemployable. The effective labour supply is reduced, and firms find there is no longer a surplus of employable labour *despite* high unemployment. The NAIRU increases. A long-term equilibrium is reached at, say, point *e* with still substantial inflation. The *long-run* Phillips curve too may thus be relatively shallow to the right of point *a*.

? *Some economists argue that recessions generate unemployment 'scarring' (i.e. various negative outcomes for the people unemployed and possibly broader society too). What might these scarring effects be and what is likely to be their longer-term impact?*

As we saw earlier, the downward stickiness of wages was significantly less in the recession of 2008/9. This was partly because of a decline in union membership and power, partly because of a rise in part-time employment, the use of agency staff and the use of zero-hour contracts, and partly because of a willingness of people to accept lower wages rather than face the possibility of redundancy. This greater flexibility of labour markets gave a steeper Phillips curve to the right of point *a* than in previous recessions.

The Keynesian criticism of non-intervention

Keynesians are therefore highly critical of the new classical conclusion that governments should not intervene other than to restrain the growth of money supply. High unemployment may persist for many years and become deeply

entrenched in the economy if there is no deliberate government policy of creating a steady expansion of demand.

Countries in the eurozone, such as Greece, Portugal and Spain, which have had to seek bailouts because of their high levels of debt have found themselves in this position. A condition of being granted bailouts has been to reduce public-sector debt. This has ruled out Keynesian expansionary fiscal policy. The very high levels of unemployment in these countries, especially amongst the young (rates of over 50 per cent in Greece and Spain in the 15–24 age group), has resulted in a problem of entrenchment and hysteresis that will make reductions in unemployment slow and difficult to achieve.

Why is it important in the Keynesian analysis for there to be a steady expansion of demand?

Section summary

1. Modern Keynesians incorporate expectations into their analysis of inflation and unemployment. They also see an important role for cost-push factors and changes in equilibrium unemployment in explaining the position of the Phillips curve.
2. A growth in equilibrium unemployment in the 1970s and 1980s was caused by rapid changes in technology, greater competition from abroad and more rapid changes in demand patterns. It was also due to the persistence of unemployment beyond the recessions of the early 1980s and early 1990s and, to a lesser extent, the early 2010s, because of a deskilling of labour during the recessions (an example of hysteresis). The effect of increased equilibrium unemployment was to shift the Phillips curve to the right.
3. Demand-deficient unemployment may persist because real wage rates may be sticky downwards, even into the longer term. This stickiness may be the result of efficiency real wage rates being above market-clearing real wage rates and/or outsiders not being able to influence wage bargains struck between employers and insiders.
4. If expectations are incorporated into Keynesian analysis, the Phillips curve will become steeper in the long run (and steeper in the short run too in the case of rational expectations). It will not become vertical, however, since people will expect changes in aggregate demand to affect output and employment as well as prices.
5. If people expect a more rapid rise in aggregate demand to be sustained, firms will invest more, thereby reducing unemployment in the long run and not just increasing the rate of inflation. The NAIRU will fall. The long-run Phillips curve will be downward sloping.
6. The short- and long-run Phillips curves may be kinked. Reductions in real aggregate demand may have only a slight effect on inflation if real wage rates are sticky downwards.

21.5 INFLATION, UNEMPLOYMENT AND OUTPUT: CREDIBILITY AND CENTRAL BANKS

This chapter has examined alternative views on the relationships between unemployment and inflation. To do so we have used a Phillips curve framework. In this final section we examine these relationships in the modern context of central banks operating within targets.

We first look at why many governments have delegated the operation of monetary policy to central banks: i.e. giving them independence in setting interest rates and/or determining the money supply. Then we see how the Phillips curve and *DAD/DAS* frameworks can be used to analyse the determination of inflation, unemployment and output in

the context of central banks operating with an inflation target.

Credibility and the delegation of monetary policy

If the natural rate hypothesis holds then policy makers cannot use demand management policy to affect real GDP (output) or the rate of unemployment, except, perhaps, in the short run. Output must adjust to its potential level, and unemployment to its natural rate. Depending on the process by which people

form their inflationary expectations and the speed by which markets adjust to shocks, the movement of the goods and labour markets to equilibrium could be very rapid.

The increased interest among economists since the 1960s in the natural rate hypothesis has been one of the key reasons for governments delegating monetary policy to central banks, sometimes through legal statute. In the UK, for example, the Bank of England was given operational independence over monetary policy in 1997.

This delegation is usually for the making of policy decisions, such as setting interest rates or whether to engage in quantitative easing. Normally, governments still decide what the policy objective(s) of the central bank should be – whether it is to achieve a target rate of inflation set by the government, or to do this while being mindful of other objectives, such as economic growth and lower unemployment.

The case for delegating monetary policy was briefly presented in Chapter 16 (see page 511). As we saw there, the principal argument is that delegation will remove the inflation bias that can result from political interference in monetary policy. It is tempting for governments to boost aggregate demand and to try to reduce unemployment below the natural rate by the time of the next election. When governments behave in this way, it is likely to result in higher inflation – an *inflation bias*. We look at a model of inflation bias in Box 21.6.

combine the dynamic aggregate demand and supply (DAD/DAS) analysis, which we looked at in section 20.3, with the expectations-augmented Phillips curve (EAPC) analysis of this chapter. Figure 21.8 illustrates the two models.

Figure 21.8(b) shows DAD and DAS curves. The DAD curve explicitly incorporates an inflation target pursued by a delegated central bank (see page 631). As we shall see, the DAS curve turns out to be closely related to the EAPC.

Figure 21.8(a) shows the expectations-augmented Phillips curve. The downward-sloping short-run EAPC illustrates the short-run trade-off between unemployment and inflation. A rise in aggregate demand (e.g. from point *a* to point *b*) will result in a movement up along the curve: there will be lower unemployment but at the cost of higher inflation. Meanwhile, the dynamic short-run aggregate supply (DAS) curve, (see page 631), shows a *positive* relationship between output and inflation: a rise in aggregate demand will result in a movement up along the curve (e.g. from point *a'* to point *b'*). Thus the DAS curve is essentially an alternative representation of the EAPC. However, rather than the rate of unemployment, we plot real national income (*Y*) on the horizontal axis.

The slopes of both the DAS curve and the EAPC therefore capture the potential short-run trade-off between inflation

The EAPC and DAD/DAS frameworks

EAPC and DAS curves

To understand the relationship between inflation and unemployment, it is therefore important to do so within the context of delegated monetary policy. To do this, we

Inflation bias The tendency of governments to pursue excessively expansionary monetary policies for political reasons, resulting in higher inflation than if the central bank was charged with targeting inflation.

Figure 21.8 EAPC and DAD/DAS frameworks

* BOX 21.6 INFLATION BIAS

A new classical 'surprise' model

We can use the expectations-augmented Phillips curve (EAPC) framework and a new classical 'surprise' model to examine how excessive inflation arises. People are assumed to form rational expectations and markets clear rapidly.

The diagram shows various expectations-augmented Phillips curves (EAPC). We assume an absence of exogenous inflation shocks ($k = 0$) so that each EAPC reflects only differences in the expected inflation rate (π^e): the higher the expected rate, the vertically higher the EAPC.

The diagram also includes a series of government indifference curves. Each one depicts a particular level of satisfaction (or happiness) of the government. In this model, the government, not the central bank, has control of monetary policy. At any point along a particular indifference curve the government derives a given level of satisfaction from the various combinations of unemployment and inflation shown.

Note that, because higher rates of unemployment and inflation *reduce* satisfaction, the government's satisfaction is higher on those indifference curves that are closer to the

origin. For example, satisfaction is higher on I_1 than it is on I_2 , and so on. Note also that because we are measuring *undesirable* things on each axis, the curves slope differently from the traditional indifference curves which we examined in section 4.3: the ones here are bowed out, rather than bowed in.

How would the policy maker's indifference curves be affected by the extent of their aversion to inflation?

The incentive for the government to stimulate the economy

Assume that the economy is currently at point a with both the goods and labour markets in equilibrium. People's expectations of inflation are zero. Given this, the government's optimal inflation-unemployment choice is at point b , with lower unemployment of U_1 but inflation of π_1 . This is the highest level of government satisfaction that can be achieved along curve EAPC₁. The government's satisfaction is likely to be mirrored by the wider public it serves. Indeed, if

and economic activity. The latter is captured by unemployment in the case of the EAPC curve but by output (real national income) in the case of the DAS curve. Meanwhile, the vertical position of both curves is determined by inflationary expectations (π^e) and exogenous inflationary shocks (k). Higher inflationary expectations or negative inflationary shocks result in both curves moving vertically upwards. We shall return to Figure 21.8 below.

Okun's law

There exists a well-known relationship that captures the cyclical relationship between unemployment and output, known as *Okun's law*. The law is named after Arthur Okun

who in a 1962 paper investigated the relationship between unemployment and output in the USA. His work suggested that for every 1 percentage point that US unemployment was above its natural rate, US output would be 3 per cent below its potential output.

Definition

Okun's law The name given to the negative statistical relationship between the unemployment rate and deviations of output from potential output.

an election was to be held around this time its chances of electoral success are increased – people preferring lower unemployment (and higher output) and being prepared to put up with slightly higher inflation

To get to point *b*, the government needs to surprise the public by relaxing monetary policy, for example by providing greater liquidity to the financial system and so putting downward pressure on real interest rates (see section 19.1). The loosening of monetary policy then raises aggregate demand.

However, point *b* is not sustainable. People will revise their inflationary expectations upwards. Consequently, real aggregate demand will fall back to the economy's potential output level and unemployment will rise again to its natural rate. If nominal aggregate demand was to continue to grow at the new rate, the economy would settle at point *c*, with higher inflation (π_1) than before.

While the government can only temporarily increase its satisfaction by generating surprise inflation, it may, nonetheless, feel that this is worth doing, especially if it helps it to win an election.

The response of the public: the issue of the government's credibility

But of course the public knows that any gain is likely to be temporary. Workers, for instance, know that any temporary increase in economic activity would be followed a period where their real wages fall. Therefore, one possibility is that people keep their inflationary expectations sufficiently high that the government no longer benefits from generating further inflation and creating a surprise economic boom.

Consider point *d* in the diagram. Again, the economy is in equilibrium with unemployment at its natural rate. But, unlike the situation when the economy was at point *a*, the government no longer benefits from a surprise loosening of monetary policy. In simple terms, the now much higher inflation rate acts as a disincentive to government to generate surprise inflation. People would react badly to even higher inflation. The additional satisfaction to the

government, therefore, from moving to say point *e* and reducing unemployment is outweighed by the dissatisfaction generated by the higher inflation.

Point *d* is described as a 'consistent equilibrium'. The reason is that if the government says that it wants to target an inflation rate of π_2 , this will be a **time-consistent policy announcement**. This means that there is no incentive, once people have set their inflationary expectations, for the government to generate surprise inflation and conduct monetary policy inconsistent with validating this high inflation rate. An inflation announcement of π_2 is therefore **credible**. People believe that the government will stick to it.

By contrast, the government stating that it wants to target point *a*, with zero inflation, is a **time-inconsistent policy announcement**. Once people have set their inflationary expectations at zero, the government then has an incentive to generate surprise inflation. In other words, it conducts monetary policy which generates a positive inflation rate. A zero inflation rate announcement by the government thus lacks **credibility**: government has an incentive to renege on it. Credible policies, on the other hand, are ones that, once that they have been announced by policy makers, people believe will be carried through.

In the diagram, the credible inflation rate is π_2 . At any point on the *LRPC* with an inflation rate below π_2 (i.e. below point *d*) there is an incentive for government to create surprise inflation.

If π_2 is above the rate that could be seen as desirable for the efficient functioning of the economy (generally thought by central banks to be around 2 per cent: see table in Box 21.7), then the government could be said to exhibit **inflationary bias**. If, for example, π_2 were 5 per cent and the efficient rate of inflation were 2 per cent, the government would be exhibiting an inflationary bias of 3 per cent (i.e. 5% – 2%).

 How would inflation bias be affected if the government placed considerable importance on its future reputation for controlling inflation?

Since Okun's law shows a close relationship between unemployment and output, movements along either *EAPCs* or *DAS* curves capture cyclical volatility: a boom would be represented by a movement up both curves (e.g. from *a* to *b* in Figure 21.8(a) and from *a'* to *b'* in Figure 21.8(b)); a recession would be represented by a movement down both curves. Both curves can be used to analyse the business cycle and to debate the extent to which fluctuations in aggregate demand have enduring effects on economic activity.

 Why might changes in the unemployment rate not match one-for-one changes in the output gap?

Definitions

Time-consistent policy announcement A policy announcement where there is an incentive for the policy maker to stick to it over time.

Time-inconsistent policy announcement A policy announcement where there is an incentive for the policy maker to renege on it at a future date.

Credibility (of policies) Policies that people believe the government will carry out once they have been announced.

BOX 21.7 INFLATION TARGETING

EXPLORING
ECONOMICS

The fashion of the age

Many countries have turned to inflation targeting as their main macroeconomic policy. The table gives the targets for a selection of countries (as of 2017).

Part of the reason is the apparent failure of discretionary macroeconomic policies. Discretionary fiscal and monetary policies suffer from time lags, from being used for short-term political purposes and from failing to straighten out the business cycle. But if discretionary policies have seemed not to work, why choose an inflation target rather than a target for the money supply or the exchange rate?

Money supply targets were adopted by many countries in the 1980s, including the UK, and this policy too was largely a failure. Money supply targets proved very difficult to achieve. As we have seen, money supply depends on the amount of credit banks create, and this is not easy for the authorities to control. Then, even if money supply is controlled, this does not necessarily mean that aggregate demand will be controlled: the velocity of circulation may change. Nevertheless, many countries do still target the money supply, although in most cases it is not the main target.

Exchange rate targets, as we shall see in Chapter 25, may have serious disadvantages if the equilibrium exchange rate is not the one that is being targeted. The main instrument for keeping the exchange rate on target is the rate of interest. But, as we shall see in Box 22.9 (on page 701), if the rate of interest is being used to achieve an exchange rate target, it cannot be used for other purposes, such as controlling aggregate demand or inflation. Raising interest rates to achieve an exchange rate target may lead to a recession.

Inflation targets have proved relatively easy to achieve. There may be problems at first, if the actual rate of inflation is way above the target level. The high rates of interest necessary to bring inflation down may cause a recession. But once inflation has been brought down and the objective is then simply to maintain it at the target level, most countries have been relatively successful. And the more successful they are, the more people will expect this success to be

maintained, which in turn will help to ensure this success.

So, have there been any problems with inflation targeting? Ironically, one of the main problems lay in its success. With worldwide inflation having fallen, and with global trade and competition helping to keep prices down, there was now less of a link between inflation and the business cycle. Booms no longer seemed to generate the inflation they once did. Gearing interest rate policy to maintaining low inflation could still see economies experiencing unsustainable booms, followed by recessions. Inflation may be controlled, but the business cycle may not be.

Some argue that the low interest rates seen in many countries during the first half of the 2000s helped to fuel unsustainable flows of lending. These boosted asset prices, including housing, which generated even higher levels of confidence among borrowers and lenders alike. However, by encouraging further investments that increasingly stretched the financial well-being of economic agents, the point was reached when a significant retrenchment by banks, business and people became inevitable.

Then there is the periodic problem of rising world inflation resulting from rapidly developing economies, such as China, India and Brazil. The resulting rise in food and commodity prices pushes up inflation rates around the world. Too strict an adherence to an inflation target could see higher interest rates and slow economic growth. This was a problem in many countries just after the financial crisis in 2010–12. Several countries, including the UK, had only just emerged from recession and their governments were embarking on a significant fiscal consolidation. Central banks faced a conundrum with the macroeconomic environment characterised on the one hand by increasing inflationary pressures but on the other by often sizeable negative output gaps. In fact, most central banks were to keep interest rates at historic lows.

Why may there be problems in targeting (a) both inflation and money supply; (b) both inflation and the exchange rate?

Country	Inflation target (%)	Details
Australia	2–3	Average over the medium term
Brazil	4.5	Tolerance band of ± 1.5 percentage points
Canada	2	Tolerance band of ± 1 percentage points
Chile	3	Tolerance band of ± 1 percentage point
Czech Republic	2	Tolerance band of ± 1 percentage point
Eurozone	<2 but close to it	Average for eurozone as a whole; over medium term
Hungary	3	Tolerance band of ± 1 percentage point
Iceland	2.5	
Israel	1–3	
Japan	2	
Mexico	3	Tolerance band of ± 1 percentage point
New Zealand	2	Tolerance band of ± 1 percentage point

Central banks and the DAD curve

The DAD curve allows us to analyse the economy in the modern context of central banks whose macroeconomic objectives include targeting inflation. Box 21.7 provides an indication of the number of central banks targeting, to one degree or another, the rate of inflation.

The DAD curve shows a *negative* relationship between output and the rate of inflation. As we saw in section 20.2, this is explained by central banks responding to higher inflation by raising nominal and real interest rates. The extent to which they do raise interest rates will reflect their policy remits and, hence, their aversion to inflation. The impact of higher interest rates on aggregate demand will then depend on the transmission mechanisms through which changes in real interest rates operate (see section 19.1).

The *slope* of the DAD curve is flatter the more inflation averse the central bank and the more interest-rate elastic is aggregate demand (see page 631). Meanwhile, *shifts* in the DAD curve will be caused by exogenous shocks to aggregate demand – in other words, changes to aggregate demand brought about by factors other than the rate of inflation causing the central bank to adjust interest rates.

 How would financial accelerator effects (see section 19.4) affect the DAD curve?

Combining the EAPC and DAD/DAS frameworks

Because of the close relationship between changes in unemployment and output, much of the earlier analysis in this chapter using the EAPC framework could readily have been undertaken through the lens of the DAS curve alongside the DAD (dynamic aggregate demand) curve. To illustrate this, let us return to Figure 21.8.

Assume that the economy is in equilibrium with inflation at the target rate π^* , unemployment at its natural rate U_n and output at its potential level Y_p . This is represented by point *a* in the EAPC framework, and by point *a'* in the DAD/DAS framework. Now assume that there is an unexpected increase in aggregate demand. The increase in aggregate demand causes the DAD curve to move rightwards from DAD_1 to DAD_2 in Figure 21.8(b).

The economy expands in the short run. In the DAD/DAS framework we move along the DAS curve to point *b'* and output expands to Y_2 . This is mirrored in the EAPC framework by a movement along $EAPC_1$ from *a* to *b*. We can also see from both diagrams that the short-run boost in economic activity (fall in the unemployment rate and rise in output) is accompanied by a rise in the rate of inflation from π^* to π_2 .

The role of the central bank. Our interest throughout this chapter has been on how the economy adjusts to shocks, such as an increase in aggregate demand. Hence, we have been concerned about the role that markets and expectations play in that adjustment. The incorporation of the DAD

curve allows us to take this one step further and consider the effect of central banks in this adjustment. Hence, how would central banks with inflation rate targets affect the relationship between inflation and unemployment or output?

For simplicity, assume that an inflation-targeting central bank responds to the rise in aggregate demand by tightening its monetary stance. Assume also that it does this under the belief that the increase in aggregate demand will persist for some time and that the increase will not affect the economy's *potential* output.

By tightening monetary policy, and hence shifting the DAD curve leftwards from DAD_2 to DAD_1 , the central bank can also help to keep inflationary expectations anchored at π^* . (If inflationary expectations were to adjust upwards this would lead to a vertical upward movement of both the EAPC and the DAS curve. This would generate a different adjustment path.)

Of course, the analysis here is based on a series of assumptions. Throughout the chapter we have seen that economists hold different views about the ways in which economies behave in the face of frequent economic shocks. The point here is that the central banks are an important factor in shaping this behaviour.

Indeed, if people believe that central banks will be successful in keeping inflation roughly at the target rate, this is likely to affect the shape of the EAPC and make it much flatter. We can see from the chart in Box 15.6 (see page 476) that variations in UK inflation in recent years have been relatively small, while variations in unemployment have been quite considerable. Some of the changes in unemployment have been due to changes in labour markets, and especially a greater labour market flexibility causing a movement left in the natural rate of unemployment (or NAIRU). But some have been due to fluctuations in real aggregate demand. For example, there was a large rise in unemployment in 2008 and 2009, following the financial crisis.

The central bank's remit. The more assiduous the central bank is perceived to be in keeping to the inflation target, the flatter the EAPC and DAS curve will be. People's expectations will be anchored at the target rate. If, however, the central bank's remit was also to be mindful of output and employment and, as a result, it was prepared to accept some fluctuations in inflation, the EAPC and DAS curve will be steeper.

Box 21.8 looks at how the EAPC and DAD/DAS frameworks can be combined to help analyse how economies might adjust in the face of supply side shocks.

The divergent views of different economists – from the market flexibility assumption of the new classicists to the market imperfections assumption of modern Keynesians – have different implications for macroeconomic policy.

The next chapter looks at demand-side policy – both fiscal and monetary. It also looks at whether the approach to them should be one based on rules (such as a target for

BOX 21.8

INFLATION SHOCKS AND CENTRAL BANKS

EXPLORING
ECONOMICSCombining the *EPAC* and *DAD/DAS* frameworks

As we saw in section 21.1, the vertical position of the expectations-augmented Phillips curve (*EAPC*) is determined by the expected rate of inflation (π^e) and by exogenous cost pressures on inflation (k). Since the dynamic aggregate supply (*DAS*) curve is an alternative representation of the *EAPC*, these factors also affect the vertical position of the *DAS*. We combine both frameworks here to analyse an adverse supply-side shock ($k > 0$). We assume that this takes the form of a temporary period of higher commodity price inflation.

Assume that the economy is in equilibrium with no output gap ($Y = Y_p$), unemployment at its natural rate U_n and inflation at its target rate π^* . This is represented by point a in the *EAPC* framework (Figure (a)), and by point a' in the *DAD/DAS* framework (Figure (b)). There then occurs an increase in commodity price inflation which causes a rise in the rate at which firms' real non-labour costs increase.

The *EAPC* and *DAS* curve move vertically upwards because the rate of inflation is now higher at any level of economic activity (unemployment or output). The *EAPC* moves from *EAPC*₁ to *EAPC*₂ and the *DAS* curve from *DAS*₁ to *DAS*₂. The equivalent vertical differences ac and $a'c'$ reflect the exogenous cost factor k .

The rate of inflation π rises above its target rate π^* . The response of the central bank is to raise the real rate of interest to dampen inflation. Even though the shock may be thought to be temporary, the central bank is likely to see the

raising of interest rates as necessary to keep inflationary expectations anchored at the target inflation rate. More generally, the extent to which rates rise will be determined by the remit of the central bank. This is reflected in the slope of *DAD* curve with a more inflation-averse central bank having a flatter *DAD* curve.

As real interest rates rise and real aggregate demand falls, there is a movement along the *DAD* curve from a' to b' . This is reflected in the *EAPC* framework by a move from a to b . The economy experiences both a negative output gap and higher inflation. Therefore, the economy incurs a period of *stagflation*. The more inflation-averse is the central bank, the larger will be the fall in output but the smaller the rise in inflation.

However, as the negative supply shock subsides the *DAS* curve and *EAPC* move back vertically downwards. As they do, real interest rates fall. Eventually the economy will have adjusted to its original equilibrium.

1. If the supply-side shock persists, explain how the economy will move to points c and c' .
2. Draw five separate graphs, known as impulse response functions, to plot the path of the unemployment rate, inflation, output, nominal interest rates and real interest rates (y -axis) against time (x -axis) to reflect the analysis in this box.

EAPC, DAD/DAS and inflation shocks

public-sector borrowing or a target for inflation) or one based on discretion, where policies are varied according to circumstances.

The chapter then concludes by developing an integrated model of the economy bringing together the *IS/MP*, *DAD/*

DAS and *EAPC* frameworks and relates them to macroeconomic policy.

Then in Chapter 23 we look at the supply side of the economy: at the causes of growth in potential output and supply-side policy.

K1 36
p451

Section summary

- Many governments around the world have delegated monetary policy to their central banks. Consequently, many central banks are charged with targeting inflation, though their remits are often supplemented by other macroeconomic objectives.
- New classical and monetarist ideas have helped provide the theoretical justifications for central bank independence. Delegating monetary policy, it is argued, can eliminate the inflation bias that would otherwise arise from monetary policies lacking credibility.
- Policy announcements lack credibility and are time inconsistent when there is an incentive for policy makers to renege on them. By depoliticising monetary policy, it is argued that low inflation target announcements become more credible. This allows people to reduce their inflationary expectations thereby reducing actual inflation.
- The dynamic aggregate supply curve is an alternative representation of the expectations-augmented Phillips curve, but with real national income rather than unemployment on the horizontal axis. We can view the behaviour of the economy and the relationship between inflation and economic activity through either the *EAPC* or the *DAD/DAS* frameworks.
- The incorporation of the dynamic aggregate demand curve allows us to consider more formally the role of inflation-targeting central banks in affecting the behaviour of economies that are frequently hit by economic shocks, such as fluctuations in aggregate demand.

Fiscal and Monetary Policy

END OF CHAPTER QUESTIONS

- Assume that inflation depends on two things: the level of aggregate demand, indicated by the inverse of unemployment ($1/U$), and the expected rate of inflation (π^e). Assume that the rate of inflation (π_t) is given by the equation

$$\pi_t = (48/U - 6) + \pi^e$$

Assume initially (year 0) that the actual and expected rate of inflation is zero.

- What is the current (natural) rate of unemployment?
 - Now assume in year 1 that the government wishes to reduce unemployment to 4 per cent and continues to expand aggregate demand by as much as is necessary to achieve this. Fill in the rows for years 0 to 4 in the following table. It is assumed for simplicity that the expected rate of inflation in a given year (π^e) is equal to the actual rate of inflation in the previous year (π_{t-1}).
- | Year | U | $48/U - 6$ | + | π^e | = | π |
|------|-----|------------|---|---------|---|-------|
| 0 | ... | ... | + | ... | = | ... |
| 1 | ... | ... | + | ... | = | ... |
| 2 | ... | ... | + | ... | = | ... |
| 3 | ... | ... | + | ... | = | ... |
| 4 | ... | ... | + | ... | = | ... |
| 5 | ... | ... | + | ... | = | ... |
| 6 | ... | ... | + | ... | = | ... |
| 7 | ... | ... | + | ... | = | ... |
- Now assume in year 5 that the government, worried about rising inflation, reduces aggregate demand sufficiently to reduce inflation by 3 per cent in that year. What must the rate of unemployment be raised to in that year?
 - Assuming that unemployment stays at this high level, continue the table for years 5 to 7.
- In the accelerationist model, if the government tries to maintain unemployment below the natural rate, what will determine the speed at which inflation accelerates?
 - What is the difference between adaptive expectations and rational expectations?
 - How can adaptive expectations of inflation result in clockwise Phillips loops? Why would these loops not be completely regular?
 - For what reasons may the NAIRU increase?
 - What is meant by inflation bias? What factors affect the potential magnitude of inflation bias?
 - Using the integrated *DAD/DAS* and *EAPC* framework, analyse the effect of an unexpected increase in aggregate demand assuming that markets adjust relatively rapidly. Compare the adjustment path of the economy when inflationary expectations remain anchored with that when expectations are based on actual inflation in the previous period.
 - In what sense is it true to say that the Phillips curve is horizontal today?

Supply-side shocks	710

Both fiscal and monetary policy can be used to control aggregate demand. Excessive growth in aggregate demand can cause unsustainable short-term growth and higher rates of inflation. Too little aggregate demand can result in a recession, with negative growth and rising unemployment.

Fiscal policy seeks to control aggregate demand by altering the balance between government expenditures and taxation. Monetary policy seeks to control aggregate demand by directly controlling money supply or by altering the rate of interest and then backing this up by any necessary changes in money supply.

In the first three sections of this chapter we examine fiscal and monetary work; how effective they are likely to be in controlling aggregate demand; and what are the potential pitfalls in their use.

We then turn to consider the arguments as to how much discretion or control policy makers should have over fiscal and monetary policy. Should governments adopt fixed targets for policy (e.g. inflation targets) or should they adjust policies according to circumstances? This is a debate reinvigorated by the global financial and economic crisis of the late 2000s and the sluggish growth of many economies since.

Finally, we integrate the *EAPC*, *IS/MP* and *DAD/DAS* models from earlier chapters. This allows us to analyse simultaneously the relationships between unemployment, output, inflation and interest rates in the context of central banks with specific macroeconomic objectives, such as an inflation rate target. We then apply the framework to focus on the possible adjustment paths of economies hit by shocks and what this means for the paths of key macroeconomic variables.

22.1 FISCAL POLICY AND THE PUBLIC FINANCES

Fiscal policy involves the government manipulating the level of government expenditure and/or rates of tax. An *expansionary* fiscal policy will involve raising government expenditure (an injection into the circular flow of income) or reducing taxes (a withdrawal from the circular flow). A *deflationary* (i.e. a contractionary) fiscal policy will involve cutting government expenditure and/or raising taxes.

But why might government wish to change its fiscal position? In other words, what are the roles for fiscal policy?

Roles for fiscal policy

Aggregate demand

Fiscal policy may be used to affect aggregate demand. There are two principal reasons for this.

Prevent the occurrence of fundamental disequilibrium in the economy. The government may wish to remove any severe deflationary or inflationary gaps. Hence, expansionary fiscal policy could be used to prevent an economy experiencing a severe or prolonged recession, such as that experienced in the Great Depression of the 1930s or in 2008/9 when substantial tax cuts and increased government expenditure were used by many countries, including the UK and the USA, to combat the onset of recession. Likewise, deflationary fiscal policy could be used to prevent rampant inflation, such as that experienced in the 1970s.

Stabilisation policies. The government may wish to smooth out the fluctuations in the economy associated with the business cycle. This involves reducing government expenditure or raising taxes when the economy begins to boom. This will dampen down the expansion and prevent 'overheating' of the economy, with its attendant problems of rising inflation and a deteriorating current account balance of payments. Conversely if a recession looms, the government should cut taxes or raise government expenditure in order to boost the economy.

If these stabilisation policies are successful, they will amount merely to 'fine-tuning'. Problems of excess or deficient demand will never be allowed to get severe. Any movement of aggregate demand away from a steady growth path would be quickly 'nipped in the bud'.

Aggregate supply

Fiscal policy can also be used to influence aggregate supply. For example, government can increase its expenditure on education, training and infrastructure, or give tax incentives for investment and research and development. Such initiatives would be intended to increase the rate of growth of the economy's potential output and reduce the natural rate of unemployment. Supply-side policies are considered in more detail in Chapter 23.

In section 22.2 we look at how fiscal policy can be used. But, first it is important to understand some of the terminology of government spending and taxation and some of the key fiscal indicators.

Government finances: some terminology

Government

When analysing government finances the term 'government' is often used interchangeably with that of 'general government'. It is important to note that general government includes both *central* and *local* government. Separate balance sheets can be presented for each. An analysis of both may be particularly important in countries where local government has considerable autonomy from central government, such as varying tax rates or raising money by issuing debt instruments.

The terms *budget deficit* and *budget surplus* are frequently used in the context of government, and especially central government. In fact, these terms can be applied to any organisation to assess its financial well-being by comparing expenditure with revenues.

If general government's expenditure (including benefits) exceeds its revenue from taxation it would be running a budget deficit, sometimes known simply as the *general government deficit*. Conversely, when general government's revenues exceed its expenditure there is a *general government surplus*.

For most of the past 50 years, governments around the world have run budget deficits. In the late 1990s and early 2000s, however, many countries, the UK included, made substantial efforts to reduce the size of general government deficits, and some achieved budget surpluses for periods of time. The position changed dramatically in 2008/9, however, as governments around the world increased their expenditure and cut taxes in an attempt to stave off recession. Government deficits in many countries soared.

Definitions

Fiscal policy Policy to affect aggregate demand by altering the balance between government expenditure and taxation.

Budget deficit The excess of an organisation's spending over its revenues. When applied to government it is the excess of its spending over its tax receipts.

Budget surplus The excess of an organisation's revenues over its expenditures. When applied to government it is the excess of its tax receipts over its spending.

General government deficit (or surplus) The combined deficit (or surplus) of central and local government.

Table 22.1 General government deficits/surpluses and debt as a percentage of GDP

	General government deficits (–) or surpluses (+)		General government debt	
	Average 1997–2007	Average 2008–18	Average 1997–2007	Average 2008–18

Note: Data for 2017–18 are forecasts.

Source: Based on data from AMECO database, Tables 16.3 and 18.1 (European Commission, DG ECFIN).

Deficits, debt and borrowing. To finance their deficits, governments will have to borrow (e.g. through the issue of bonds (gilts) or Treasury bills). As we saw in section 18.3, this will lead to an increase in the money supply to the extent that the borrowing is from the banking sector. The purchase of bonds or Treasury bills by the (non-bank) private sector, however, will not lead to an increase in the money supply.

Deficits represent *annual* borrowing: a flow concept. The accumulated deficits over the years (minus any surpluses) gives total *debt*: a stock concept. It is the total amount owed by the government. Central and general government debt are known as *national debt* and *general government debt* respectively.

Note that the national debt is not the same thing as the country's overseas debt. In the case of the UK, only around 27 per cent of national debt is owed overseas. The remainder is owed to UK residents. In other words, the government finances its budget deficits largely by borrowing at home and not from abroad.

Table 22.1 shows general government deficits/surpluses and debt for selected countries. They are expressed as a proportion of GDP.

? *Why are historical and international comparisons of deficit and debt measures best presented as proportions of GDP?*

As you can see, in the period from 1997 to 2007, all the countries, with the exception of Ireland and Sweden, ran an average deficit. In the period from 2008 to 2018 the average deficits increased for most countries. And the bigger the deficit, the faster debt increased.

Public sector

To get a more complete view of public finances, we would need to look at the entire public sector: namely, central government, local government and public corporations.

There is one important caveat to this: we have to be aware that corporations can transfer between the public and private sectors (a result of privatisation or nationalisation). Consequently, public finance statistics can be distorted by such movements. As we shall see in Chapter 24, in recent times many countries have privatised major industries, such as transport, energy and telecommunications.

The financial crisis of the late 2000s saw various banking corporations transferred wholly or partly to the public sector (nationalisation) in order to ensure their survival and the stability of the financial system. In the UK, this included banking groups such as Lloyds, Northern Rock and the Royal Bank of Scotland. The hope was to return these institutions to the private sector in due course. Case 22.1 on the student website discusses the UK government's financial interventions during the financial crisis and their cost to the public purse.

Definitions

National debt The accumulated deficits of central government. It is the total amount owed by central government, both domestically and internationally.

General government debt The accumulated deficits of central plus local government. It is the total amount owed by general government, both domestically and internationally.

Current and capital expenditures. In presenting the public finances, it has become the custom to distinguish between **current** and **capital expenditures**. Current expenditures involve the operational expenditures of the public sector, including the wages and salaries of public-sector staff, and the payments of welfare benefits. Capital expenditures are public-sector investment. Examples include expenditure on roads, hospitals and schools. Like all types of investment, they give rise to a stream of benefits over time.

So why might we wish to distinguish between current and capital expenditures? One reason for the distinction is that capital expenditures generate long-term economic benefits which can be enjoyed into the future. In other words, by benefiting more than just the current generation, capital expenditure may help to promote intergenerational fairness.

Another reason is that capital expenditures can increase potential output and thereby positively affect future growth rates. This, in turn, could increase future tax revenues and help to provide more sustainable foundations for the public finances over the longer term.

However, the distinction between current and capital expenditures and the associated reasons for it is not without issues. Teachers and doctors, for instance, whose wages form part of public-sector current expenditure, would reasonably argue that their work generates benefits for future generations.

Figure 22.1 shows the scale and composition of public-sector expenditures in the UK since the 1960s. The figures are presented as shares of GDP. Over the period, total spending has averaged 40 per cent of GDP, current spending 34 per cent of GDP and capital spending just 6 per cent of GDP. However, a closer inspection of the chart shows that capital spending by the UK government decreased consistently as a

proportion of GDP from the late 1960s through to 2000. It then rose during the 2000s but has since declined again (but not as fast as current expenditure).

What could have driven the changes in the composition of UK public expenditure? Do such changes matter?

Final expenditure and transfers. We can also distinguish between **final expenditure** on goods and services, and **transfers**. This distinction recognises that the public sector directly adds to the economy's aggregate demand through its spending on goods and services, including the wages of public-sector workers, but also that it redistributes incomes between individuals and firms. Transfers include subsidies and benefit payments, such as payments to the unemployed.

Public-sector borrowing and debt. If the public sector spends more than it earns, it will have to finance the deficit

Definitions

Current expenditure Recurrent spending on goods and factor payments.

Capital expenditure Investment expenditure; expenditure on assets.

Final expenditure Expenditure on goods and services. This is included in GDP and is part of aggregate demand.

Transfers Transfers of money from taxpayers to recipients of benefits and subsidies. They are not an injection into the circular flow but are the equivalent of a negative tax (i.e. a negative withdrawal).

Figure 22.1 UK Public-sector current and capital expenditures

Note: Data based on financial years; forecasts from 2017/18.

Sources: Public Finances Databank, Office for Budget Responsibility.

through borrowing, known as **public-sector net borrowing (PSNB)**. The principal form of borrowing is through the sale of gilts (bonds). The precise amount of money the public sector needs to borrow in any one year is known as the **public-sector net cash requirement (PSNCR)**. It differs slightly from the PSNB because of time lags in the flows of public-sector incomes and expenditure.

As with central and general government debt, **public-sector debt** is the current stock of the accumulated deficits over the years. In assessing the sustainability of this stock of debt – a theme we return to shortly – it is usual to focus on **public-sector net debt**. This is the sector's gross debt less its liquid assets, which comprise official reserves and deposits held with financial institutions.

Key fiscal indicators

Sustainability of the public finances

We can use a range of fiscal indicators to assess the financial position of government and the whole public sector. The most commonly used indicators are those that convey information about the prudence or sustainability of the public sector's finances.

We can identify four measures which, in one way or another, allow us to say something about prudence or sustainability. First is **public-sector net borrowing** (or its close counterpart in the public-sector net cash requirement); second is **public-sector net debt**. As we have seen, the first captures the relative flow of the public sector's receipts in comparison to its total expenditure, while the second measures the accumulated debt stock that has arisen from the sector's deficits.

A third indicator of sustainability is the **public-sector current budget deficit**. If public-sector revenues are less than the sum of its **current** expenditures, then the public sector runs a deficit on the current budget. This means that the public sector, by not even meeting the full cost of its current expenditures out of its receipts, is also unable to meet any of the cost of its capital expenditures. As well as implications for the immediate sustainability of public finances, the constraints that a current budget deficit can place on capital expenditures could, as we discussed above, have implications for future economic growth and for the well-being of future generations.

The fourth indicator of sustainability is the **primary surplus (or deficit)**. This occurs when public-sector receipts are greater (or less) than public-sector expenditures **excluding** interest payments. The primary surplus is important for analysing the path of the **public-sector debt-to-GDP ratio**. For this ratio to fall requires that the public sector operates a given primary surplus-to-GDP ratio.

To see this a little more readily we can use a rule of thumb that connects the primary surplus-to-GDP (S_p/Y_n) ratio and the public-sector debt-to-GDP (D/Y_n) ratio. Each ratio is

calculated using nominal values, so Y_n , for example, is nominal GDP. Then, to calculate the required primary surplus-to-GDP ratio to maintain the current value of the public-sector debt-to-GDP ratio, we multiply the current debt-to-GDP ratio (D/Y_n) by the sum of the **real** rate of interest (r) minus the **real** economic growth rate ($\Delta Y_t/Y_t$). This gives us what is referred to as the 'debt sustainability rule':

$$\frac{S_p}{Y_n} = \frac{D}{Y_n} \times \left(r - \frac{\Delta Y_t}{Y_t} \right) \quad (1)$$

To illustrate the sustainability arithmetic, consider a country where the public-sector net debt-to-GDP ratio (D/Y_n) is currently 0.5 (i.e. 50 per cent). Assume that the real interest rate on borrowing (r) is 3 per cent and the annual real rate of economic growth ($\Delta Y_t/Y_t$) is 1 per cent. For the debt-to-GDP ratio to remain at its current level, the country will need to run a primary surplus equivalent to 1 per cent of GDP ($0.5 \times (3 - 1)$). If, however, the current debt-to-GDP ratio were currently 1 (i.e. 100 per cent), then it would need to run a primary surplus-to-GDP ratio of 2 per cent ($1 \times (3 - 1)$).

Thus a country where the average real interest rate on public debt instruments (r) is greater than the real economic growth rate ($\Delta Y_t/Y_t$) will have to run primary surpluses for its debt-to-GDP ratio to fall. Furthermore, the required primary surplus-to-GDP ratio will be higher if the country has an already high debt-to-GDP ratio. In other words, the sustainability arithmetic tends to get more difficult for governments to comply with, the higher their existing debt-to-GDP ratio.

What primary balance-to-GDP ratio would a country need to run to sustain a debt-to-GDP ratio of 60 per cent if the real interest rate is 2 per cent and economic growth is 4 per cent?

Definitions

Public-sector net borrowing (PSNB) The difference between the expenditures of the public sector and its receipts from taxation and the revenues from public corporations.

Public-sector net cash requirement (PSNCR) The (annual) deficit of the public sector, and thus the amount that the public sector must borrow. In the UK the principal measure, which takes into account financial transactions by the public sector, is known as the public-sector net cash requirement.

Public-sector net debt Gross public-sector debt minus liquid financial assets.

Public-sector current budget deficit The amount by which public-sector expenditures classified as current expenditures exceed public-sector receipts.

Primary surplus (or deficit) The situation when the sum of public-sector expenditures excluding interest payments on public-sector debt is less than (greater than) public-sector receipts.

Figure 22.2 UK public-sector deficit balances and debt stock

Note: Data based on financial years; forecasts from 2017/18.
Sources: Public Finances Databank, Office for Budget Responsibility.

Figure 22.2 shows the four key fiscal indicators for the UK since 1975. During this time, net borrowing has averaged 3.4 per cent, the current deficit 1.4 per cent and the primary deficit 1.0 per cent of GDP. We can also see how the deterioration in the deficit balances and the interventions to help shore up the financial system in the late 2000s led to a marked increase in the public-sector net debt-to-GDP ratio.

The business cycle and the public finances

When analysing the fiscal indicators, it is important to recognise that their values are affected by the state of the economy. In other words, there is both a structural and a cyclical component determining the path of our fiscal measures.

If the economy is booming, with people earning high incomes, the amount paid in taxes will be high. In a booming economy the level of unemployment will be low. Thus the amount paid out in unemployment benefits will also be low. The combined effect of increased tax revenues and reduced benefits is to improve public-sector balances, such as public-sector net borrowing. Indeed, rather than a reduced deficit there could be public-sector surplus. By contrast, if the economy were depressed, tax revenues would be low and the amount paid in benefits would be high. The public-sector deficit would thus be high.

? How is the public-sector debt-to-GDP ratio likely to be affected by the state of the economy?

Definition

Structural deficit (or surplus) The public-sector deficit (or surplus) that would occur if the economy were operating at the potential level of national income: i.e. one where there is a zero output gap.

Since, therefore, the values of fiscal indicators are not entirely due to deliberate government policy, they may not give a very good guide to government intentions or to the longer-term financial well-being of government. By cyclically-adjusting measures of public-sector deficits or surpluses we remove their cyclical component. The deficit or surplus that would arise if the economy were producing at the potential level of national income is termed the *structural deficit or surplus*. Remember that the potential level of national income is where there is no excess or deficiency of aggregate demand: where the output gap is zero (see page 457 and Box 15.3).

This relationship between the public-sector deficit or surplus and the state of the economy is illustrated in Figure 22.3. The tax revenue function is upward sloping. Its slope depends on tax rates. The government expenditure function (which in this diagram includes transfer payments, such as unemployment benefits) is drawn as downward sloping, showing that at higher levels of income and employment

Figure 22.3 National income and the size of the public-sector deficit or surplus

BOX 22.1

PRIMARY SURPLUSES AND SUSTAINABLE DEBT

CASE STUDIES AND APPLICATIONS

The fiscal arithmetic of government debt

One way of thinking about the sustainability of the public finances is the conditions needed for the public sector's debt-to-GDP ratio to cease rising. It turns out that given an existing debt-to-GDP ratio (D/Y_n), an expected annual real rate of interest on public-sector debt (r) and an expected annual rate of real economic growth ($\Delta Y_r/Y_r$) the public sector needs to run a particular primary surplus-to-GDP ratio (S_p/Y_n). As explained in the text, this sustainability condition can be written as:

$$\frac{S_p}{Y_n} = \frac{D}{Y_n} \times \left(r - \frac{\Delta Y_r}{Y_r} \right)$$

A primary surplus occurs when the public sector's revenues are greater than its expenditures when excluding its interest payments on its debts. Only in the case where the economic growth rate is greater than the real interest rate can the public sector run a primary deficit without its debt-to-GDP ratio rising.

General government and the financial crisis

Concerns about the sustainability of public-sector finances were put into sharp focus following the financial crisis of 2007–8. Governments in many countries made interventions to shore up their financial systems and to support aggregate demand as private-sector expenditures fell sharply.

The following table helps us to understand the evolution of the finances of general government in a sample of advanced economies following the financial crisis. The table shows the debt-to-GDP ratio in each country in 2008 and 2016. It also shows the average primary surplus-to-GDP ratio and economic growth rate over the period from 2009 to 2016

as well as the average real short-term interest rate for each economy. The latter should be treated as indicative of the average interest rate facing government on its debt. The actual interest costs could be somewhat different, not least because of the turbulence in government debt markets during this period and because, more generally, governments issue a range of debt instruments with different terms to maturity.

The final column of the table shows an estimate for each country of their required primary surplus-to-GDP ratio to maintain the initial debt-to-GDP ratio in 2008 based on the average real interest rate and growth rate that they subsequently experienced from 2009 to 2016. In most cases countries would have been able to run primary deficits, as indicated by the negative values. Despite this, if we compare the required primary balance values with the actual values we can see that only Germany ran a primary balance which exceeded that needed to stabilise the debt-to-GDP ratio.

Hence, other than in Germany, the countries in our sample experienced primary balances that fell short of the values needed to stabilise the debt-to-GDP ratio. Furthermore, in many cases the debt-to-GDP ratio rose very sharply indeed. This is important because it needs even healthier primary balances in the future for countries to maintain the now higher debt-to-GDP ratio. Consequently, the sustainability constraints become ever more binding on the fiscal choices of governments. This reduces their ability to use fiscal policy to cushion economies against adverse economic shocks.

Some argue that the sustainability arithmetic is even more significant for countries in the eurozone. What might be the explanation for this argument?

General government fiscal indicators

less is paid out in benefits. As can be clearly seen, there is only one level of income (Y_1) where there is a public-sector financial balance. Below this level of income there will be a public-sector deficit. Above this level there will be a surplus. The further income is from Y_1 , the bigger will be the deficit or surplus.

The fiscal stance

The government's *fiscal stance* refers to whether it is pursuing an expansionary or contractionary fiscal policy. Does the fact that countries such as the UK in most years run public-sector deficits mean that their government's fiscal stance is mainly expansionary? Would the mere

existence of a surplus mean that the stance was contractionary? The answer is no. Whether the economy expands or contracts depends on the balance of *total* injections and *total* withdrawals.

What we need to focus on is *changes* in the size of the deficit or surplus. If the deficit this year is lower than last year, then (*ceteris paribus*) aggregate demand will be lower this year than last. The reason is that either government expenditure (an injection) must have fallen, or tax revenues (a withdrawal) must have increased, or a combination of the two.

To conclude, the size of the deficit or surplus is a poor guide to the stance of fiscal policy. A large deficit *may* be due to a deliberate policy of increasing aggregate demand, but it may be due simply to the fact that the economy is depressed.

Section summary

1. The public sector comprises general government and public corporations. There exist a range of fiscal indicators that allow us to analyse the fiscal position and well-being of the public sector or its component sectors.
2. Key fiscal indicators include those that assess the sustainability of the public sector's finances. We can estimate a required primary surplus-to-GDP ratio needed to prevent the ratio of public-sector debt to GDP from rising. Countries with higher existing debt-to-GDP ratios, higher real interest costs and lower real rates of economic growth will need to operate larger primary surpluses (or smaller deficits) to prevent the ratio from rising further.
3. The government's fiscal policy influences the size of its budget deficit or surplus. Its size alone, however, is a poor guide to the government's fiscal stance. A large deficit, for example, may simply be due to the fact that the economy is in recession and therefore tax receipts are low. A better guide is whether the change in the deficit or surplus will be expansionary or contractionary.

22.2 THE USE OF FISCAL POLICY

The fiscal choices of government relate to decisions about public expenditures and taxation. These choices can shape future government receipts or expenditures. For example, the design of a country's income tax or benefits system evolves over time. As governments make policy changes they shape the tax and benefit systems, including their relationship with macroeconomic variables such as national income or unemployment.

More generally, today's choices by government can commit future governments to certain expenditure and taxation flows. Indeed, some expenditure and taxation receipts *automatically* change as the macroeconomic environment changes. For example, income tax receipts automatically increase as nominal national income increases. The design of the income tax system and the rates and bands determine just how much receipts will change as nominal national income changes.

However, governments also make *discretionary* choices which deliberately manipulate taxes or levels of spending to affect current levels of aggregate demand, regardless of the automatic effects that occur across the business cycle. These decisions may then be reversed as economic conditions change. For example, Box 22.2 (and Case Study 22.1 on the

student website) discusses the fiscal measures taken by the UK government following the financial crisis. These measures initially focused on stimulating aggregate demand. Then, as the policy focus shifted to reducing the burgeoning public-sector deficit, fiscal policy was tightened.

In this section we begin by considering how expenditure and taxation flows automatically change across the business cycle and, in so doing, help to stabilise the economy. We then move on to discuss why governments might make deliberate changes to taxation and government expenditures and how effective they may be in managing the economy.

Automatic fiscal stabilisers

We saw from Figure 22.3 that the size of the public-sector surplus or deficit will automatically vary according to the level of national income. The effect of this will be to reduce

Definition

Fiscal stance How expansionary or contractionary the Budget is.

the level of fluctuations in national income without the government having to take any deliberate action.

Taxes whose revenues rise as national income rises and benefits that fall as national income rises are called **automatic stabilisers**. They have the effect of reducing the size of the multiplier, reducing both upward and downward movements of national income. Thus, in theory, the business cycle should be dampened by such built-in stabilisers. The more taxes rise or benefits fall, the bigger will be the *mpt* (the net marginal tax propensity). Remember that we defined this as the proportion of any rise in income going in taxes and reduced benefits. The bigger the *mpt*, the smaller will be the multiplier and the greater will be the stabilising effect.

Draw an injections and withdrawals diagram, with a fairly flat W curve. Mark the equilibrium level of national income. Now draw a second steeper W curve passing through the same point. This second W curve would correspond to the case where tax rates were higher. Assuming now that there has been an increase in injections, draw a second J line above the first. Mark the new equilibrium level of national income with each of the two W curves. You can see that national income rises less with the steeper W curve. The higher tax rates are having a dampening effect on the multiplier.

The effectiveness of automatic stabilisers

Automatic stabilisers have the obvious advantage that they act instantly as soon as aggregate demand fluctuates. By contrast, it may take some time before the government can institute discretionary changes in taxes or government expenditure, especially if forecasting is unreliable.

Nevertheless, automatic stabilisers can never be the complete answer to the problem of fluctuations. Their effect is merely to reduce the multiplier – to reduce the severity of fluctuations, not to eliminate them altogether.

In addition, they tend to suffer two specific drawbacks: adverse effects on aggregate supply and the problem of ‘fiscal drag’. Let us examine each in turn.

Adverse supply-side effects

High tax rates may discourage effort and initiative. The higher the marginal tax rate (*mpt*), the greater the stability provided by the tax system. But the higher tax rates are, the more likely they are to create a disincentive to work and to invest. For example, steeply progressive income taxes may discourage workers from doing overtime or seeking promotion. A higher marginal rate of income tax is equivalent to a higher marginal cost of working. People may prefer to work less and substitute leisure for income. The substitution effect of more progressive taxes may thus outweigh the income effect. These issues were examined in detail in section 11.2 (see pages 336–8).

High unemployment benefits may increase equilibrium unemployment. High unemployment benefits, by reducing the

hardship of being unemployed, may encourage people to spend longer looking for the ‘right’ job rather than taking the first job offered. This has the effect of increasing unemployment and thus of shifting the Phillips curve to the right. This is because a longer average period of job search represents a higher level of friction in the economy and thus a higher natural (or equilibrium) level of unemployment.

High income-related benefits may create a poverty trap. The higher the level of income-related benefits and the more steeply they taper off, the greater will be the problem of the ‘poverty trap’. What is the point in unemployed people seeking jobs, or people in very low-paid jobs seeking better ones, if as a result they lose their benefits and end up being little or no better off than before? The more that people are discouraged in this way, the lower will be the level of aggregate supply. (The question of the poverty trap was also examined in Chapter 11 (see pages 342–3).)

The problem of fiscal drag

Automatic stabilisers help to reduce upward and downward movements in national income. This is fine if the current level of income is the *desirable* level. But suppose that there is currently a deep recession in the economy, with mass unemployment. Who would want to stabilise the economy at this level?

In these circumstances, if the economy began to recover, the automatic stabilisers would act as a drag on the expansion. This is known as **fiscal drag**. By reducing the size of the multiplier, the automatic stabilisers reduce the magnitude of the recovery. Similarly, they act as a drag on discretionary policy: the more powerful the automatic stabilisers are, the bigger the change in *G* or *T* that would be necessary to achieve a given change in national income.

Discretionary fiscal policy

Automatic stabilisers cannot prevent fluctuations. They merely reduce their magnitude. If there is a fundamental disequilibrium in the economy or substantial fluctuations in other injections and withdrawals, the government may choose to *alter* the level of government expenditure or the rates of taxation. This is known as **discretionary fiscal policy**. It involves *shifting* the *J* and *W* lines.

Definitions

Automatic fiscal stabilisers Tax revenues that rise and government expenditure that falls as national income rises. The more they change with income, the bigger the stabilising effect on national income.

Fiscal drag The tendency of automatic fiscal stabilisers to reduce the recovery of an economy from recession.

Discretionary fiscal policy Deliberate changes in tax rates or the level of government expenditure in order to influence the level of aggregate demand.

In the UK, changes in taxation and some changes in government expenditure are announced by the Chancellor of the Exchequer in the Budget (now held in the autumn). Some of these changes apply to the coming financial year; some apply to the next financial year or even the one after that.

Since Budgets are normally held only once per year, 'fine-tuning' aggregate demand on a week-by-week or month-by-month basis is left to monetary policy – to changes in interest rates (see section 22.3). Very occasionally, however, changes are made between Budgets. Thus in September 2008 the government raised the threshold above which stamp duty must be paid on house purchase in an attempt to help first-time buyers. Then, in the Pre-Budget Report of November 2008, as recession deepened, VAT was cut and planned public-sector projects were brought forward (see Box 22.2).

Note that discretionary changes in taxation or government expenditure, as well as being used to alter the level of aggregate demand (fiscal policy), are also used for other purposes, including the following:

- **Altering aggregate supply.** Examples include tax incentives to encourage people to work more, or increased government expenditure on training or on transport infrastructure (e.g. roads and railways). We look at such 'supply-side policies' in Chapter 23.
- **Altering the distribution of income.** As Chapter 11 explained, taxation and benefits are the government's major means of redistributing incomes from the rich to the poor.

Let us now compare the relative effects of changing government expenditure and changing taxes. Will a £100 million increase in government expenditure have the same effect as a £100 million cut in taxes? Will the multiplier be the same in each case?

Discretionary fiscal policy: changing G

If government expenditure on goods and services (roads, health care, education, etc.) is raised, this will create a full multiplied rise in national income. The reason is that all the money gets spent and thus all of it goes to boosting aggregate demand.

 Show the effect of an increase in government expenditure by using (a) the injections and withdrawals diagram; (b) the income/expenditure diagram (see Figures 17.8 and 17.10 on pages 534 and 536).

Discretionary fiscal policy: changing T

Cutting taxes by £1 million will have a smaller effect on national income than raising government expenditure on goods and services by £1 million. The reason is that cutting taxes increases people's *disposable* incomes, of which only *part* will be spent. Part will be withdrawn into extra savings, imports and other taxes. In other words, not all the tax cuts will be passed on round the circular flow of income as extra expenditure.

The proportion of the cut in taxes that will be withdrawn is given by the mpw , and the proportion that will circulate round the flow is given by the mpc_d . Thus if the mpc_d were $4/5$, the tax multiplier would only be $4/5$ of the normal multiplier.¹ If the mpc_d were $2/3$, the tax multiplier would only be $2/3$ of the normal multiplier, and so on. The formula for the tax multiplier (k_t) becomes

$$k_t = mpc_d \times k$$

Thus if the normal multiplier were 5 (given an mpc_d of $4/5$), the tax multiplier would be $4/5 \times 5 = 4$. If the normal multiplier were 4 (given an mpc_d of $3/4$), the tax multiplier would be $3/4 \times 4 = 3$, and so on. It should be obvious from this that the tax multiplier is always 1 less than the normal multiplier:

$$k_t = k - 1$$

Since the tax multiplier is smaller than the government expenditure multiplier, to achieve a given rise in income through tax cuts would therefore require a bigger budget deficit than if it were achieved through increased government expenditure. In other words, the required tax cut would be bigger than the required government expenditure increase.

Why will the multiplier effect of government transfer payments such as child benefit, pensions and social security be less than the full multiplier effect given by government expenditure on goods and services? Will this 'transfer payments multiplier' be the same as the tax multiplier? (Clue: will the recipients of such benefits have the same mpc_d as the average person?)

The effectiveness of discretionary fiscal policy

How successful will discretionary fiscal policy be? Can it 'fine-tune' demand? Can it achieve the level of national income that the government would like it to achieve?

There are two main problem areas with discretionary fiscal policy. The first concerns the *magnitude* of the effects. If G or T is changed, how much will *total* injections and withdrawals change? What will be the size of the multiplier? How much will a change in aggregate demand affect output and employment, and how much will it affect prices?

The second concerns the *timing* of the effects. How quickly can policy be changed and how quickly will the changes affect the economy?

Problems of magnitude

Before changing government expenditure or taxation, the government will need to calculate the effect of any such change on national income, employment and inflation. Predicting these effects, however, is often very unreliable for a number of reasons.

¹ Strictly speaking, the tax multiplier is negative, since a *rise* in taxes causes a *fall* in national income.

Predicting the effect of changes in government expenditure

A rise in government expenditure of £ x may lead to a rise in total injections (relative to withdrawals) that is smaller than £ x . This will occur if the rise in government expenditure *replaces* a certain amount of private expenditure. For example, a rise in expenditure on state education may dissuade some parents from sending their children to private schools. Similarly, an improvement in the National Health Service may lead to fewer people paying for private treatment.

Crowding out. If the government relies on *pure fiscal policy* – that is, if it does not finance an increase in the budget deficit by increasing the money supply – it will have to borrow the money from the non-bank private sector. It will thus be competing with the private sector for finance and will have to offer higher interest rates. This will force the private sector also to offer higher interest rates, which may discourage firms from investing and individuals from buying on credit. Thus government borrowing *crowds out* private borrowing. In the extreme case, the fall in consumption and investment may completely offset the rise in government expenditure, with the result that aggregate demand does not rise at all.

Figure 22.4 illustrates the extent of crowding out. (It is the same as Figure 19.8 on page 601.) The rise in government expenditure shifts the injections line from J_1 to J_2 in Figure 22.4(a). The full multiplier effect of this would be a rise in national income to Y_2 . However, the increased government expenditure leads to an increased demand for money. In Figure 22.4(b), the liquidity preference curve shifts to L' . This raises the real interest rate to r_2 . Note that we are assuming that the money supply is purely *exogenous* – i.e. does not vary with the demand for money – and that, therefore, the money supply ‘curve’ is a vertical straight line (M_s).

Definition

Pure fiscal policy Fiscal policy that does not involve any change in money supply.

The higher real rate of interest reduces investment. The injections line falls below J_2 , and, as a result, national income does not rise as far as Y_2 . The amount by which actual income falls short of Y_2 measures the extent of crowding out.

The amount of crowding out from pure fiscal policy depends on three things:

- The shape of the L curve. The flatter the curve, the less will interest rates rise. A greater amount of liquidity will be released from idle balances and there will be a bigger increase in the velocity of circulation.
- Whether money supply is exogenous. If the extra demand for money leads to banks creating extra credit, the money supply curve will be upward sloping, not vertical. The more money is created, the flatter will be the M_s curve, the less interest rates will rise and the less will be the crowding out.
- The responsiveness of investment (and consumption) to a change in real interest rates. The more responsive investment is to a rise in real interest rates, the more will the J curve shift downwards and the bigger will be the crowding-out effect.

If the fiscal policy is not *pure* fiscal policy, if the extra government borrowing is financed by borrowing from the banking sector, then the supply of money curve will shift to the right. If it were to shift as far as M'_s , the real rate of interest would remain at r_1 and there would be no crowding out.

How do people's expectations influence the extent of crowding out?

Predicting the effect of changes in taxes

A cut in taxes, by raising people's real disposable income, increases not only the amount they spend but also the amount they save. The problem is that it is not easy to predict the relative size of these two increases. In part it depends on whether people feel that the cut in tax is only temporary, in which case they may simply save the extra disposable income, or permanent, in which case they may adjust their consumption upwards.

BOX 22.2 THE FINANCIAL CRISIS AND THE UK FISCAL POLICY YO-YO

Trying to find the balance between rules and discretion

Fiscal rules prior to the financial crisis

On being elected in 1997, the UK's Labour government introduced two fiscal rules.

The golden rule. First, under its 'golden rule', it pledged over the cycle to achieve a *current budget balance*, where total receipts equal total current expenditures (i.e. excluding capital expenditures). This rule was designed not to unduly inhibit the automatic stabilisers from working and recognised both the current and future economic benefits of investment spending.

Sustainable investment rule. Second, under its 'sustainable investment rule', the government set itself the target of maintaining public-sector net debt at no more than 40 per cent of GDP, again averaged over the economic cycle. This rule, in conjunction with the golden rule, was designed to signal to the public the government's commitment to sustainable public finances.

The rules provided a framework within which discretionary policy choices would be made. They inevitably placed some constraints on these choices but the economic benefits were thought to be worthwhile – until the financial crisis began to unfold.

What followed was an initial expansionary policy as attempts were made to mitigate the worst of the economic slowdown. But then, with a new government in place and with a burgeoning budget deficit, the UK turned rapidly to a policy of fiscal consolidation. Within a short space of time the stance of fiscal policy changed markedly: a fiscal policy yo-yo.

Expansionary discretion

The impact of the financial crisis on economic growth in the UK was stark. The UK economy entered recession in the second quarter of 2008. After having expanded by an average of 2.8 per cent per year in the five-year period ending in 2007, the UK economy contracted in 2008 by 0.6 per cent and then by 4.3 per cent in 2009.

The severity of the economic downturn, the government argued, required more discretion than its fiscal policies

allowed it. Consequently, its fiscal rules were lifted. The hope was that they could be reinstated in due course.

In the Pre-Budget Report of November 2008, amongst other measures, the Labour government introduced a 13-month cut in VAT from 17.5 per cent to 15 per cent. It also brought forward from 2010/11 £3 billion of capital spending on projects such as motorways, new social housing, schools and energy efficiency.

The effect of the capital spending projects was to increase public-sector gross investment to 5.3 per cent and 5.5 per cent of GDP in 2008/9 and 2009/10 respectively (see Figure 22.1 on page 672). In the previous 10 years the typical amount of public-sector gross investment spending had been just 3.1 per cent of GDP.

Meanwhile, as the chart shows, total government spending (excluding financial interventions) began to rise rapidly, fuelled by rising transfer payments on the back of the faltering economy, peaking at just over 45 per cent in 2009/10.

The UK came out of recession in the second quarter of 2009 after five consecutive quarters of declining output which saw the economy shrink by 6.3 per cent. Meanwhile, the rate of unemployment, which had stood at 5.2 per cent at the start of 2008, peaked at 8 per cent in early 2010 and stood at 7.8 per cent in May when 13 years of Labour government came to an end. Not only did this mark a change of government as a Conservative–Liberal Democrat coalition took charge, but it also marked a change in the direction of fiscal policy.

Consolidation and the fiscal mandate

In 2009/10, public-sector net borrowing hit 9.9 per cent of GDP, up from 2.6 per cent in 2007/8 (see the chart). Consequently, public-sector net debt grew rapidly (see Figure 22.2 on page 674). From £557 billion (35.5 per cent of GDP) in 2007/8 it rose to £1.0 trillion (64.8 per cent of GDP) by 2009/10.

The response of the new government was to begin a policy of consolidation. The framework for this was to be known as the *fiscal mandate*. The initial mandate was for a balanced current budget (after adjusting for the position in the economic cycle) five years ahead. Therefore, at the end of a rolling five-year forecast period public-sector receipts should

? Do theories of the long-run and short-run consumption function help us to understand consumer reactions to a change in taxes? (See section 17.1 and Case Studies 17.1, 17.2, 17.3 and 17.4 on the student website.)

Predicting the resulting multiplied effect on national income

Even if the government *could* predict the net initial effect on injections and withdrawals, the extent to which national income will change is still hard to predict for the following reasons:

- The size of the *multiplier* may be difficult to predict. This is because the mpc_d and mpw may fluctuate. For example, the amount of a rise in income that households save or consume will depend on their expectations about future price and income changes.
- Induced investment through the *accelerator* (see pages 542–5) is also extremely difficult to predict. It may be that a relatively small fiscal stimulus will be all that is necessary to restore business confidence, and that induced investment will rise substantially. In such a case, fiscal policy can be seen as a 'pump primer'. It is used to *start* the

Note: Forecasts from 2017/18.

Source: Public Finances Databank, Office for Budget Responsibility.

at least equal public-sector current expenditures, after adjusting for the economy's output gap. This mandate was supplemented by a target for public-sector net debt as a percentage of GDP to be falling by 2015/16.

To achieve this, the government embarked on a series of spending cuts and tax rises. This started with a 'discretionary consolidation' of £8.9 billion in 2010/11 comprising spending cuts of £5.3 billion and tax increases worth £3.6 billion. It was announced that the consolidation would continue up to 2015/16. By the end of 2015/16 the government planned to have delivered a discretionary consolidation of £122 billion, with £99 billion coming from discretionary reductions in spending and £23 billion from tax increases. As it turned out, however, in real terms total public-sector spending fell by just 1.5 per cent between 2010/11 and 2014/15.

The principal fiscal objectives were thus not met during the 2010–15 parliamentary period, although the government

claimed that 'significant progress' had been made on its fiscal consolidation.

During the 2015–20 Parliament, the fiscal mandate was to be amended. This ultimately resulted in a looser set of rules, with targets (a) to reduce cyclically adjusted public-sector net borrowing to below 2 per cent of GDP by 2020/21 and (b) for public-sector net debt as a percentage of GDP to be falling in 2020/21. The government believed that these rules struck a balance between ensuring the long-term sustainability of the public finances and providing government with sufficient discretion to provide further support for the economy, particularly with the uncertainty arising from the UK's move to leave the European Union.

Is it possible to design a fiscal framework that is sufficiently flexible to deal with all the shocks and events that economies face?

process of recovery, and then the *continuation* of the recovery is left to the market. But for pump priming to work, businesspeople must *believe* that it will work. Business confidence can change very rapidly and in ways that could not have been foreseen a few months earlier.

- The behaviour of commercial banks may also be hard to predict. Credit conditions may be pro-cyclical, perhaps significantly so, resulting in a financial accelerator (see pages 611–13). In the presence of financial accelerator effects small changes in fiscal policy can have amplified effects on national income.

- Multiplier/accelerator interactions. If the initial multiplier and accelerator effects are difficult to estimate, their interaction will be virtually impossible to estimate. Small divergences in investment from what was initially predicted will become magnified as time progresses.

Random shocks

Forecasts cannot take into account the unpredictable, such as the attack on the World Trade Center in New York in September 2001. Even events that, with hindsight, should have been predicted, such as the banking crisis of 2007–9,

often are not. Unfortunately, unpredictable or unpredicted events do occur and may seriously undermine the government's fiscal policy.

? Give some examples of these random shocks.

Problems of timing

Fiscal policy can involve considerable time lags. If these are long enough, fiscal policy could even be destabilising. Expansionary policies taken to cure a recession may not come into effect until the economy has *already* recovered and is experiencing a boom. Under these circumstances, expansionary policies are quite inappropriate: they simply worsen the problems of overheating. Similarly, contractionary policies taken to prevent excessive expansion may not take effect until the economy has already peaked and is plunging into recession. The contractionary policies only deepen the recession.

This problem is illustrated in Figure 22.5. Path (a) shows the course of the business cycle without government intervention. Ideally, with no time lags, the economy should be dampened in stage 2 and stimulated in stage 4. This would make the resulting course of the business cycle more like path (b), or even, if the policy were perfectly stabilising, a straight line.

With time lags, however, contractionary policies taken in stage 2 may not come into effect until stage 4, and expansionary policies taken in stage 4 may not come into effect until stage 2. In this case, the resulting course of the business cycle will be more like path (c). Quite obviously, in these circumstances 'stabilising' fiscal policy actually makes the economy less stable.

There are five possible lags associated with fiscal policy.

Time lag to recognition. Since the business cycle can be irregular and forecasting unreliable, governments may be unwilling to take action until they are convinced that the problem is serious.

Time lag between recognition and action. Most significant changes in government expenditure have to be planned well in advance. The government cannot increase spending on motorways overnight or suddenly start building new hospitals. As far as taxes are concerned, these can normally be changed only at the time of the Budget, and will not be instituted until the new financial year or at some other point in the future. As Budgets normally occur annually, there could be a considerable time lag if the problems are recognised a long time before the Budget.

Time lag between action and changes taking effect. A change in tax rates may not immediately affect tax payments, as some taxes are paid in arrears and new rates may take a time to apply.

Time lag between changes in government expenditure and taxation and the resulting change in national income, prices and employment. The multiplier round takes time. Accelerator effects take time. The multiplier and accelerator go on interacting. It all takes time.

Consumption may respond slowly to changes in taxation. The short-run consumption function tends to be flatter than the long-run function.

If the fluctuations in aggregate demand can be forecast, and if the lengths of the time lags are known, then all is not lost. At least the fiscal measures can be taken early and their delayed effects can be taken into account.

Fiscal rules

Given the problems of pursuing active fiscal policy, many governments in recent years took a much more passive approach. Instead of the policy being changed as the economy changes, countries applied a set of fiscal rules. These rules typically relate to measures of government deficits and to the stock of accumulated debt. Taxes and government expenditure can then be planned to meet these rules.

However, designing rules for fiscal policy can be problematic. Economies are regularly hit by shocks. Some shocks may

Figure 22.5 Fiscal policy: stabilising or destabilising?

BOX 22.3

RIDING A SWITCHBACK

EXPLORING
ECONOMICS

A parable for Chancellors

Imagine that you are driving a car along a straight but undulating road. These undulations are not regular: some of the hills are steep, some are gentle; some are long, some are short.

You are given the instruction that you must keep the car going at a constant speed. To do this, you will need to accelerate going up the hills and brake going down them.

There is a serious problem, however. The car is no ordinary car. It has the following distinctly unusual features:

- The front windscreen and side windows are blacked out, so you cannot see where you are going! All you can see is where you have been by looking in your rear-view mirror.
- The brake and accelerator pedals both work with a considerable and unpredictable delay.
- The car's suspension is so good that you cannot feel whether you are going up or downhill. You can only judge this by looking in your mirror.
- Finally (you are relieved to know), the car has a special sensor and automatic steering that keep it in the correct lane.

As you are going along, you see that the road behind you is higher, and you realise that you are going downhill. The car gets faster and faster. You brake – but nothing happens. In your zeal to slow the car down, you put your foot down on the brake as hard as you can.

When the brake eventually does come on, it comes on very strongly. By this time, the car has already reached the bottom of the hill. As yet, however, you do not realise this and are still braking. But now the car is going up the next hill with the brakes still on. Looking in your mirror, you eventually realise this. You take your foot off the brake and start accelerating. But the pedals do not respond. The car is still slowing down rapidly, and you only just manage to reach the top of the hill.

Then, as you start going down the other side, the brakes eventually come off and the accelerator comes on . . .

This famous parable – first told by Frank Paish, Professor of Economics at the LSE, some 40 years ago – demonstrates how 'stabilising' activity can in fact be destabilising. When applied to fiscal policy, long and uncertain time lags can mean that the government can end up stimulating the economy in a boom and contracting it in a slump.

So what should be done? One alternative, of course, would be to try to reduce the time lags and to improve forecasting. But failing this, the best policy may be to do nothing: to take

a 'steady as you go' or 'fixed throttle' approach to running the economy. Going back to the car analogy, a fixed throttle will not prevent the car from going faster downhill and slower uphill, but at least it will not make the speed even more irregular.

A recent version of the parable

In an article in the *New Statesman* on what Keynes' response would have been to the recovery and getting the public-sector deficit down, Vince Cable, the then UK Business Secretary, wrote:

As in many economic policy disputes, much of the ideological rhetoric conceals different forecasting assumptions – in respect of the cyclical, as opposed to structural, deficit; the influence of asset prices on consumer behaviour; the impact of the unorthodox monetary policy of quantitative easing (QE) and its interaction with the velocity of circulation of money; and the weight to be attached to business confidence and sentiment in financial markets. Amid such uncertainty, economic policymaking is like driving a car with an opaque windscreen, a large rear-view mirror and poor brakes.¹

So what are the policy implications of this uncertainty and the time lags in response to government policy initiatives? The Coalition government saw the answer in a fiscal rule of getting the deficit down and thereby restoring long-term confidence in financial markets and encouraging private investment.

Critics of the government argued that policy needed to be flexible and responsive to current circumstances. Even with the time lags associated with fiscal policy, it was probably better to ease back on cutting the deficit so quickly if demand appeared to falter rather than just sticking with the planned government expenditure cuts.

But at least there were the automatic fiscal stabilisers – the car's accelerator would automatically come on and the brake would be eased if the economy slowed down.

What would a fixed throttle approach to fiscal policy involve?

¹ Vince Cable, 'Keynes would be on our side', *New Statesman*, 12 January 2011.

require more discretion than the current rules allow for. Hence, how flexible should any rules be?

Following the severe disruption to the global economy that occurred with the credit crunch of 2008, countries around the world resorted to discretionary fiscal policy to boost aggregate demand. Many abandoned fiscal rules – at least temporarily. However, rules were generally reinstated

around the world as the global economy pulled out of recession. In Boxes 22.2 and 22.4 we detail how the fiscal rules in the UK and the eurozone, respectively, evolved following the events of the late 2000s.

In section 22.4 we review the debate concerning constraints on a government's discretion – over both its fiscal and its monetary policies.

BOX 22.4 THE EVOLVING FISCAL FRAMEWORK IN THE EUROPEAN UNION**Constraining government discretion over fiscal policy****Preparing for the euro**

In signing the Maastricht Treaty in 1992, the EU countries agreed that to be eligible to join the single currency (i.e. the euro), they should have sustainable deficits and debts. This was interpreted as follows: the general government deficit should be no more than 3 per cent of GDP and general government debt should be no more than 60 per cent of GDP, or should at least be falling towards that level at a satisfactory pace.

But in the mid-1990s, several of the countries that were subsequently to join the euro had deficits and debts substantially above these levels (see chart). Getting them down proved a painful business. Government expenditure had to be cut and taxes increased. These fiscal measures, unfortunately, proved to be powerful! Unemployment rose and growth remained low.

The EU Stability and Growth Pact (SGP)

In June 1997, at the European Council meeting in Amsterdam, the EU countries agreed a Stability and Growth Pact (SGP). Under the SGP, governments adopting the euro should seek to balance their budgets (or even aim for a surplus) averaged over the course of the business cycle, and deficits should not exceed 3 per cent of GDP in any one year. A country's deficit was permitted to exceed 3 per cent only if its GDP declined by at least 2 per cent (or 0.75 per cent with special permission from the Council of Ministers). Otherwise, countries with deficits exceeding 3 per cent were required to make deposits of money with the European Central Bank. These would then become fines if the excessive budget deficit were not eliminated within two years.

There were two main aims of targeting a zero budget deficit over the business cycle. The first was to allow automatic stabilisers to work without 'bumping into' the 3 per cent deficit ceiling in years when economies were slowing. The second was to allow a reduction in government debts as a proportion of GDP (assuming that GDP grows on average at around 2–3 per cent per year).

From 2002, with slowing growth, Germany, France and Italy breached the 3 per cent ceiling (see chart). By 2007,

however, after two years of relatively strong growth, deficits had been reduced well below the ceiling.

But then the credit crunch hit. As the EU economies slowed, so deficits rose. To combat the recession, in November 2008 the European Commission announced a €200 billion fiscal stimulus plan, mainly in the form of increased public expenditure; €170 billion of the money would come from member governments and €30 billion from the EU, amounting to a total of 1.2 per cent of EU GDP. The money would be for a range of projects, such as job training, help to small businesses, developing green energy technologies and energy efficiency. Most member governments quickly followed in announcing how their specific plans would accord with the overall plan.

The combination of the recession and the fiscal measures pushed most eurozone countries' budget deficits well above the 3 per cent ceiling, as the chart shows. The recession in EU countries deepened markedly in 2009, with GDP declining by 4.5 per cent in the eurozone as a whole, and by 5.6 per cent in Germany, 5.5 per cent in Italy, 3.6 per cent in Spain and 2.9 per cent in France. Consequently, the deficits were not seen to breach SGP rules.

In some cases, countries' public finances deteriorated unsustainably. Following high-profile rescue packages to Greece, Ireland and Portugal involving the International Monetary Fund and EU, the EU established a funding mechanism for eurozone countries in financial difficulties, known as the European Stability Mechanism (ESM). The ESM can provide loans to such countries or purchase the countries' bonds in the primary market. It became operational in October 2012. As well as taking on the management of existing rescue packages, financial assistance was granted subsequently to Spain and Cyprus.

The Fiscal Compact

With many countries experiencing burgeoning deficits and some countries requiring financial assistance, the SGP was no longer seen as a credible vehicle for constraining deficits: it needed reform. The result was an intense period of negotiation that culminated in early 2012 with a new

Section summary

1. Automatic fiscal stabilisers are tax revenues that rise, and benefits that fall, as national income rises. They have the effect of reducing the size of the multiplier and thus reducing cyclical upswings and downswings.
2. Automatic stabilisers take effect as soon as aggregate demand fluctuates, but they can never remove fluctuations completely. They also create disincentives and act as a drag on recovery from recession.
3. Discretionary fiscal policy is where the government deliberately changes taxes or government expenditure in order to alter the level of aggregate demand. Changes in government expenditure on goods and services have a full multiplier effect. Changes in taxes and benefits, however, have a smaller multiplier effect. The tax multiplier has a value 1 less than the full multiplier.
4. There are problems in predicting the magnitude of the effects of discretionary fiscal policy. Expansionary fiscal policy can act as a pump primer and stimulate increased private expenditure, or it can crowd out private expenditure. The extent to which it acts as a pump primer

General government deficits in the eurozone

intergovernmental treaty on limiting spending and borrowing. The treaty, known as the Fiscal Compact, requires that from January 2013 national governments not only abide by the excessive deficit procedure of the SGP but also keep structural deficits no higher than 0.5 per cent of GDP.

Structural deficits are that part of a deficit not directly related to the economic cycle and so would exist even if the economy were operating at its potential output. In the cases of countries with a debt-to-GDP ratio significantly below 60 per cent, the structural deficit is permitted to reach 1 per cent of GDP. Finally, where the debt-to-GDP ratio exceeds 60 per cent, countries should, on average, reduce it by one-twentieth per year.

The average structural deficit across the eurozone fell from 4.3 per cent of GDP in 2010 to 1.1 per cent in 2016. This

improvement was mirrored in most individual eurozone countries, with particularly large improvements in Greece (–10 to +3.7 per cent) and Ireland (–9.9 to –1.9 per cent), which had received financial assistance but with conditions attached that they cut spending and raise taxes. Nonetheless, most countries still had structural deficits in excess of the target levels of the Fiscal Compact.

Where a national government is found by the European Court of Justice not to comply with the Fiscal Compact, it has the power to fine that country up to 0.1 per cent of GDP payable to the European Stability Mechanism (ESM).

If there is a danger of recession, should governments loosen the straitjacket of fiscal policy targets?

depends crucially on business confidence – something that is very difficult to predict beyond a few weeks or months. The extent of crowding out depends on monetary conditions and the government's monetary policy.

- There are five possible time lags involved with fiscal policy: the time lag before the problem is diagnosed, the lag between diagnosis and new measures being announced, the lag between announcement and implementation, the lag while the multiplier and accelerator work themselves out, and the lag before

consumption fully responds to new economic circumstances.

- In recent years, many governments preferred a more passive approach towards fiscal policy. Targets were set for one or more measures of the public-sector finances, and then taxes and government expenditure were adjusted so as to keep to the target.
- Nevertheless, in extreme circumstances, as occurred in 2008/9, governments were prepared to abandon rules and give a fiscal stimulus to their economies.

22.3 MONETARY POLICY

The Bank of England's Monetary Policy Committee (MPC) regularly meets to set the Bank Rate and possibly consider whether or not to alter the money supply directly through quantitative easing (see Box 22.10). The event often gets considerable media coverage, especially when a change is expected.

The fact is that changes in interest rates have gained a central significance in macroeconomic policy. And it is not just in the UK. Whether it is the European Central Bank setting interest rates for the eurozone countries, or the Federal Reserve Bank setting US interest rates, or any other central bank around the world choosing what the level of interest rates should be, monetary policy is seen as having a major influence on a whole range of macroeconomic indicators.

But is setting interest rates simply a question of making an announcement? In reality, it involves the central bank intervening in the money market to ensure that the interest rate announced is also the *equilibrium* interest rate.

The policy setting

In framing its monetary policy, the government must decide on what the goals of the policy are. Is the aim simply to control inflation, or does the government wish also to affect output and employment, or does it want to control the exchange rate?

The government also has to decide the role of the central bank in carrying out monetary policy. There are three possible approaches.

In the first, the government both sets the policy and decides the measures necessary to achieve it. Here the government would set the interest rate, with the central bank simply influencing money markets to achieve this rate. This first approach was used in the UK before 1997.

The second approach is for the government to set the policy *targets*, but for the central bank to be given independence in deciding interest rates. This is the approach adopted in the UK today. The government has set a target rate of CPI inflation of 2 per cent, but then the MPC is free to choose the rate of interest.

The third approach is for the central bank to be given independence not only in carrying out policy, but in setting the policy target itself. The ECB, within the statutory objective of maintaining price stability over the medium term, has decided on the target of keeping inflation below, but close to, 2 per cent over the medium term.

Finally, there is the question of whether the government or central bank should take a long-term or short-term perspective. Should it adopt a target for inflation or money supply growth and stick to it come what may? Or should it adjust its policy as circumstances change and attempt to 'fine-tune' the economy?

We will be looking primarily at *short-term* monetary policy: that is, policy used to keep to a set target for inflation or money supply growth, or policy used to smooth out fluctuations in the business cycle.

It is important first, however, to take a longer-term perspective. Governments generally want to prevent an excessive growth in the money supply over the longer term. Likewise they want to ensure that money supply grows enough and that there is not a shortage of credit, such as that during the credit crunch. If money supply grows too rapidly over the longer term, then high inflation is likely to become embedded in the economy, which will feed inflationary expectations; if money supply grows too slowly, or even falls, then recession is likely to result, investment may fall and long-term growth may be subdued.

Control of the money supply over the medium and long term

There are two major sources of monetary growth: (a) banks choosing to hold a lower liquidity ratio (probably in response to an increase in the demand for loans); (b) public-sector borrowing financed by borrowing from the banking sector. If the government wishes to restrict monetary growth over the longer term, it could attempt to control either or both of these.

Banks' liquidity ratio

The central bank could impose a statutory *minimum reserve ratio* on the banks, *above* the level that banks would otherwise choose to hold. Such ratios come in various forms. The simplest is where the banks are required to hold a given minimum percentage of deposits in the form of cash or deposits with the central bank. Other versions are where they are required to hold a given minimum percentage of certain specified types of deposit in the form of various liquid assets. This was the system used in the UK up to 1981. Various types of liquid asset had to add up to at least 12.5 per cent of certain 'eligible liabilities'.

The effect of a minimum reserve ratio is to prevent banks choosing to reduce their cash or liquidity ratio and creating more credit. This was a popular approach of governments in many countries in the past. Some countries imposed very high ratios indeed in their attempt to slow down the growth in the money supply.

Definition

Minimum reserve ratio A minimum ratio of cash (or other specified liquid assets) to deposits (either total or selected) that the central bank requires banks to hold.

Minimum reserve ratios also have the effect of reducing the bank deposits multiplier, since, for any expansion of the monetary base, less credit can be created. For example, if banks would otherwise choose a 10 per cent cash ratio, and if the central bank imposes a 20 per cent cash ratio, the bank deposits multiplier is reduced from 10 ($= 1/1/10$) to 5 ($= 1/1/5$).

A major problem with imposing restrictions of this kind is that banks may find ways of getting round them. After all, normally banks would like to lend and customers would like to borrow. It is very difficult to regulate and police every single part of countries' complex financial systems.

Nevertheless, attitudes changed substantially after the excessive lending of the mid-2000s. The expansion of credit had been based on 'liquidity' achieved through secondary marketing between financial institutions and the growth of securitised assets containing sub-prime debt (see pages 558–63 and Box 18.3). After the credit crunch and the need for central banks or governments to rescue ailing banks, such as Northern Rock and later the Royal Bank of Scotland in the UK and many other banks around the world, there were calls for greater regulation of banks to ensure that they had sufficient capital and operated with sufficient liquidity and that they were not exposed to excessive risk of default. As we saw in section 18.2, a number of measures were taken.

Public-sector deficits

In section 18.3, we showed how government borrowing tends to lead to an increase in money supply. To prevent this, deficits must be financed by selling *bonds* (as opposed to bills, which could well be taken up by the banking sector, thereby increasing money supply). However, to sell extra bonds the government will have to offer higher interest rates. This will have a knock-on effect on private-sector interest rates. The government borrowing will thus crowd out private-sector borrowing and investment.

If governments wish to reduce monetary growth and yet avoid financial crowding out, they must therefore reduce deficits. It is partly for this reason that many governments have constrained fiscal policy choices by applying fiscal rules or agreements, such as the 'fiscal mandate' in the UK or the Fiscal Compact in the eurozone (see Boxes 22.2 and 22.4).

How could long-term monetary growth come about if the government persistently ran a public-sector surplus?

Long-term monetary control and inflation

Although there are issues with achieving long-term control of the money supply, there is widespread agreement that it is important to do so. The argument is that *increasing* the money supply cannot increase output in the long run; all that will happen is an increase in prices.

It is argued that in the long run – after all adjustments in the economy have worked through – a change in the quantity of money in the economy will be reflected in a change in the general level of prices. But it will not induce permanent changes in real variables such as real output or unemployment.

This general principle, referred to as the **long-run neutrality of money**, underlies much macroeconomic thinking. Real income or the level of employment are, in the long term, essentially determined by real factors, such as technology, population growth or the preferences of economic agents.²

If inflation is to be kept under control, therefore, it is important to control the supply of money. And if long-term control is to be achieved, it is also important not to allow excessive expansion (or contraction) of the money supply in the short term too. But what instruments does a central bank have at its disposal? We examine these next.

The operation of monetary policy in the short term

Assume that inflation is above its target rate and that the central bank wishes to operate a tighter monetary policy in order to reduce aggregate demand and so the rate of inflation. What can it do?

Aggregate demand is dependent on real interest rates (r). Assuming that in the short term the central bank is able to take the expected rate of inflation (π^e) as given, any change in the nominal rate of interest (i) will be matched by an equivalent change in the real rate of interest (r).

For any given supply of money (M_s) there will be a particular equilibrium real rate of interest at any one time: where the supply of money (M_s) equals the demand for money (L). This is shown as r_1 in Figure 22.6.

Thus to operate a tighter monetary policy, the authorities can do one of the following:

- Reduce money supply and accept whatever equilibrium interest rate results. Thus if money supply is reduced to Q_2 in Figure 22.6, a new higher rate of interest, r_2 , will result.
- First raise interest rates to r_2 and then manipulate the money supply to reduce it to Q_2 . The more endogenous the money supply is, the more this will occur automatically through banks adjusting credit to match the lower demand at the higher rate of interest and the less the central bank will have to take deliberate action to reduce liquidity.

Definition

Long-run neutrality of money Changes in money supply over the long run will only affect prices and not real output or employment.

² See European Central Bank, www.ecb.int/mopo/intro/role/html/index.en.html

Figure 22.6 The demand for and supply of money

There is another possibility. This is to keep interest rates low (at r_1), but also reduce money supply to a level of Q_2 . The trouble here is that the authorities cannot both control the money supply *and* keep interest rates down without running into the problem of disequilibrium. Since the demand for money now exceeds the supply by $Q_1 - Q_2$, some form of credit rationing would have to be applied.

Credit rationing was widely used in the past, especially during the 1960s. The aim was to keep interest rates low, so as not to discourage investment, but to restrict credit to more risky business customers and/or to consumers. In the UK the Bank of England could order banks to abide by such a policy, although in practice it always relied on persuasion. The government also, from time to time, imposed restrictions on hire-purchase credit, by specifying minimum deposits or maximum repayment periods.

Such policies were progressively abandoned around the world from the early 1980s. They were seen to stifle competition and prevent efficient banks from expanding. Hire-purchase controls could badly hit certain industries (e.g. cars and other consumer durables), whose products are bought largely on hire-purchase credit. What is more, with the deregulation and globalisation of financial markets up to 2007, it had become very difficult to ration credit. If one financial institution was controlled, borrowers could simply go elsewhere.

With the excessive lending in sub-prime markets that had triggered the credit crunch of 2007–9, however, there were calls around the world for tighter controls over bank lending. But this was different from credit rationing as we have defined it. In other words, tighter controls, such as applying counter-cyclical buffers of capital to all banks (see pages 564–5), would be used to prevent reckless behaviour by banks, rather than to achieve a particular level of money at a lower rate of interest.

We thus focus on the two major approaches to monetary policy: (a) controlling the money supply and (b) controlling interest rates.

Techniques to control the money supply

There are two broad approaches to controlling the money supply.

The first is to alter the level of liquidity in the banking system, on which credit is created. Suppose, for example, that banks operate a rigid 10 per cent cash ratio and have just two types of asset: cash and advances. Suppose also that the authorities are able to reduce cash in banks by £1 million. With a bank multiplier of 10 ($= 1/\text{cash ratio}$), advances must be reduced by £9 million, and hence (broad) money supply by £10 million (see Table 22.2).

? *If banks operated a rigid 5 per cent cash ratio and the government reduced cash in banks by £1 million, how much must credit contract? What is the bank deposits multiplier?*

The second approach is to alter the size of the bank deposits multiplier, by altering the ratio of reserves to deposits. Thus if the bank deposits multiplier can be reduced, credit will have to be reduced for any given reserve base.

Before they can apply techniques of monetary control, the authorities must make two preliminary decisions:

- Should a statutory minimum reserve or a minimum liquidity ratio be imposed on the banks, or should the banks be allowed to choose whatever ratios they consider to be prudent?
- Should the authorities attempt to control a range of liquid assets, or should they focus on controlling just the monetary base?

There are four techniques that a central bank could use to control the money supply. Assume in each case that the central bank wishes to *reduce* money supply.

Open-market operations

Open-market operations (OMOs) are the most widely used of the four techniques around the world. They alter the monetary base (cash in circulation outside the central

Table 22.2 Reducing the money supply

Change in liabilities		Change in assets	
Deposits	£10m ↓	Cash	£1m ↓
		Advances	£9m ↓

Definition

Open-market operations The sale (or purchase) by the authorities of government securities in the open market in order to reduce (or increase) money supply.

bank). This then affects the amount of credit that banks can create and hence the level of broad money (M4 in the UK; M3 in the eurozone).

Open-market operations involve the sale or purchase by the central bank of government securities (bonds or bills) in the open market. These sales or purchases are *not* in response to changes in the level of government deficits/surpluses. Rather, they are being conducted to implement monetary policy. Hence, they are best understood in the context of an unchanged deficit.

Assume that the central bank wishes to *reduce* the money supply. It will conduct OMOs so as to reduce financial institutions' reserves. It can do this by borrowing from financial institutions against government securities. To do so, it will use reverse repos on banks' balance sheets: i.e. temporarily selling government securities, with an agreement to buy them back later. These securities include government bonds or short-term Treasury or central bank bills. Alternatively the central bank can sell securities outright.

The borrowing against securities or the direct sale of securities reduces the reserve balances of financial institutions at the central bank. If the reduction in banks' balances brings bank reserves below their prudent ratio (or statutory ratio, if one is in force), banks will reduce advances. There will be a multiple contraction of credit and hence of (broad) money supply. (Details of how open-market operations work in the UK are given in Box 22.5.)

The effect will be limited if the extra securities are bills (as opposed to bonds) and if some are purchased by banks. The reduction in one liquid asset (balances with the central bank) will be offset to some extent by an increase in another liquid asset (bills). Open-market operations are more likely to be effective in reducing the money supply, therefore, when conducted in the bond market.

1. Explain how open-market operations could be used to increase the money supply.
2. Why would it be difficult for a central bank to predict the precise effect on money supply of open-market operations?

Adjusting central bank lending to the banks

In most countries, the central bank is prepared to provide extra money to banks (through rediscounting bills, gilt repos or straight loans). If banks obtain less money in this way, they will have to cut back on lending. Less credit will be created and broad money supply will thereby be reduced.

Whether or not banks *choose* to obtain extra money from the central bank depends on (a) the rate of interest charged by the central bank (i.e. its discount rate, repo rate or lending rate); and (b) its willingness to lend (or repurchase securities).

In some countries, it is the policy of the central bank to keep its interest rate to banks *below* market rates, thereby encouraging banks to borrow (or sell back securities) whenever such facilities are available. By controlling the amount

of money it is willing to provide at these low rates, the central bank can control the monetary base and hence the amount of credit that banks can create.

In other countries, such as the UK and the eurozone countries, it is not so much the amount of money made available that is controlled, but rather the rate of interest (or discount). The higher this rate is relative to other market rates, the less willing will banks be to borrow and, hence, the lower will be the monetary base. Raising the central bank's interest rate, therefore, has the effect of reducing the money supply.

In some countries, central banks operate two rates: a main repo rate (or 'refinancing rate') on a set amount of money that the central bank wants to be made available, and a higher rate (a penal rate) used for 'last-resort' lending to banks short of liquidity. The European Central Bank operates such a system (see Box 22.7). Its higher rate is known as the 'marginal lending facility rate'.

Some central banks, including the ECB, have a third, lower rate. This is the rate they are willing to pay banks for short-term deposits of surplus money in the central bank. In some countries this rate became negative (a charge on banks) in the mid-2010s to encourage banks to lend money rather than merely keeping it on deposit at the central bank.

In response to the credit crunch of the late 2000s, central banks in several countries extended their willingness to lend to banks. The pressure on central banks to act as the 'liquidity backstop' grew as the inter-bank market ceased to function effectively in distributing reserves and, hence, liquidity between financial institutions. As a result, inter-bank rates rose sharply relative to the central bank's main rate. Increasingly, the focus of central banks was on providing the necessary liquidity to ensure the stability of the financial system. Yet, at the same time, by providing more liquidity, central banks were ensuring that monetary policy was not being compromised. The additional liquidity was needed to alleviate the upward pressure on market interest rates.

Changing the method of funding the national debt

Rather than focusing on controlling the monetary base (as in the case of the above two techniques), an alternative is for the authorities to attempt to alter the overall liquidity position of the banks. An example of this approach is a change by the authorities (the Debt Management Office in the UK) in the balance of *funding* the national debt. To reduce money supply the authorities issue more bonds and fewer bills. Banks' balances with the central bank will be little affected, but to the extent that banks hold fewer bills,

Definition

Funding (in monetary policy) Where the authorities alter the balance of bills and bonds for any given level of government borrowing.

BOX 22.5

THE OPERATION OF MONETARY POLICY IN THE UK

What goes on at Threadneedle Street?

The Bank of England (the 'Bank') does not normally attempt to control money supply directly. Instead it seeks to control interest rates. There are two principal elements to the framework in which it conducts monetary policy. First, it conducts *open-market operations* (OMOs) to adjust the aggregate amount of banks' reserves. Second, *standing facilities* allow individual banks to borrow reserves overnight directly from the Bank or to deposit reserves overnight at the Bank.

The framework is designed to determine short-term interest rates, which then have a knock-on effect on longer-term rates, as returns on different forms of assets must remain competitive with each other.

Normal operation of the monetary framework

The Monetary Policy Committee (MPC) of the Bank of England meets several times per year to decide on Bank Rate. Changes in the Bank Rate are intended to affect the whole structure of interest rates in the economy, from inter-bank rates to bank deposit rates and rates on mortgages and business loans. The monetary framework works to affect the general structure of interest rates, principally by affecting short-term *inter-bank rates*.

Central to the process are the reserve accounts of financial institutions at the Bank of England (see section 18.2, page 566). From the inception of the current system in May 2006, commercial banks have agreed with the Bank of England the average amount of reserve balances they would hold between MPC meetings. So long as the average over the month is within a small range, the reserves are remunerated at Bank Rate.

In order for individual banks to meet their reserve targets, the Bank of England needs to provide sufficient reserves. To do so, it uses OMOs. In normal circumstances, the Bank of England conducts short-term OMOs every week (on a Thursday) at Bank Rate. The size of the weekly OMO is adjusted to help banks maintain reserves at the target level and to reflect variations in the amount of cash withdrawn or deposited in banks.

To supply reserves the Bank of England will either enter into short-term repo operations, lending against collateral ('high-quality' government securities), or buy securities outright. Although there is usually a shortage of liquidity in the banking system, in some weeks there may be a surplus. This would ordinarily drive market interest rates down. Depending on the Bank Rate, the Bank may look to reduce banks' reserves. To do this it can sell government securities on a repo basis, invite bids for Bank of England one-week sterling bills or sell outright some of its portfolio of securities.

At the end of the period between MPC interest rate decisions, the Bank of England conducts a 'fine-tuning' OMO. This is conducted on a Wednesday – the day before the MPC decision on interest rates. The idea is to ensure that banks meet their reserve targets as closely as possible. This OMO could expand or contract liquidity as appropriate.

Longer-term finance is available through longer-term open market operations. Prior to the financial crisis of the late 2000s, longer-term OMOs would normally be conducted once per month. As well as the outright purchase of gilts, the Bank would conduct repo lending with 3-, 6-, 9- or 12-month maturities.

there will be a reduction in their liquidity and hence a reduction in the amount of credit created. Funding is thus the conversion of one type of government debt (liquid) into another (illiquid).

One problem with this approach is that bonds are likely to command a higher interest rate than bills. By switching from bills to bonds, the government will be committing itself to these interest rates for the life of the bond.

 If the Bank of England issues £1 million of extra bonds and buys back £1 million of Treasury bills, will there automatically be a reduction in credit by a set multiple of £1 million?

Variable minimum reserve ratios

If banks are required to maintain a statutory minimum reserve ratio and if the central bank is free to alter this ratio, it can use it as a means of controlling the money supply. It does this by affecting not the monetary base, but the size of the bank multiplier.

Assume that there are just two types of asset: cash and advances, and that banks are required to maintain a

minimum 10 per cent cash ratio (a ratio above that which the banks would have chosen for reasons of prudence). The bank multiplier is thus $10 (= 1/1/10)$. Assume that banks' total assets are £100 billion, of which £10 billion are cash reserves and £90 billion are advances. This is illustrated in the first part of Table 22.3.

Now assume that the central bank raises the minimum reserve ratio to 20 per cent. Banks still have £10 billion cash reserves, and so they have to reduce their advances to £40 billion (giving total assets of £50 billion, of which the £10 million cash is the required 20 per cent). This is shown in the second part of Table 22.3. The bank multiplier has been reduced to $5 (= 1/1/5)$.

In the past, central banks that imposed minimum reserve ratios on the banks tended to vary them in this way as a means of altering the money supply for any given monetary base. For example, several of the EU countries used this technique before joining the euro. Increasingly, countries that still have minimum reserve ratios are relying on open-market operations or direct lending to banks, rather than on varying the ratio. This is the case with the ECB, which has a fixed

The rate of interest on the repos is market determined. Banks bid for the money and the funds are offered to the successful bidders. The bigger the demand for these funds by banks and the lower the supply by the Bank of England, the higher will be the interest rate that banks must pay. By adjusting the supply, therefore, the Bank of England can look to influence longer-term interest rates too.

With the aggregate amount of banks' reserves determined by the Bank of England's OMOs, the task now is for individual banks to meet their agreed reserve targets. This requires that they manage their balance sheets and, in particular, their level of liquidity. In doing so, commercial banks can make use of either the *inter-bank* market or the 'standing facilities' at the Bank of England. These standing facilities allow individual banks to borrow overnight (secured against high-quality collateral) at a rate *above* Bank Rate or to deposit reserves with the Bank at a rate *below* Bank Rate. Consequently, banks will trade reserves with each other if inter-bank rates fall within the corridor created by the interest rates of the standing facilities.

The financial crisis and the monetary framework

The financial crisis meant that normal OMOs were no longer sufficient to maintain liquidity for purposes of monetary policy. There was a severe liquidity crisis – one which posed grave risks for financial stability.

In response, from January 2009 the Bank of England deliberately injected narrow money in a process known as 'quantitative easing' (see Box 22.10). This involved the Bank

of England purchasing assets, largely gilts, from financial institutions. The Bank argued that its asset purchase programme was an important monetary policy tool in meeting its inflation rate target.

Between January 2009 and July 2012 the Bank of England injected £375 billion through the purchase of gilts. In August 2016, following the UK's vote to leave the European Union and concerns about deteriorating prospects for growth, the Bank of England decided to increase its gilt purchases by a further £60 billion and in addition to purchase up to £10 billion of UK corporate bonds.

As a result of this significant increase in aggregate reserves, banks were no longer required to set reserve targets. The supply of reserves was now being determined by MPC policy decisions. All reserves were to be remunerated at the Bank Rate.

Furthermore, short-term OMOs were temporarily suspended. Long-term repo operations continued but these were modified to allow financial institutions to sell a wider range of securities. It also adapted its means of providing liquidity insurance (see section 18.2, pages 566–9). This includes the introduction of the Discount Window Facility (DWF), which enables banks to borrow government bonds (gilts) against a wide range of collateral which can then be used in repo operations to secure liquidity.

Assume that the Bank of England wants to raise interest rates. Trace through the process by which it achieves this.

Table 22.3 Effect of raising the minimum reserve ratio from 10% to 20%

Initial position: 10% reserve ratio				New position: 20% reserve ratio			
Liabilities		Assets		Liabilities		Assets	
Deposits	£100bn	Reserve assets	£10bn	Deposits	£50bn	Reserve assets	£10bn
		Advances, etc.	£90bn			Advances, etc.	£40bn
Total	£100bn	Total	£100bn	Total	£50bn	Total	£50bn

reserve ratio.³ Nevertheless, in January 2012 it was lowered from 2 per cent to 1 per cent in a 'one-off' effort to increase lending. It remains at 1 per cent. The USA, however, still uses variable minimum reserve ratios as a monetary policy tool, although increasingly less so (see Box 22.6).⁴

³ It was lowered from 2 per cent to 1 per cent in January 2012.

⁴ In one sense, it could be argued that the imposition of a minimum reserve ratio is a *form* of credit rationing. It restricts the ability of banks to expand credit as much as they would like for the amount of reserves they hold. In Figure 22.6, however, higher minimum reserves would still shift the *supply* curve, given that this curve measures broad money and not the monetary base. It is for this reason that we considered minimum reserve ratios under the heading of 'techniques to control the money supply'.

Difficulties in controlling money supply

The authorities may experience considerable difficulties in controlling broad money supply. Difficulties occur whether they focus on doing this via control of narrow money – the 'monetary base' – or whether they attempt to control a wider range of liquid assets.

Problems with monetary base control

Assume that the authorities seek to control narrow money: i.e. notes and coin. This could be done by imposing a statutory cash ratio on banks. Assume that a statutory ratio of 10

BOX 22.6 CENTRAL BANKING AND MONETARY POLICY IN THE USA

How the 'Fed' works

The central bank in the USA is called the Federal Reserve System (or 'Fed'). It was set up in 1913 and consists of 12 regional Federal Reserve Banks, each of which is responsible for distributing currency and regulating banks in its region. But despite its apparent regional nature, it is still a national system. The Federal Reserve Board, based in Washington, decides on monetary policy and then the Federal Open Market Committee (FOMC) decides how to carry it out. The FOMC meets eight times a year. The Fed is independent of both the President and the Congress, and its chairman is generally regarded as having great power in determining the country's economic policy.

Its macroeconomic objectives include low inflation, sustainable economic growth, low unemployment and moderate long-term interest rates. Of course, these objectives may well conflict from time to time. In such a case, an assessment has to be made of which is the most pressing problem.

When there is no threat of rising inflation, the Fed may use monetary policy aggressively to pursue these other goals. Thus, from January to December 2001, with the US economy moving into recession, the FOMC cut interest rates 10 times. In January the rate was 6 per cent; by December it was down to 1.75 per cent.

Even when inflation is rising, the Fed may still cut interest rates if the economy is slowing. With the onset of the credit crunch of 2007/8, the Fed cut rates several times. In August 2007, the rate was 5.25 per cent. By August 2008 it had been cut to 2 per cent, even though inflation was rising. Then as inflation fell and recession deepened, rates were cut again to stand at between 0 and 0.25 per cent by December 2008.

The Fed's policy instruments

To carry out its objectives, the FOMC has traditionally had three policy instruments.

Open-market operations. The most important one is *open-market operations*. These are conducted through the Federal Reserve Bank of New York, which buys and sells Treasury bills and government bonds. For example, if the FOMC wishes to increase money supply, the New York Fed will buy more of these securities. The purchasers, whether they be banks,

corporations or individuals, will have their bank accounts duly credited. In other words, the Fed credits the accounts of sellers with a deposit and this enables a multiple increase in credit.

The discount rate. The second policy instrument is the *discount rate*. Known as the 'federal funds rate', this is the rate of interest at which the Fed is willing to lend to banks, thereby providing them with liquidity on which they can create credit. This is known as 'lending through the discount window'. If this rate is raised, banks are discouraged from borrowing, and credit is thereby squeezed. Since 1995, the FOMC has published its target federal funds rate. Sometimes this rate merely mirrors other market rates and is not, therefore, an active instrument of policy. On other occasions, however, the Fed changes it ahead of other market rates in order to signal its intentions to tighten (or loosen) monetary policy.¹

Variable minimum reserve requirements. Banks are legally required to hold a certain minimum percentage of eligible deposit liabilities as reserves. Interest is paid on these reserves. The reserve requirement is dependent on the size of a bank's eligible deposit liabilities. Banks with an amount of liabilities falling within an adjustable exemption range have no reserve requirement. Above this is the 'low-reserve tranche' range. As of January 2017, banks with eligible deposit liabilities within this range must hold 3 per cent of deposits in reserves. Banks with an eligible deposit total in excess of this must hold 10 per cent in reserves.

Currently the only deposit accounts subject to reserve requirements are transaction accounts, which include sight accounts ('checking accounts') and time deposits. The Fed can vary the types of deposits subject to the reserve requirement as well as the size and number of bands and the reserve ratios. Given that any change in the reserve ratio causes a multiplied effect on advances, changes are made only occasionally and by a small amount.

Response to the credit crunch

With the credit crunch of 2007/8 and the difficulties of banks in obtaining finance from the inter-bank market, the Fed extended its activities. It made considerable liquidity

per cent is imposed. Then provided the authorities control the supply of cash by, say, open-market operations, it would seem that they can thereby control the creation of credit and hence deposits. There would be a bank multiplier of 10. For every £1 million decrease in cash held by the banks, money supply would fall by £10 million. There are serious problems, however, with this form of *monetary base control*:

- Banks could hold cash in excess of the statutory minimum. For a time, therefore, they could respond to any

restriction of cash by the authorities by simply reducing their cash ratio towards the minimum, rather than having to reduce credit.

Definition

Monetary base control Monetary policy that focuses on controlling the monetary base (as opposed to broad liquidity).

available to banks by swapping Treasury bills for hard-to-trade securities, such as mortgage-backed bonds and other securitised assets, including those backed by student loans. It also extended the period of its short-term loans through the discount window and was now willing to lend not only to retail banks but to investment banks and mortgage lenders too.

Then in October 2008, the US government adopted a \$700 billion rescue package for the ailing US financial system. This was known as the Troubled Asset Relief Program (TARP). The plan was to purchase 'distressed assets' including collateralised debt obligations (see section 18.2). The purchases were designed to provide liquidity for the holders of these CDOs, to stabilise the financial system and, in turn, encourage bank lending. In return for participating in TARP, financial institutions effectively gave the US Treasury part-ownership. Revisions to the TARP programme saw the first \$250 billion allocated for the programme used to purchase preference shares from nine of the largest US banks. Subsequently, purchases of toxic assets took place, including mortgage-backed securities.

The US government's measures were backed up the Fed, which embarked on an aggressive policy of increasing the money supply through the purchase of long-term securities. The first round of quantitative easing (QE1) was announced in November 2008 with the intention to purchase \$100 billion of corporate debt issued by government-sponsored financial enterprises and \$500 billion of mortgage-backed securities (MBSs), including MBSs guaranteed by the two main mortgage lenders Fannie Mae and Freddie Mac, which had recently been nationalised to save them from collapse.

In March 2009, the Fed announced that it would increase its purchases of debt issued by government-sponsored financial enterprises by a further \$100 billion and its purchases of MBSs by a further \$750 billion. The hope was to stimulate bank lending and revive the collapsed housing market. It also announced that it would purchase \$300 billion of longer-term Treasury securities

Despite these measures the economy remained fragile. In November 2010 a second round of quantitative easing (QE2) was announced. Between November 2010 and June 2011 it expanded its holding of longer-term Treasury securities by \$600 billion. The aim was 'to promote a stronger pace of economic recovery'.

In September 2011, the Fed announced that in the period up to June 2012 it would buy up to \$400 billion of long-term government bonds in the market and sell an equal amount of shorter-dated ones (of less than three years). The plan became known as 'Operation Twist'. It is a way of altering the *funding* of national debt, rather than directly altering the monetary base. The idea was to drive up the price of long-term bonds and hence drive down their yield and thereby drive down long-term interest rates. The hope was to stimulate investment and longer-term borrowing. The plan was expanded in June 2012 with the sale of a further \$267 billion in Treasury securities by the end of the year.

In September 2012, the US Federal Reserve bank launched a third round of quantitative easing (QE3). The Fed would buy mortgage-backed securities of \$40 billion per month, extended to \$85 billion per month in December 2012. And this would go on for as long as it took for the employment market to show significant improvement. It was this open-ended commitment which made QE3 different from QE1 and QE2. Under QE1 and QE2, the Fed purchased \$2.3 trillion of assets.

In December 2013, the Federal Reserve announced the start of a tapering of its quantitative easing programme. In other words, monthly purchases of MBSs and longer-term Treasury securities were reduced. The conclusion of QE3 was formally announced in October 2014 after accumulating assets of \$2.5 trillion.

As the rate of US economic growth increased to over 2 per cent by 2014 and as unemployment fell, so it was expected that interest rates would eventually begin to rise and that more 'normal' times would return. In December 2015, the Fed raised the federal funds rate by 0.25 percentage points (the first increase since June 2006) and by another 0.25 percentage points in December 2016 and in March and June 2017 (see Figure 22.8 on page 695).

1. In what ways is the Fed's operation of monetary policy (a) similar to and (b) different from the Bank of England's?
2. Could there be a potential moral hazard problem arising out of the actions taken by the Fed and the US government in response to the financial crisis?

1 For details of the Fed's interest rate policy, see www.federalreserve.gov/fomc/fundsrate.htm

- Unless cash ratios were imposed on every single financial institution, the control of certain institutions' lending would merely shift business to other uncontrolled institutions, including overseas ones. Banks operate in a global market. Thus UK banks can do business with UK borrowers using money markets abroad, thereby diverting potentially profitable business away from London. This is an example of Goodhart's law (see Box 22.8 on page 700).
- Alternatively, if those banks subject to statutory cash requirements were short of cash, they could attract cash away from the uncontrolled institutions.

The switching of business away from controlled banks is known as *disintermediation*. To avoid this problem and to allow the greatest freedom of competition between financial institutions, the alternative is to use monetary base control with no *statutory* cash ratio.

Definition

Disintermediation The diversion of business away from financial institutions that are subject to controls.

But two major problems with monetary base control, with or without a statutory cash ratio, are the most serious of all. The first is that central banks *are always prepared to increase the monetary base, through repos or rediscounting, if it is demanded*. This makes it virtually impossible to have a precise control of the monetary base.

The second is the size and variability of the money multiplier. As we saw in section 18.3 (pages 575–6), the money multiplier is the number of times greater the rise in (broad) money supply is than the rise in the monetary base. As Figure 18.5 (see page 576) demonstrates, the broad money multiplier can be highly variable. In other words, controlling the monetary base would have a highly unpredictable effect on the money supply.

For these reasons, the support for monetary base control has waned in recent years.

1. Trace through the effects of a squeeze on the monetary base from an initial reduction in cash to banks' liquidity being restored through gilt repos. Will this restoration of liquidity by the central bank totally nullify the initial effect of reducing the supply of cash? (Clue: what is likely to happen to the rate of interest?)
2. Given the difficulties of monetary base control, would you expect cash in circulation and broader measures of the money supply, such as M4, to rise and fall by the same percentage as each other?

Problems with controlling broad money supply

One solution to the problems of monetary base control would be for the authorities to attempt to control broader money supply directly. In the UK, targets for the growth in broad money were an important part of monetary policy from 1976 to 1985. The UK has not targeted money supply growth since the 1980s, however. The European Central Bank has a 'reference value' of 4.5 per cent for M3 growth of the euro (see Box 18.4 on page 573 for a definition of M3). This, however, is only a guideline and not a strict target.

How would such a policy work? Assume that the authorities want to operate a tight monetary policy. They sell bonds on the open market. Banks, now short of cash, obtain money from the central bank through rediscounting bills or through repos. Thus although the central bank has been obliged to restore the amount of cash it had withdrawn from the system, there has been a decrease in bills and short-term bonds held by the banks. Banks' *overall* liquidity has thus been reduced. Such measures could be backed up by changing the funding methods.

But as with monetary base control, there are problems with attempting to control broad money supply. Banks may be prepared to reduce their liquidity ratio. This is likely if they already have surplus liquidity, or if their customers are prepared to switch from sight to time accounts (for which banks require fewer cash reserves). This will involve offering higher interest rates on time accounts, and hence charging higher interest rates on bank loans. But if the demand for

loans is relatively insensitive to interest rate changes, this will have little effect on credit or on overall deposits.

The use of open-market operations or funding to reduce money supply involves selling more bonds. But if potential purchasers believe interest rates will rise in the future (highly likely when the government is attempting to operate a tighter monetary policy), they will hold off buying bonds now and may even attempt to sell bonds before bond prices fall. Thus the authorities may be forced into a large immediate increase in bond interest rates.

In circumstances where the central bank wants to *increase* broad money, the problem can be even more serious. Purchasing bonds may increase liquidity in the banking sector, but (a) people may not want to borrow if the economy is going into recession and people are trying to cut back on spending; (b) banks may be reluctant to lend, preferring to keep the extra liquidity in reserve as a precaution against people defaulting on debts. These were the problems facing various central banks around the world which were to engage in quantitative easing (see Box 22.10) following the financial crisis of the late 2000s and the subsequent economic slowdown.

Perhaps the biggest problem is the effect on interest rates.

The effect on interest rates

A policy of controlling money supply can lead to severe fluctuations in real interest rates. This can cause great uncertainty for business and can be very damaging to long-term investment and growth.

The problem is more acute if the overall demand for money is inelastic and is subject to fluctuations. In Figure 22.7, with money supply controlled at M_s , even a fairly moderate increase in demand from L to L' leads to a large rise in real interest rates from r to r_1 .

And yet, if the authorities are committed to controlling money supply, they will have to accept that equilibrium interest rates may well fluctuate in this way.

Figure 22.7

The effect on interest rates of a change in demand for money when money supply is kept under control

Because of the above difficulties in controlling the money supply directly, countries have become increasingly reliant on controlling interest rates (backed up, normally, by open-market operations).

Techniques to control interest rates

The approach to monetary control today in many countries is to focus directly on interest rates. Normally an interest rate change will be announced, and then open-market operations will be conducted by the central bank to ensure that the money supply is adjusted so as to make the announced interest rate the *equilibrium* one. Figure 22.8 shows central bank (nominal) interest rates in the UK, USA and the eurozone since 2005.

Central banks look to affect *real* interest rates through their monetary operations that affect nominal interest rates. Assuming inflationary expectations are constant in the short term, then, by announcing a particular change in nominal rates, this results in an equivalent change in real interest rates. Thus, in Figure 22.6 (on page 688), the central bank announces a rise in nominal interest rates which corresponds to an equivalent rise in real interest rates from r_1 to r_2 and then conducts open-market operations to ensure that the money supply is reduced from Q_1 to Q_2 .

In the UK, since the Bank of England was made independent in 1997, interest rate changes have been made by the Bank's Monetary Policy Committee (MPC) at its meetings, which take place eight times per year. These are then backed up through the Bank's operations in the gilt repo and discount markets (see Box 22.5). Similarly, in the eurozone, the ECB's Governing Council decides on interest rates every six weeks (see Box 22.7).

Let us assume that the central bank decides to raise interest rates. What does it do? In general, it will seek to keep banks short of liquidity. This will happen automatically on any day when tax payments by banks' customers exceed the money they receive from government expenditure. This excess is effectively withdrawn from banks and ends up in the government's account at the central bank. Even when this does not occur, issues of government debt will effectively keep the banking system short of liquidity.

This 'shortage' can then be used as a way of forcing through interest rate changes. Banks will obtain the necessary liquidity from the central bank through gilt repos or by selling it back (rediscounting) bills. The central bank can *choose the rate of interest to charge* (i.e. the gilt repo rate or the bill rediscount rate). This will then have a knock-on effect on other interest rates throughout the banking system.

The effects can be illustrated in Figure 22.9, both parts of which assume that the central bank wishes to raise the real interest rate (the real repo or discount rate) from r_1 to r_2 .

In Figure 22.9(a), it is assumed that banks are short of liquidity and are seeking to sell gilts to the central bank on a repo basis. It is assumed that the central bank will supply as much cash (i.e. demand as many gilts through repos) as banks choose, but only at the central bank's chosen repo rate. The demand for gilts is thus perfectly elastic at the central bank's repo rate. The supply curve of gilts by the banks represents their demand for cash from the central bank, and hence is *downward* sloping: the lower the real repo rate, the cheaper it is for the banks to obtain cash. If the central bank raises the real repo rate to r_2 (via a rise in the nominal rate), banks will supply fewer gilts (i.e. demand less cash from the central bank). If there is less liquidity in the banking system, the money supply will fall.

Figure 22.8 Central bank interest rates

BOX 22.7 MONETARY POLICY IN THE EUROZONE

The role of the ECB

The European Central Bank (ECB) is based in Frankfurt and is charged with operating the monetary policy of those EU countries that have adopted the euro. Although the ECB has the overall responsibility for the eurozone's monetary policy, the central banks of the individual countries, such as the Bank of France and Germany's Bundesbank, were not abolished. They are responsible for distributing euros and for carrying out the ECB's policy with respect to institutions in their own countries. The whole system of the ECB and the national central banks is known as the European System of Central Banks (ESCB).

In operating the monetary policy of a 'euro economy' roughly the size of the USA, and in being independent from national governments, the ECB's power is enormous and is equivalent to that of the Fed (see Box 22.6). So what is the structure of this giant on the European stage, and how does it operate?

The structure of the ECB

The ECB has two major decision-making bodies: the Governing Council and the Executive Board.¹

The Governing Council consists of the members of the Executive Board and the governors of the central banks of each of the eurozone countries. The Council's role is to set the main targets of monetary policy and to oversee the success (or otherwise) of that policy. It also sets interest rates at six-weekly meetings. Decisions are by simple majority. In the event of a tie, the president has the casting vote.

The Executive Board consists of a president, a vice-president and four other members. Each serves for an eight-year, non-renewable term. The Executive Board is responsible for implementing the decisions of the Governing Council and for preparing policies for the Council's consideration. Each member of the Executive Board has a responsibility for some particular aspect of monetary policy.

The targets of monetary policy

The overall responsibility of the ECB is to achieve price stability in the eurozone. The target is a rate of inflation below, but close to, 2 per cent over the medium term. It is a weighted average rate for all the members of the eurozone, not a rate that has to be met by every member individually.

Alongside its definition of price stability, the ECB's monetary policy strategy comprises what it calls 'a two-pillar approach to the analysis of the risks to price stability'. These two pillars are any analysis of monetary developments and of economic developments. The former includes an analysis of monetary aggregates, including M3. The latter includes an analysis of economic activity, the labour market, cost indicators, fiscal policy and the balance of payments.

The ECB then attempts to 'steer' short-term interest rates to influence economic activity to maintain price stability in the euro area in the medium term. In March 2017, the rates were as follows: 0.00 per cent for the main 'refinancing operations' of the ESCB (i.e. the minimum rate of interest at which liquidity is offered once per week to 'monetary financial institutions' (MFIs) by the ESCB); a 'marginal lending' rate of 0.25 per cent

(for providing overnight support to the MFIs); and a 'deposit rate' of -0.40 per cent (the rate paid to MFIs for depositing overnight surplus liquidity with the ESCB). The negative deposit rate meant that banks were being charged for 'parking' money with the ECB rather than lending it. The hope was that this would encourage banks to lend to each other or to households and businesses and, consequently, stimulate the economy.

The operation of monetary policy

The ECB sets a minimum reserve ratio. The ratio is designed primarily to prevent excessive lending and hence the need for excessive borrowing from the central bank or from other financial institutions. This, in turn, should help to reduce the volatility in interest rates.

The minimum reserve ratio was not designed, however, to be used to make changes in monetary policy. In other words, it was not used as a variable minimum reserves ratio, and for this reason it was set at a low level. From 1 January 1999 to 17 January 2012 the ratio (also known as the reserve coefficient) was 2 per cent of key liquid and relatively liquid liabilities. However, as of 18 January 2012 the ratio was reduced to 1 per cent in an attempt to help stimulate bank lending. In other words, it was now being used for the first time as part of an active monetary policy. However, it has not been used for this purpose since.

The main instrument for keeping the ECB's desired interest rate as the equilibrium rate is open-market operations in government bonds and other recognised assets, mainly in the form of repos. These repo operations are conducted by the national central banks, which must ensure that the repo rate does not rise above the marginal overnight lending rate or below the deposit rate.

The ECB uses four types of open-market operations:

Main refinancing operations. These are short-term repos with a maturity of one week. They take place weekly and are used to maintain liquidity consistent with the chosen ECB interest rate.

Longer-term refinancing operations. These take place monthly and typically have a maturity of three months. Longer maturities are available, but such operations are conducted more irregularly. They are to provide additional longer-term liquidity to banks as required at rates determined by the market, not the ECB.

Fine-tuning operations. These can be short-term sales or purchases of short-term assets. They are designed to combat unexpected changes in liquidity and hence to keep money market rates at the ECB's chosen rate.

Structural operations. These are used as necessary to adjust the amount of liquidity in the eurozone. They can involve either the purchase or sale of various assets.

ECB independence

The ECB is one of the most independent central banks in the world. It has very little formal accountability to elected politicians. Although its president can be called before the European Parliament, the Parliament has virtually no powers to influence the ECB's actions. Until its January 2015 meeting, its deliberations were secret and no minutes of Council meetings were published. Subsequently, an account of meetings is published (usually with a lag of around two weeks) with an explanation of the policy stance. However, the minutes do not include details of how Council members voted or of future policy intentions, unlike the minutes published by the Bank of England which, from 2015, are available at the time of the policy announcement.

There is one area, however, where the ECB's power is limited by politicians and this concerns the exchange rate of the euro. Under the Maastricht Treaty, EU finance ministers have the responsibility for deciding on exchange rate policy (even though the ECB is charged with carrying it out). If the finance ministers want to stop the exchange rate of the euro rising, in order to prevent putting EU exporters at a competitive disadvantage, this will put pressure on the ECB to lower interest rates, which might run directly counter to its desire to meet its inflation and money supply targets. This is an example of the principle of 'targets and instruments'. If you have only one instrument (the rate of interest), it cannot be used to achieve two targets (the exchange rate and inflation) if these two targets are in conflict (see Box 22.9).

Financial crisis

The financial crisis put incredible strains on commercial banks in the eurozone and, hence, on the ECB's monetary framework. Consequently, monetary operations were gradually modified.

A Securities Market Programme (SMP) began in May 2010 designed to supply liquidity to the ailing banking system. It allowed for ECB purchases of central government debt in the secondary market (i.e. not directly from governments) as well as purchases both in primary and secondary markets of private-sector debt instruments. By June 2012, €214 bn of purchases had been made, largely of government bonds issued by countries experiencing financing difficulties, including Portugal, Ireland, Greece and Spain.

The SMP was supplemented in December 2011 by the introduction of three-year refinancing operations (LTROs) worth €529.5 billion and involving some 800 banks. These were cheap loans (repos) to the banks by the ECB. These were followed in January by a fall in the minimum reserve ratio to 1 per cent (as we saw above).

By the end of February 2012, a further €489.2 billion of three-year loans to 523 banks took place, taking the total to over €1 trillion. The hope was that the funds would help financially distressed banks pay off maturing debt and again increase their lending.

Then in September 2012 with worries about the continuing difficulties of some eurozone countries, such as Greece, Spain

and Italy, to borrow at affordable rates and possibly, as a result, their being driven from the euro, the ECB announced a replacement for the SMP programme. This would involve a more extensive programme of purchasing existing government bonds with up to three years of maturity in the secondary market. The aim would be to drive down these countries' interest rates and thereby make it cheaper to issue new bonds when old ones matured. These Outright Monetary Transactions (OMTs) were in principle unlimited, with the ECB president, Mario Draghi, saying that the ECB would do 'whatever it takes' to hold the single currency together.

Critics argued that this was still not enough to stimulate the eurozone economy and help to bring countries out of recession. The principal problem, it was argued, was that OMTs would differ from the quantitative easing programmes used in the UK and the USA. ECB purchases of these bonds would not increase the eurozone money supply as the ECB would sell off other assets to compensate. This process is known as **sterilisation**.

Despite the eurozone economy contracting by 0.6 per cent in 2012 and by a further 0.4 per cent in 2013, OMTs had still not been used. Nonetheless, the ECB argued that the announcement that it was prepared to intervene had acted to prevent 'self-reinforcing fears' in sovereign bond markets.

Subsequent measures were to follow. In June 2014, the ECB announced that it was adopting a negative deposit rate (see above), that it was embarking on a further series of targeted long-term refinancing operations so as to provide long-term loans to commercial banks at cheap rates until September 2018, and that it would stop sterilising its SMP programme.

Quantitative easing. Finally, in September 2014, it announced that it would be commencing quantitative easing by purchasing marketable debt instruments, including public-sector bonds and asset-backed private-sector securities, such as securitised mortgages and commercial loans (see section 18.2). From March 2015 until March 2016 the average monthly purchase was €60 billion, which was increased to €80 billion from April 2016 before being reduced back to €60 billion from April 2017. Purchases were intended to be carried out until the end of 2017, dependent on economic conditions in the eurozone.

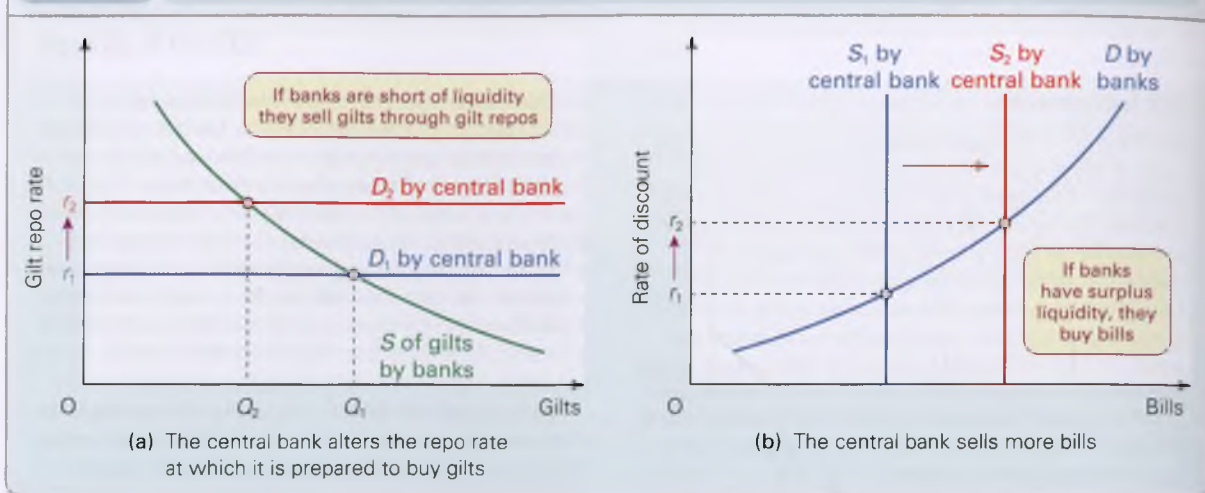

What are the arguments for and against publishing the minutes of the meetings of the ECB's Governing Council and Executive Board?

Definition

Sterilisation Actions taken by a central bank to offset the effects of foreign exchange flows or its own bond transactions so as to leave money supply unchanged.

Figure 22.9 Central bank operations in the gilt repo and bill markets to affect interest rates

In the event of banks having a surplus of liquidity, Figure 22.9(b) applies. Here banks are seeking to use their surplus liquidity to *buy* bills from the central bank. Their demand curve is *upward* sloping: the higher the rate of discount (i.e. the lower the price that banks have to pay for bills), the more the banks will demand. In this case, the central bank can raise the rate of discount by offering more bills for sale. By increasing the supply of bills from S_1 to S_2 , it can increase the equilibrium real rate from r_1 to r_2 .

In both cases, the central bank will first decide on the repo rate (or discount rate) and then adjust the supply or demand of gilts or bills to ensure that the chosen rate is the equilibrium rate (see Boxes 22.5, 22.6 and 22.7 for details of how the Bank of England, the Fed and the ECB do this in practice).

A change in the repo rate will then have a knock-on effect on other interest rates. For example, in the UK, banks normally automatically adjust their base rates (to which they gear their other rates) when the Bank of England announces a change in the Bank Rate (i.e. the nominal repo rate). Thus a 0.25 percentage point rise in Bank Rate will normally mean a 0.25 percentage point rise in banks' deposit rates, overdraft rates, etc.

Changes in Bank Rate, however, will not necessarily have an *identical* effect on other interest rates. In section 19.4 we saw how some economists argue that interest rate differentials, such as those between saving and borrowing products, can be dependent on the macroeconomic environment. Economic growth may help to reduce the cost of borrowing relative to the return on saving, which further fuels spending and aggregate demand.

While interest rate differentials may vary across the business cycle, they can also be affected by disruptions in the functioning of financial markets. The financial crisis of the late 2000s can be seen in this light, with interest rate differentials between borrowing and saving or deposit rates rising sharply. This is illustrated in Figure 22.10, which shows the UK's Bank Rate alongside the average mortgage rate and one-month LIBOR (*inter-bank* lending rate).

Because of the financial crisis, inter-bank rates did not follow Bank Rate changes precisely. The chart illustrates how

during the height of the credit crunch in 2008, the LIBOR diverged considerably from Bank Rate as banks became reluctant to lend to each other for fear that banks would default on their loans. From 2011, however, the inter-bank rate converged once more with Bank Rate.

Similarly, the average mortgage rate did not fall nearly as much as Bank Rate in 2008/9. But, unlike the inter-bank rate, the higher spread between Bank Rate and mortgage rate persisted through the 2010s.

 How could we model a credit market disruption and its impact on interest rate differentials using the Keynesian cross (Keynesian 45° line) diagram?

Problems with controlling interest rates

Even though central bank adjustment of the repo rate is the current preferred method of monetary control in most countries, it is not without its difficulties. The problems centre on the nature of the demand for loans. If this demand is (a) unresponsive to interest rate changes or (b) unstable because it can be significantly affected by other determinants (e.g. anticipated income or foreign interest rates), it will be very difficult to control by controlling the rate of interest.

Problem of an inelastic demand for loans

If the demand for loans is inelastic, as in Figure 22.11, any attempt to reduce demand (e.g. from Q_1 to Q_2) will involve large rises in real interest rates (r_1 to r_2). The problem will be compounded if the demand curve shifts to the right, due, say, to a consumer spending boom. High interest rates lead to the following problems:

- They may discourage long-term investment (as opposed to current consumption) and hence long-term growth.
- They add to the costs of production, to the costs of house purchase and generally to the cost of living. They are thus cost inflationary.
- They are politically unpopular, since the general public do not like paying higher interest rates on overdrafts, credit cards and mortgages.

Figure 22.10 Average (nominal) monthly interest rates

Source: Based on series IUMABEDR (Bank Rate), IUMTLMV (mortgage rate) and IUMAVNEA (inter-bank rate) from *Statistical Interactive Database* (Bank of England) (data published 7 December 2017).

- The authorities may need to ensure a sufficient supply of longer-term securities so that liquidity can be constrained. This could commit the government to paying high rates on these bonds for some time.
- High interest rates encourage inflows of money from abroad. This makes it even more difficult to restrain bank lending. This drives up the exchange rate. A higher exchange rate makes domestic goods expensive relative to goods made abroad. This can be very damaging for export industries and industries competing with imports. Many firms in the UK suffered badly between 1997 and 2007 from a high exchange rate, caused partly by higher interest rates in the UK than in the eurozone and the USA.

Evidence suggests that the demand for loans may indeed be quite inelastic, especially in the short run. Although investment plans may be curtailed by high interest rates, borrowing to finance current expenditure by many firms cannot easily be curtailed. Similarly, while householders may be discouraged from taking on new mortgages, they may find it difficult to reduce current expenditure as a means of reducing their credit card debt. What is more, although high interest rates may discourage many firms from taking out long-term fixed-interest loans, some firms may merely switch to shorter-term variable-interest loans.

Problem of an unstable demand

Accurate monetary control requires the authorities to be able to predict the demand curve for money. Only then can they set the appropriate level of interest rates. Unfortunately, the demand curve may shift unpredictably, making control very difficult. The major reason is *speculation*:

- If people think interest rates will rise and bond prices fall, in the meantime they will want to hold their assets in liquid form. The demand for money will rise.
- If people think exchange rates will rise, they will demand sterling while it is still relatively cheap. The demand for money will rise.
- If people think inflation will rise, the transactions demand for money may rise. People spend now while prices are still relatively low.
- If people think the economy is going to grow faster, the demand for loans will increase as firms seek to increase their investment.

Figure 22.11 An inelastic demand for loans

BOX 22.8 GOODHART'S LAW

EXPLORING
ECONOMICS

'To control is to distort'

'If you want to tackle a problem, it's best to get to the root of it.'

This is a message that economists are constantly preaching. If you merely treat the symptoms of a problem rather than its underlying causes, the problem may simply manifest itself in some other form. What is more, the symptoms (or lack of them, if the treatment makes them go away) will now be a poor indicator of the problem. Let's illustrate this with a medical example.

Assume that you suffer from deteriorating eyesight. As a result, you get increasingly bad headaches. The worse the headaches become, the worse it suggests your eyesight is getting. The headaches are thus a symptom of the problem and an indicator of the problem's magnitude. So what do you do? One approach is to treat the symptoms. You regularly take painkillers and the headaches go away. But you haven't treated the underlying problem – by getting stronger glasses, or perhaps even having eye surgery – all you have done is to treat the symptoms. As a result, headaches (or rather the lack of them) are now a poor indicator of your eyesight.

If you control the indicator rather than the underlying problem, the indicator ceases to be a good indicator. 'To control [the indicator] is to distort [its use as an indicator].' This is **Goodhart's law** and it has many applications in economics, especially when targets are set by the government. Let us take the example of a money supply target.

Goodhart's law: Controlling a symptom (i.e. an indicator) of a problem will not cure the problem.

Instead, the indicator will merely cease to be a good indicator of the problem.

Money as an indicator of aggregate demand

Monetarists from the 1960s argued that the level of money supply determines the level of nominal aggregate demand

and prices. They therefore argued in favour of setting targets for the growth of money supply. Critics, however, argued that the level of money supply is only an indicator of the level of nominal aggregate demand (and a poor one at that). As soon as you start to control money supply, they said, the relationship between them breaks down. If, for example, you restrict the amount of money and yet people still want to borrow, money will simply circulate faster (the velocity of circulation (V) will rise), and hence aggregate demand may not decline.

The choice of money supply target

If targets for the growth of money supply are to be set, which measure of money supply should be chosen? Goodhart's law suggests that whichever measure is chosen it will, by virtue of its choice, become a poor indicator. If the government targets cash in circulation and directs its policy to reducing the amount of notes and coin in the economy, banks may try to reduce their customers' demand for cash by, say, increasing the charges for cash advances on credit cards. As a result, cash may well be constrained, but M4 may well go on rising.

The choice of institutions

If bank advances are a good indicator of aggregate demand, the government may choose to control bank lending. But as soon as it does so, bank lending will become a poor indicator. If people's demand for loans is still high and bank loans are becoming difficult to obtain, people will simply go elsewhere to borrow money. If you regulate part of the financial system, you are likely to end up merely diverting business to other parts which are unregulated.

1. Give some everyday examples of Goodhart's law.
2. How may the use of targets in the health service (such as getting waiting lists down) provide an example of Goodhart's Law?

It is very difficult for the authorities to predict what people's expectations, and hence speculation, will be. Speculation depends largely on world political events, rumour and 'random shocks'.

If the demand curve shifts very much, and if it is inelastic, monetary control will be very difficult. Furthermore, the central bank will have to make frequent and sizeable adjustments to interest rates. These fluctuations can be very damaging to business confidence and may discourage long-term investment.

Why does an unstable demand for money make it difficult to control the supply of money?

The net result of an inelastic and unstable demand for money is that substantial interest rate changes may be necessary to bring about the required change in aggregate

demand. For example, central banks had to cut interest rates to virtually zero in their attempt to tackle the global recession of the late 2000s. Indeed, as we see in Box 22.9, central banks took to other methods as the room for interest rate cuts simply disappeared.

Using monetary policy

It is impossible to use monetary policy as a precise means of controlling aggregate demand. It is especially weak when it

Definition

Goodhart's law Controlling a symptom of a problem or only one part of the problem will not cure the problem: it will simply mean that the part that is being controlled now becomes a poor indicator of the problem.

BOX 22.9

USING INTEREST RATES TO CONTROL BOTH AGGREGATE DEMAND AND THE EXCHANGE RATE

EXPLORING ECONOMIES

A problem of one instrument and two targets

Assume that the central bank is worried about excessive growth in the money supply and rising inflation. It thus decides to raise interest rates. One effect of these higher interest rates is to attract deposits into the country (causing a financial account surplus) and thus drive up the exchange rate. This makes imports cheaper and exports less competitive. This will result in a current account deficit, which will match the financial (plus capital) account surplus.

Now let us assume that the central bank becomes worried about the damaging effect on exports and wants to reduce the exchange rate. If it uses interest rates as the means of achieving this, it will have to lower them: lower interest rates will cause deposits to flow out of the country, and this will cause the rate of exchange to depreciate.

But there is a dilemma here. The central bank wants high interest rates to contain inflation, but low interest rates to help exporters. If interest rates are the only policy instrument, one objective will have to be sacrificed for the other.

Another example, but this time the reverse case, was when the UK voted to leave the EU in June 2016. Worried about the possible dampening effect on investment and economic

growth from worries about trade relationships, the Bank of England *lowered* Bank Rate from 0.5 to 0.25 per cent and backed this up with another round of quantitative easing. However, the worries about UK trade also drove down the exchange rate, which increased the price of imports and increased inflation – at least temporarily. If the Bank of England had wanted to dampen this inflation, it would have to have *raised* Bank Rate. Clearly, it could not both lower and raise Bank Rate at the same time.

These examples illustrate a rule in economic policy: you must have at least as many instruments as targets. If you have two targets (e.g. low inflation and a low exchange rate), you must have at least two policy instruments (e.g. interest rates and one other).

1. Give some other examples of the impossibility of using one policy instrument to achieve two policy objectives simultaneously.
2. If the central bank wanted to achieve a lower rate of inflation and also a higher exchange rate, could it under these circumstances rely simply on the one policy instrument of interest rates?

is pulling against the expectations of firms and consumers, and when it is implemented too late. However, if the authorities operate a tight monetary policy firmly enough and long enough, they should eventually be able to reduce lending and aggregate demand. But there will inevitably be time lags and imprecision in the process.

An expansionary monetary policy is even less reliable. If the economy is in recession, no matter how low interest rates are driven, people cannot be forced to borrow if they do not wish to. Firms will not borrow to invest if they predict a continuing recession.

A particular difficulty in using interest rate reductions to expand the economy arises if the repo rate is nearly zero but this is still not enough to stimulate the economy. The problem is that (nominal) market interest rates cannot be negative (except in the case for overnight deposits by banks in the central bank), for clearly nobody would be willing to lend in these circumstances. The UK and many eurozone countries were in this position in the early 2010s. They found themselves caught in the 'liquidity trap' (see pages 590). Despite record low interest rates and high levels of liquidity, borrowing and lending remained low given worries about fiscal austerity and its dampening effects on economic growth.

One way in which central banks, like the Federal Reserve, the Bank of England and the ECB, attempted to encourage

spending following the financial crisis of the late 2000s was by publicly indicating the expected path of future interest rates. By stating that interest rates were likely to remain low for some time, central banks hoped that *forward guidance* would give economic agents confidence to bring forward their spending.

Despite these problems, changing interest rates can be quite effective in the medium term. After all, they can be changed very rapidly. There are not the time lags of implementation that there are with various forms of fiscal policy. Indeed, since the early 1990s, most governments or central banks have used interest rate changes as the major means of keeping inflation and/or aggregate demand under control.

In the UK, the eurozone and many other countries, the government or central bank sets a target for the rate of inflation for the medium term. In the UK, the target is 2 per cent CPI inflation in two years' time plus or minus 1 per cent. In the eurozone, the target is a rate of CPI inflation⁵ below, but close to, 2 per cent over the medium term (where the precise period is unspecified). If forecasts suggest that inflation is going to be off-target, interest rate changes are announced, and then appropriate open-market operations are conducted to support the new interest rate. The use of such targets is examined in section 22.4.

One important effect of changing interest rates in this very public way is that it sends a clear message to people that inflation *will* be kept under control. People will therefore be more likely to adjust their expectations accordingly and keep their borrowing in check.

⁵ In the eurozone the CPI is known as the 'harmonised index of consumer prices (HICP)'.

BOX 22.10 QUANTITATIVE EASING**Rethinking monetary policy in hard times**

As the economies of the world slid into recession in 2008, central banks became more and more worried that the traditional instrument of monetary policy – controlling interest rates – was insufficient to ward off a slump in demand.

Running out of options?

Interest rates had been cut at an unprecedented rate. Central banks were reaching the end of the road for interest rate cuts. The Fed was the first to be in this position. It had made several cuts in the target federal funds rate – the overnight rate at which the Fed lends to banks. By December 2008 it had been cut to a range between 0 and 0.25 per cent. Meanwhile in the UK, Bank Rate had fallen to 0.5 per cent by March 2009. But you cannot, in most cases, cut nominal rates below zero – otherwise you would be paying people to borrow money, which would be like giving people free money!

The problem was that there was an acute lack of willingness of banks to lend and firms and consumers to borrow as people saw the oncoming recession. So the cuts in interest rates were not having enough effect on aggregate demand.

Increasing the money supply

So what were central banks to do? The answer was to increase money supply directly, in a process known as **quantitative easing**. This involves an aggressive version of open-market operations, where the central bank buys up a range of assets, such as securitised mortgage debt and long-term government bonds. The effect is to pump large amounts of additional cash into the economy in the hope of stimulating demand and, through the process of credit creation, to boost broad money too.

In the USA, in December 2008, at the same time as the federal funds rate was cut to a range of 0 to 0.25 per cent, the

Fed was already embarking on large-scale quantitative easing. As we saw in Box 22.6, the Fed began buying hundreds of billions of dollars worth of mortgage-backed securities on the open market and planned also to buy large quantities of long-term government debt.

The Federal Open Market Committee (the interest rate setting body in the USA) said that, 'The focus of the committee's policy going forward will be to support the functioning of financial markets and stimulate the economy through open-market operations and other measures that sustain the size of the Federal Reserve's balance sheet at a high level.' The result was that considerable quantities of new money were injected into the system. At the conclusion of three rounds of QE in October 2014 it had purchased assets of \$2.5 trillion.

A similar approach was adopted in the UK. In January 2009, the Bank of England was given powers by the Treasury to buy on the open market up to £50 billion of existing government bonds (gilts) and high-quality private-sector assets, such as corporate bonds and commercial paper. The purchases from non-bank financial institutions were with newly created electronic money. But this was only the start.

In March 2009, as the recession deepened, the Chancellor agreed to increase the scale of purchases, so beginning the second and substantive phase of quantitative easing. These purchases, mainly government bonds (gilts) resulted in a substantial increase in banks' reserves at the Bank of England and hence in the Bank's balance sheet (see Table 18.2 on page 566). By July 2012, asset purchases had been made totalling £375 billion. In August 2016, with concerns about the prospects for the UK economy following the vote to leave the European Union, the Bank of England increased its gilt purchases by a further £60 billion to £435 billion.

Section summary

1. Control of the growth in the money supply over the longer term will normally involve governments attempting to restrict the size of their deficits. Whilst this is relatively easy once inflation has been brought under control, it can lead to serious problems if inflation is initially high. Increases in taxes and cuts in government expenditure are not only politically unpopular, but could also result in a recession.
2. In the short term, the authorities can use monetary policy to restrict the growth in aggregate demand in one of two major ways: (a) reducing money supply directly; (b) reducing the demand for money by raising interest rates.
3. The money supply can be reduced directly by using open-market operations. This involves the central bank selling more government securities and thereby reducing banks' reserves when their customers pay for them from their bank accounts. Alternatively, the central bank can reduce the amount of lending or rediscounting it is prepared to do (other than as a last-resort measure). Rather than

Definition

Quantitative easing A deliberate attempt by the central bank to increase the money supply by buying large quantities of securities through open-market operations.

These securities could be securitised mortgage and other private-sector debt or government bonds.

Additionally, it agreed to purchase up to £10 billion of UK corporate bonds.

The ECB was more reticent about adopting quantitative easing. But with growth in the eurozone averaging only 0.4 per annum from 2011 to 2014 and deflation emerging towards the end of 2014, a programme of quantitative easing began in March 2015 at a rate of €60 billion per month. Initially, the scheme was to run to September 2016 with total purchases of up to €1.08 trillion. However, with the inflation rate averaging zero per cent in early 2016, the scheme was extended into 2017, with monthly purchases rising in March 2016 to €80 billion (and including corporate bonds for the first time). However, with eurozone growth beginning to increase, monthly purchases fell back to €60 billion per month from April 2017, but the scheme was extended to the end of 2017. Total asset purchases were expected to be around €2.3 trillion.

The transmission mechanism of asset purchases

By financing asset purchases through the creation of central bank reserves, quantitative easing involves increasing the amount of narrow money. It can also, indirectly, increase broad money. There are two principal ways in which this can happen.

The first is through the effects on asset prices and yields. When non-bank financial intermediaries, including insurance companies and pension funds, sell assets to the central bank they can use the money to purchase other assets. In doing so, this will drive up their prices. This, in turn, reduces the yields on these assets (at a higher price there is less dividend or interest per pound spent on them), which should help to reduce interest rates and make the cost of borrowing cheaper for households and firms, so boosting aggregate demand.

Also, for those holding these now more expensive assets there is a positive wealth effect. For instance, households with longer-term saving plans involving securities will now have greater financial wealth. Again, this will boost spending.

The second mechanism is through bank lending. Banks will find their reserve balances increase as those selling assets deposit the proceeds in their bank accounts. This will increase the liquidity ratio of banks, which could encourage them to grant more credit.

However, it is all very well increasing the monetary base, but a central bank cannot force banks to lend or people to borrow. That requires confidence. We observed in Box 18.6 the continued weakness of bank lending to the non-bank private sector through the late 2000s and into the early 2010s.

This is not to say that quantitative easing failed in the UK and elsewhere: growth in credit and broad money could have been weaker still. However, it does illustrate the potential danger of this approach if, in the short run, little credit creation takes place. In the equation $MV = PY$, the rise in (narrow) money supply (M) may be largely offset by a fall in the velocity of circulation (V) (see pages 591–9).

On the other hand, there is also the danger that if this policy is conducted for too long, the growth in money supply could prove to be excessive, resulting in inflation rising above the target level. It is therefore important for central banks to foresee this and turn the monetary ‘tap’ off in time. This would involve ‘quantitative tightening’ – selling assets that the central bank had purchased, thereby driving down asset prices and driving up interest rates.

Would it be appropriate to define the policy of quantitative easing as ‘monetarist’?

controlling the monetary base in either of these two ways, the central bank could adjust its funding of the national debt. This would involve increasing the sale of bonds relative to bills, thereby reducing banks’ liquid assets. Finally, it could operate a system of variable minimum reserve ratios. Increasing these would force banks to cut back the amount of credit they create.

4. Controlling either the monetary base or broad liquidity in the short term, however, is difficult given that central banks are always prepared to provide liquidity to the banks on demand. Even if the authorities are successful in controlling the money supply, there then arises the problem of severe fluctuations in interest rates if the demand for money fluctuates and is relatively inelastic.
5. The current method of control in the UK and many other countries involves the central bank influencing interest rates by its operations in the gilt repo and discount markets. The central bank keeps banks short of liquidity and then supplies them with liquidity, largely through gilt repos, at its chosen interest rate (gilt repo rate). This then has a knock-on effect on interest rates throughout the economy.
6. With an interest-inelastic demand for loans, however, changes in interest rates may have to be very large to bring the required changes in monetary growth. High interest rates are politically unpopular and discriminate against those with high borrowing commitments. They also drive up the exchange rate, which can damage exports. Controlling aggregate demand through interest rates is made even more difficult by fluctuations in the demand for money. These fluctuations are made more severe by speculation against changes in interest rates, exchange rates, the rate of inflation, etc.
7. It is impossible to use monetary policy as a precise means of controlling aggregate demand in the short term. Nevertheless, controlling interest rates is a rapid way of responding to changing forecasts, and can be an important signal to markets that inflation will be kept under control, especially when, as in the UK and the eurozone, there is a firm target for the rate of inflation.

22.4 THE POLICY-MAKING ENVIRONMENT

Debates over the control of demand have shifted ground somewhat in recent years. There is now less debate over the relative effectiveness of fiscal and monetary policy in influencing aggregate demand. There is general agreement that a *combination* of fiscal and monetary policies will have a more powerful effect on demand than either used separately.

Economists have become increasingly interested in the environment within which policy is made. In this section we analyse debates around the extent to which governments ought to pursue active demand management policies or adhere to a set of policy rules.

Those in the Keynesian tradition prefer discretionary policy – changing policy as circumstances change. Those in the monetarist and new classical tradition prefer to set firm rules (e.g. targets for inflation, public deficits or growth in the money supply) and then stick to them.

The case for rules

There are two important arguments against discretionary policy and for rules: the political incentives of governments and time lags.

Political behaviour

Politicians may attempt to manipulate the economy for their own political purposes – such as the desire to be re-elected. As we saw in section 21.2 when discussing the *political business cycle* (see page 650), the government, if not constrained by rules, may overstimulate the economy some time before an election so that growth is strong at election time. After the election, the government strongly dampens the economy to deal with the higher inflation which is now beginning to accelerate, and to create enough slack for another boost in time for the next election.

A less extreme version is where governments from time to time use monetary and fiscal policy to try to boost their popularity. The manipulation of policy instruments is not necessarily systematic or regular in the way that the political business cycle model implies. Nonetheless, the manipulation is intended to court short-term favour with the public and may store up problems for the economy and, in the case of fiscal policy, for the public finances.

It is argued that when politicians behave in this way, fiscal policy may exhibit a *deficit bias*. Because governments are more willing to use their discretion to loosen fiscal policy than they are to tighten fiscal policy, persistent deficits and a rising debt-to-GDP ratio can result. Table 22.1 (on page 671) provides some support for this. Therefore, fiscal rules may be needed to ensure the long-term sustainability of public finances.

It is also argued that politically motivated policy makers can lose *credibility* concerning sound economic management. This can lead to higher inflationary expectations, uncertainty and lower long-term investment. Trade unions are likely to bargain for increases in wages that protect their purchasing power should government loosen its policy

stance to try and boost its popularity. The result could be an *inflation bias*, with inflation typically higher than it would otherwise be, but with unemployment no lower.

As we saw in section 21.5 (and Box 21.6), the possibility of inflation bias (see pages 660–63) is one of the principal arguments behind the move in many countries for the delegation of monetary policy to central banks.

Time lags with discretionary policy

Both fiscal and monetary policies can involve long and variable time lags. These can make policy at best ineffective and at worst destabilising (see Figure 22.5 on page 682). Taking the measures *before* the problem arises, and thus lessening the problem of lags, is usually not an option since forecasting tends to be unreliable.

In contrast, by setting and sticking to rules, and then not interfering further, the government can provide a sound fiscal and monetary framework in which there is maximum freedom for individual initiative and enterprise, and in which firms are not cushioned from market forces and are therefore encouraged to be efficient. By the government setting a target for a steady reduction in the growth of money supply, or a target for the rate of inflation, and then resolutely sticking to it, people's expectations of inflation will be reduced, thereby making the target easier to achieve.

This sound and stable monetary environment, with no likelihood of sudden contractionary or expansionary fiscal or monetary policy, will encourage firms to take a longer-term perspective and to plan ahead. This could then lead to increased capital investment and long-term growth.

The optimum situation is for all the major countries to adhere to mutually consistent rules, so that their economies do not get out of line. This will create more stable exchange rates and provide the climate for world growth (we explore this issue in section 26.1).

Advocates of this point of view in the 1970s and 1980s were monetarists and new classical macroeconomists, but support for the setting of targets was to become widespread. As we have seen, in both the UK and the eurozone countries, targets are set for both inflation and public-sector deficits.

Would it be desirable for all countries to stick to the same targets?

The case for discretion

Keynesians typically reject the argument that rules provide the environment for high and stable growth. Demand, argue Keynesians, is subject to many and sometimes violent

Definitions

Deficit bias The tendency for frequent fiscal deficits and rising debt-to-GDP ratios because of the reluctance of policy makers to tighten fiscal policy.

exogenous shocks: e.g. changes in expectations, domestic political events (such as an impending election), financial market effects (such as the credit crunch), world economic factors (such as the global economic recession of 2008–9) or world political events (such as a war). The resulting shifts in injections or withdrawals cause the economy to deviate from a stable full-employment growth path.

Any change in injections or withdrawals will lead to a cumulative effect on national income via the multiplier and accelerator and via changing expectations. These endogenous effects take time and interact with each other, and so a process of expansion or contraction can last many months before a turning point is eventually reached.

Since the exogenous changes in demand occur at irregular intervals and are of different magnitudes, the economy is likely to experience cycles of irregular duration and of varying intensity.

Given that the economy is inherently unstable and is buffeted around by various exogenous shocks, Keynesians argue that the government needs actively to intervene to stabilise the economy. Otherwise, the uncertainty caused by unpredictable fluctuations will be very damaging to investment and hence to long-term growth in potential output (quite apart from the short-term effects of recessions on actual output and employment).

If demand fluctuates in the way Keynesians claim, and if the policy of having a money supply or inflation rule is adhered to, interest rates must fluctuate. But excessive fluctuations in interest rates will discourage long-term business planning and investment. What is more, the government may find it difficult to keep to its targets. This too may cause uncertainty and instability.

Problems with targets

Assume that the government or central bank decides to set policy rules. Should they stick to these rules, come what may? What degree of flexibility should be designed into any rules? Should policy makers at least have the discretion to *change* the rules, even if only occasionally?

For example, when a target has been in force for some time, it may cease to be the appropriate one. Economic circumstances might change. For example, a faster growth in productivity or a large increase in oil revenues may increase potential growth and thus warrant a faster growth in money supply. Or an extended period of relatively low inflation may warrant a lower inflation target.

If an inflation target is chosen, then again the problem of Goodhart's Law is likely to apply. If people believe that their central bank will be successful in achieving its inflation target, then those expectations will feed into their inflationary expectations, and not surprisingly the target will be met.

The problem with inflation targets therefore is that they can become consistent with both a buoyant and a depressed economy. In other words, the Phillips curve may become *horizontal*. Consequently, as we explained in section 21.5, the *DAS* curve too becomes horizontal (at least up to near full capacity in the economy). Shifts in the *DAD* curve will

simply lead to changes in real national income. Thus achieving an inflation target may not tackle the much more serious problem of creating stable economic growth and an environment which will encourage long-term investment.

In extreme cases, as occurred in 2008, the economy may slow down rapidly and yet cost-push factors may cause inflation to rise. Strictly adhering to an inflation rate target in these circumstances would demand *higher* interest rates, which could further restrict growth. A similar argument applied to the UK after the Brexit vote. The fall in the pound threatened to push up inflation and yet the Bank of England decided to cut Bank Rate. The aim was to ward off a downswing in the economy.

But if rules should not be stuck to religiously, does this mean that the policy makers can engage in fine-tuning? Keynesians today recognise that fine-tuning may not be possible; nevertheless, significant and persistent excess or deficient demand *can* be corrected by demand management policy. For example, the actions taken in the late 2000s following the financial crisis by several central banks to cut interest rates substantially, and by governments to increase expenditures and to cut taxes, helped to stave off even deeper recessions.

Improvements in forecasting, a willingness of governments to act quickly and the use of quick-acting policies can all help to increase the effectiveness of discretionary demand management.

Under what circumstances would adherence to money supply targets lead to (a) more stable interest rates and (b) less stable interest rates than pursuing discretionary demand management policy?

Central banks and a Taylor rule

Given the potential problems in adhering to simple inflation rate targets, many economists have advocated the use of a *Taylor rule*.⁶ A Taylor rule takes two objectives into account – (1) inflation and (2) either real national income or unemployment – and seeks to get the optimum degree of stability of the two. The degree of importance attached to each of the two objectives can be decided by the government or central bank. The central bank adjusts interest rates when either the rate of inflation diverges from its target or the level of real national income (or unemployment) diverges from its potential (or natural) level.

Definitions

Taylor rule A rule adopted by a central bank for setting the rate of interest. It will raise the interest rate if (a) inflation is above target or (b) real national income is above the potential level (or unemployment is below the natural rate). The rule states how much interest rates will be changed in each case.

⁶ Named after John Taylor, from Stanford University, who in a 1993 paper, 'Discretion versus policy rules in practice' (*Carnegie-Rochester Conference Series on Public Policy* 39 (North-Holland, 1993)), proposed a representative monetary policy rule based on the rate of inflation over the past four quarters and the percentage deviation of real GDP from a target.

A general form of the Taylor rule can be written as follows:

$$r = r^* + b(\pi - \pi^*) + c(Y - Y_p) \quad (2)$$

where r is the real rate of interest set by the central bank; r^* is the real rate of interest consistent with long-run equilibrium in the economy, also known as ‘the natural real interest rate’; π is the current rate of inflation; π^* is the target rate of inflation, Y is the current level of real national income and Y_p the potential level of real national income.

What this equation says is that if inflation goes above its target, or if real national income rises above its potential level, the central bank will raise the real rate of interest, the amount depending on the values of b and c respectively. John Taylor proposed that for every 1 per cent that inflation rises above its target level, real interest rates should be raised by 0.5 percentage points (i.e. nominal rates should be raised by 1.5 percentage points), and that for every 1 per cent that real national income rises above its potential level, real interest rates should be raised by 0.5 percentage points (i.e. nominal rates should be raised by 0.5 percentage points).

? The terms ‘doves’ and ‘hawks’ are frequently used to describe central banks. How do these terms relate to the Taylor rule?

Taylor rules and the DAD/DAS framework

We can illustrate the economic significance of the relative weights in the Taylor rule given by the central bank to inflation (b) and real national income (c) using the DAD/DAS framework introduced in section 20.2. Consider Figure 22.12. It shows two alternative DAD (dynamic aggregate demand) curves. Assume that the economy is currently at point a , with inflation on target and real national income at Y_p , which happens to be the potential level. Now assume that inflation rises to π_1 . As this is above the target level, the central bank raises the rate of interest. This causes real national income to fall and is represented by a movement up along the DAD curve.

If the central bank puts a high weight on controlling inflation rather than on stabilising real national income around its potential level, the curve will be relatively flat, like DAD_1 in Figure 22.12. The bank will be prepared to raise interest rates a lot and, as a result, see real national income fall a lot in the short term.

If, however, it puts a relatively high weight on stabilising real national income around its potential level, the curve will be relatively steep, like DAD_2 . The bank will not be prepared to see real national income fall very much and will thus only raise interest rates modestly.

Thus the central bank has to trade off inflation stability against real income stability. Its Taylor rule shows its optimum trade-off and is illustrated by the slope of the DAD curve.

K1 36
DAS

Conclusions

The following factors provide us with a framework to help analyse the relative merits of rules or discretion.

- The confidence of people in the effectiveness of either discretionary policies or rules: the greater the confidence, the more successful is either policy likely to be.
- The degree of self-stabilisation of the economy (in the case of rules), or conversely the degree of inherent instability of the economy (in the case of discretion).
- The size and frequency of exogenous shocks to demand: the greater they are, the greater the case for discretionary policy.
- In the case of rules, the ability and determination of governments to stick to the rules and the belief by the public that they will be effective.
- In the case of discretionary policy, the ability of governments to adopt and execute policies of the correct magnitude, the speed with which such policies can be effected and the accuracy of forecasting.

Figure 22.12 DAD curves based on different Taylor rules

Section summary

1. The case against discretionary policy is that it involves unpredictable time lags that can make the policy destabilising. Also, the government may ignore the long-run adverse consequences of policies designed for short-run political gain.
2. The case in favour of rules is that they help to reduce deficit bias and inflationary bias and help create a stable environment for investment and growth.
3. The case against sticking to money supply or inflation rules is that they may cause severe fluctuations in interest rates and thus create a less stable economic environment for business planning. Given the changing economic environment in which we live, rules adopted in the past may no longer be suitable for the present.
4. Although perfect fine-tuning may not be possible, Keynesians argue that the government must have the discretion to change its policy as circumstances demand.

22.5 CENTRAL BANKS, ECONOMIC SHOCKS AND THE MACROECONOMY: AN INTEGRATED MODEL

Developing an integrated macroeconomic model

Shocks regularly hit economies. The adjustment of economies is affected, in part, by the way in which people and the markets in which they interact subsequently behave.

But then there is the behaviour of policy makers too. In recent decades there has been a general shift to place some constraints on the discretion of policy makers. This is particularly so in the case of monetary policy, with many countries having delegated monetary policy to central banks. The result is that many central banks now have macroeconomic remits which include targeting inflation. This objective is often supplemented with a requirement that the central bank be mindful of the implications of its monetary policy for other macroeconomic variables, such as growth or employment.

The purpose of this section is to develop an integrated model of an economy bringing together the *IS/MP*, *DAD/DAS* and *EAPC* frameworks. It is developed in the modern context of central banks with monetary policy rules, which include the targeting of inflation. Specifically, we model the possible response of a series of endogenous macroeconomic variables – output, unemployment inflation and interest rates – to exogenous economic shocks. These responses characterise the dynamics of economies. We consider first a demand shock and then a supply shock.

Assumptions and simulations

In developing our integrated model we necessarily make certain assumptions. Yet these assumptions affect the adjustment paths of our key variables to the shocks. Consequently, it is important to think about the sensitivity of our results to any changes in our assumptions. It is for this reason that forecasters will run simulations and then compare the response of the economy to shocks under different assumptions. These assumptions include, for example, the monetary policy rule, the speed at which prices in goods and labour markets adjust and the formation of expectations.

We will assume that the central bank behaves according to a Taylor rule and adjusts real interest rates in response to

deviations in the rate of inflation from its target ($\pi - \pi^*$) and real national income from its potential level ($Y - Y_p$). We assume too that input prices exhibit a degree of stickiness in the short run which enables a short-run trade between inflation and economic activity. We will show that this is reinforced when past inflation rates determine expectations of inflation.

Demand-side shocks

Constant inflationary expectations

Figure 22.13 combines the three principal models that we have used to analyse the macroeconomy. Diagrams (a) and (b) combine the expectations-augmented Phillips curve (*EAPC*) and *DAD/DAS* models, as shown previously in section 21.5. The economy is assumed to be in long-run equilibrium. From these two models, we can see that unemployment is at the natural rate (U_n) (point *a'*), real national income at potential level (Y_p) (point *a*), the rate of inflation is at the target rate (π^*) and the expected rate of inflation is equal to the target rate ($\pi^e = \pi^*$).

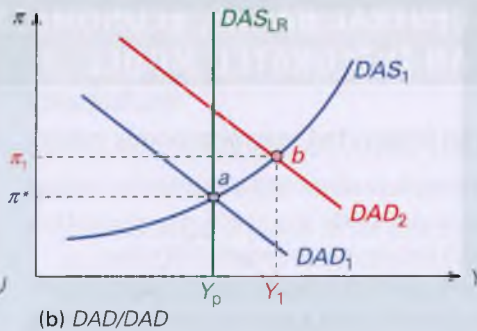

From the *IS/MP* model in diagram (c), we can see that the central bank is setting a real rate of interest r^* (point *a''*). With the economy in long-run equilibrium at Y_p this interest rate is referred to as the economy's equilibrium or 'natural' real interest.

Short-run adjustment to a rise in aggregate demand. Now assume that there is a rise in aggregate demand from, say, a rise in consumer confidence. The *DAD* and *IS* curves shift to the right, to DAD_2 and IS_2 respectively. The rise in aggregate demand causes a rise in real national income, but also a rise in inflation. This is shown by a movement upwards along the short-run *DAS* curve to point *b* in diagram (b), which corresponds to movement upwards along the expectations-augmented Phillips curve to point *b'* in diagram (a).

In response to the higher rate of inflation of π_1 , the central bank raises the nominal rate of interest (*i*) more than the rise in inflation (π), thereby raising the *real* rate of interest (*r*). The extent to which the real interest rate rises depends on how strictly the central bank targets inflation stabilisation.

Figure 22.13 Increase in real aggregate demand with anchored inflationary expectations

The demand shock causes output and inflation to rise. The central bank increases real interest rates which chokes off some of the increase in demand. As the shock dissipates, real interest rates and inflation fall and the economy returns to its initial equilibrium.

Consequently, there is a movement upwards along a short-run MP curve in diagram (c). A new short-run equilibrium is reached at point b'' , with a real interest rate of r_1 .

With the economy's real national income above its potential level and the unemployment rate below its natural rate, inflation rises to π_1 – above the target rate (π^*).

Long-term adjustment. The analysis now turns to the longer-term adjustment path of the economy (assuming inflationary expectations remained anchored).

A likely scenario, given the volatility of economies, is that the positive demand-side shock will gradually subside. If so, the DAD will move leftwards in diagram (b). As aggregate demand falls we slide back down the short-run DAS curve and the rate of inflation falls. This movement is mirrored by a corresponding movement down the $EAPC$ in diagram (a). As the inflation rate falls the central bank reduces real interest rates. The nominal interest rate falls by more than the fall in the rate of inflation. Eventually, the economy returns to the original long-run equilibrium.

Another possibility is that the positive demand-shock may persist for some time – or that the central bank may forecast that it will. In this case, if the central bank is to return the economy to point a in diagram (b) with inflation on target and real national income at the potential level, it must shift the DAD curve back again. It does this by adopting a tighter monetary policy (i.e. a higher real interest rate for each rate of inflation). It thus raises the real interest rate above r_1 , initially to r_2 , as shown in diagram (c). In other words, the MP curve will shift upwards to MP_2 .

The effect of the tighter monetary policy will be to shift the DAD_2 curve back towards DAD_1 and equilibrium will be

restored at point a . This is matched in diagram (a) by a move from b' to a' . In diagram (c), the tighter monetary policy is represented by a movement up along curve IS_2 to point c'' .

? How will the composition of aggregate demand at points c'' and a'' in Figure 22.13(c) differ?

Adaptive inflationary expectations

Up to this point we have assumed that inflationary expectations are 'anchored'. We now consider how the economy's adjustment to a demand shock is affected if people's inflationary expectations *adjust* during this process. We assume that there is a lag in the adjustment of inflationary expectations with people using past inflation rates as a predictor of current inflation rates.

Each $EAPC$, short-run DAS curve and short-run MP curve is based on a given expected rate of inflation, which will directly impact on the actual rate of inflation. But what happens in the next time period when expectations adjust? The answer is that each short-run curve shifts upwards if the expected rate of inflation rises, and shifts downwards if it falls. This is illustrated in Figure 22.14.

Again we assume that at the initial equilibrium real national income is at its potential level (Y_p), unemployment is at the natural rate (U_n) and that expected inflation is the actual (targeted) inflation ($\pi^e = \pi^*$). Finally, the natural real rate of interest is r^* .

An initial positive demand shock. Now, as before, assume there is a positive demand shock with a rise in consumer confidence. To make the analysis more straightforward we will assume that the shock lasts two periods, at which point

Figure 22.14 Increase in real aggregate demand with adaptive inflationary expectations

The demand shock causes output and inflation to rise. The central bank raises real interest rates and output weakens. An increase in inflationary expectations and then the disappearance of the shock cause economic activity to fall further. Real interest rates and inflationary expectations fall and the economy gradually returns to its initial equilibrium.

demand conditions return to their previous state. This rise in aggregate demand shifts the DAD curve to DAD_2 and the IS curve to IS_2 . In the short run there is a movement along the DAS_1 and MP_1 curves to point b and b'' respectively.

The rise in real aggregate demand and in economic activity is mirrored by the move along $EAPC_1$ from point a' to b' . In the process, the rate of inflation rises from π^* to π_1 . The central bank raises nominal and real interest rates, which chokes off some of the increase in aggregate demand. The extent to which it raises rates again depends on the monetary policy rule (and hence the shape of the MP and DAD curves).

Adjustment of inflationary expectations. We now assume that in the second period people raise their inflationary expectations to the now higher rate of inflation π_1 , which, in turn, drives up the actual rate of inflation. This causes an upward shift in the $EAPC$ and the DAS and MP curves, say to $EAPC_2$, DAS_2 and MP_2 .

The central bank responds to the further rise in the rate of inflation by increasing real interest rates, which rise to r_2 . The new short-run equilibrium in the second period sees the inflation rate at π_2 , real national income fall from Y_1 to Y_2 and unemployment rise from U_1 to U_2 . Thus, while the inflation rate is higher, economic activity falls back following its initial increase.

We now move into the third period. Inflationary expectations rise further to π_2 . This is in response to the higher inflation rate experienced in the second period. Consequently, the $EAPC$ and the DAS and MP curves shift upwards again, say to $EAPC_3$, DAS_3 and MP_3 respectively. But the aggregate demand shock is assumed now to disappear so that the DAD curve shifts leftwards back to its original position DAD_1 . Therefore,

the economy moves from point c to d in the DAD/DAS model and point c' to d' in the $EAPC$ model. As it does, output falls below its potential level and unemployment rises above its natural rate. The central bank now reduces real interest rates in response, but because inflation is still above its target rate, the real interest rate r_3 is still above its natural level r^* .

Over the following periods, economic activity recovers as inflation and expected inflation fall. As it does so, the $EAPC$ and the DAS and MP curves shift downwards. The economy therefore returns to its initial long-run equilibrium. The quicker expectations adjust, the sooner the economy will return to its long-run equilibrium.

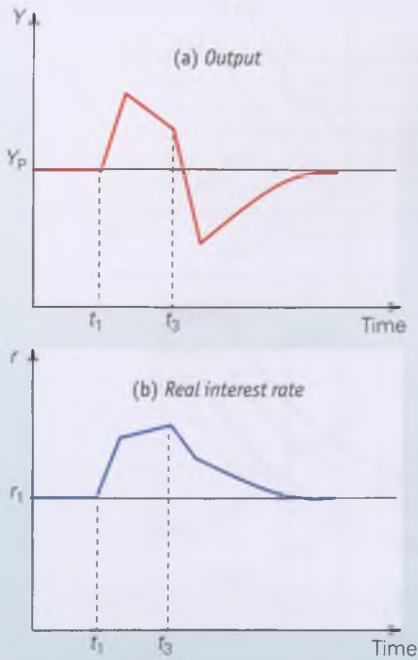

? If expectations were formed rationally with no time lags, what would be the implications for short-run DAS curves and for the response to a rise in aggregate demand?

Impulse response functions. The adjustment path of key macroeconomic variables to economic shocks can be represented in diagrams known as **impulse response functions**. In Figure 22.15 we show the impulse response functions for output (real national income) and real interest rates consistent with the analysis in Figure 22.14. These time paths illustrate how both output and real interest rates adjust following the shock in period 1. For example, we can see clearly how output falls below its potential level during

Definition

Impulse response functions The time paths of key macroeconomic variables following economic shocks.

Figure 22.15 Impulse response functions for a positive demand shock

period 3. Both variables are assumed to gradually return to their original equilibrium levels

? Based on the analysis in Figure 22.14, what would an impulse response function look like for the rate of inflation?

Assumptions about potential national income

The actual adjustment path of the economy to demand shocks is dependent on many factors. In the analysis above, the demand shock had no impact on potential national income. But, some Keynesians argue that potential national income depends to some extent on aggregate demand. If the economy experiences high aggregate demand and high output, this may encourage investment, both domestic and inward, and lead to an expansion of capacity and hence in potential national income. A rightward shift in the DAD curve may thus also result in a rightward shift in both the short-run and vertical long-run DAS curves.

If the increase in potential national income also corresponds to a lower natural rate of unemployment or lower NAIRU, the vertical long-run Phillips curve will also shift - in this case to the left.

? Under what circumstances would a rise in potential real income not result in a fall in the NAIRU?

Supply-side shocks

We finish by considering a temporary supply-side shock. We will look at permanent changes in aggregate supply within the context of our integrated framework at the start of the next chapter, which focuses on long-term economic growth.

We assume that there is a one-period negative economic shock, say caused by higher commodity price inflation. We also assume that people form their inflationary expectations adaptively based on the previous period's inflation rate.

In Figure 22.16 the economy is at its long-run equilibrium when the inflationary shock occurs. There is now a higher

Figure 22.16 Negative supply shock with adaptive inflationary expectations

The supply shock causes the inflation rate to rise. The central bank raises real interest rates which limits the rise in inflation but dampens economic activity. Despite the shock disappearing, inflationary expectations remain high and the economy only gradually returns to its initial equilibrium.

inflation rate at any of level of economic output or unemployment because of the exogenous cost pressures. This has the effect of causing the *EAPC* and the *DAS* and *MP* curves to shift vertically upwards to *EAPC*₂, *DAS*₂ and *MP*₂ respectively. We can see from diagram (b) that we therefore move upwards along the *DAD* curve from point *a* to point *b*. The central bank raises real interest rates in response to the higher rate of inflation. In diagram (c) real interest rates rise from *r** to *r*₂. The extent of the rise again depends on the monetary policy rule. The more the central bank targets inflation stabilisation the more that the economy contracts.

Despite the dampening effect on inflation from the fall in output, in the following period inflationary expectations

rise. Hence, although the initial inflationary shock has now disappeared, the *EAPC* and the *DAS* and *MP* curves remain above their initial position. Thereafter, they gradually shift downwards as inflationary expectations fall, for example to *EAPC*₃, *DAS*₃ and *MP*₃. As they do, real interest rates fall and economic activity increases: real national income increases and the rate of unemployment falls. Eventually, the economy returns to its initial long-run equilibrium.

Based on the analysis in Figure 22.16 what would the impulse response functions look like for output, unemployment, inflation and real and nominal interest rates?

Section summary

1. Many central banks nowadays are tasked with using monetary policy to help deliver pre-defined macroeconomic objectives. This frequently involves targeting inflation.
2. By combining the *EAPC*, *DAD/DAS* and *IS/MP* models it is possible to analyse the relationships between output, unemployment, inflation and interest rates in a contemporary policy-making context.
3. The combined frameworks can be used to analyse the effects of demand and supply shocks. Different adjustment paths for the economy result from different assumptions about the workings of the economy.
4. We can plot the adjustment paths for key macroeconomic variables following demand or supply shocks. The time plots are known as impulse response functions.

END OF CHAPTER QUESTIONS

1. What are the problems of relying on automatic fiscal stabilisers to ensure a stable economy at full employment?
2. Does it matter if a country has a large national debt as a proportion of its national income?
3. If the government is running a budget deficit, does this mean that national income will increase?
4. Of what significance are primary deficits or surpluses for the dynamics of a government's debt-to-GDP ratio?
5. What factors determine the effectiveness of discretionary fiscal policy?
6. Why is it difficult to use fiscal policy to 'fine-tune' the economy?
7. Assume that a bank has the following simplified balance sheet, and is operating at its desired liquidity ratio:

Liabilities	(£m)	Assets	(£m)
Deposits	100	Balances with central bank	10
		Advances	90
	100		100

Now assume that the central bank repurchases £5 million of government bonds on the open market. Assume that the people who sell the bonds all have their accounts with this bank and keep a constant amount of cash outside the bank.

 - (a) Draw up the new balance sheet directly after the purchase of the bonds.
 - (b) Now draw up the eventual balance sheet after all credit creation has taken place.
 - (c) Would there be a similar effect if the central bank rediscounted £5 billion of Treasury bills?
 - (d) How would such open-market operations affect the rate of interest?
8. Is it possible for the government to target the money supply over the longer term without targeting the level of public-sector net borrowing?
9. What are the mechanics whereby the central bank raises the rate of interest?
10. What is Goodhart's law? How is it relevant to (a) monetary policy; (b) using assignment grades to assess a student's ability; (c) paying workers according to the amount of output they produce; (d) awarding local authority contracts to cleaning or refuse disposal companies on the basis of tendered prices?
11. 'It is easier to control the monetary base than broader money, but it is less relevant to do so.' Do you agree with this statement?
12. Compare the relative merits of targeting (a) the money supply; (b) the exchange rate; (c) the rate of inflation.
13. Is there a compromise between purely discretionary policy and adhering to strict targets?
14. Assume that the economy is at potential output and the natural rate of unemployment and that inflation is at

the target rate set for the central bank by the government. In each of the following scenarios apply the integrated *EAPC*, *DAD/DAS* and *IS/MP* framework to analyse the economy's adjustment path.

- (a) A temporary fall in aggregate demand under the assumption that inflationary expectations remain anchored.
- (b) A temporary fall in aggregate demand where inflationary expectations are based on the rate of inflation in the previous period.
- (c) A temporary positive supply shock where inflationary expectations are based on the rate of inflation in the previous period.

- 22.7 Credit and the business cycle.** This case traces cycles in the growth of credit and relates them to the business cycle. It also looks at some of the implications of the growth in credit.
- 22.8 Effective monetary policy versus banking efficiency and stability.** This case examines potential conflicts between banking stability, efficiency and the effective operation of monetary policy.
- 22.9 Should central banks be independent of government?** An examination of the arguments for and against independent central banks.
- 22.10 The Bank of England and Taylor rules.** A comparison of the Bank of England's monetary policy rule with a simple Taylor rule.
- 22.11 *IS/MP*, policy and the aftermath of the banking crisis.** Using the *IS/MP* framework we analyse the banking crisis and the subsequent recession and slow recovery.
- 22.12 Fiscal and monetary policy in the UK.** An historical overview of UK fiscal and monetary policy.
- 22.13 *IS/LM* analysis of fiscal and monetary policy.** An illustration of how we can use the *IS/LM* framework to examine the effects of fiscal and monetary policy taking into account both the goods and money markets.

The case for intervention	738
Examples of interventionist supply-side policy	738
Regional and urban policy	741

In this chapter we turn our attention to the determinants of long-run economic growth. All developed countries have experienced economic growth over the past 60 years, but rates have differed significantly from one country to another. We look at some of these differences in section 23.1.

If an economy is to achieve sustained economic growth over the longer term, there must be a sustained increase in potential output. An important ingredient for long-term economic growth is the growth in labour productivity. This, in turn, depends on two major factors: a growth in the amount of capital that workers use, and technological progress. We can see these two elements if we look around us. Take a modern car factory, with its high-tech robot-driven equipment: it is no surprise that workers' productivity is much higher than it was, say, 30 years ago. Take a modern office, with powerful computers: again it is no surprise that today's office staff are much more productive than their counterparts of past years.

In section 23.2 we look at the effects of an increase in the rate of capital investment when there is no change in technology. As we shall see, the effect will simply be growth to a new higher level of national income, not a permanently higher rate of economic growth. If economic growth is to

be higher over the long term, therefore, there must be an increase in the rate of technological progress. We look at how this affects economic growth in section 23.3.

In the final three sections we look at various policy options to increase aggregate supply. Supply-side policies can be put into two broad categories: market orientated and

interventionist. Market-orientated policies focus on 'freeing up' markets and improving market incentives. They involve policies such as tax cuts, privatisation and deregulation. Interventionist policies, by contrast, focus on ways of countering the inadequacies of markets through direct government provision of transport infrastructure, training or R&D, or financial support for private provision.

23.1 INTRODUCTION TO LONG-TERM ECONOMIC GROWTH

Twin characteristics of growth

Our focus so far in Part F has been on economic volatility. This is not surprising given that economies are inherently volatile and often experience significant fluctuations in economic activity. Yet when we step back and look at the longer span of history, these short-term fluctuations take on less significance. What we see is that economies tend to experience long-term economic growth.

These twin characteristics of growth are nicely captured in Figure 23.1, which plots for the UK both the *level* of real GDP and annual percentage *changes* in real GDP. It shows that while the rate of economic growth is volatile, the volume of output grows over time.

The rate of long-term economic growth in developed nations, such as the UK, has meant that average living standards have improved markedly. When measured in terms of real GDP per head, all developed nations are considerably richer today than they were, say, 50 or 60 years ago.

The picture, however, is not one of universal improvement. People are not necessarily happier; there are many

stresses in modern living; the environment is in many respects more polluted; inequality has increased in most countries, especially over the past 20 years; for many people work is more demanding and the working day is longer than in the past; there is more crime and more insecurity. Hence, 'more' is not always 'better'.

Nevertheless, most people *want* more consumer goods; they want higher incomes. In this chapter, we examine what causes long-term economic growth, and how it can be increased. We leave you to judge whether a materially richer society is a better society.

Long-run growth and the DAD/DAS and IS/MP models

Sustained economic growth over the longer term requires a sustained increase in *potential output*. This means that there has to be a continuous rightward shift in aggregate supply. When viewed through the DAD/DAS model, long-run growth therefore means a continuous rightward shift of the

Figure 23.1 Output and economic growth in the UK since 1850

Note: Growth is the annual growth in constant-price GDP.

Sources: 1850–1948 based on data from Bank of England available at <http://www.bankofengland.co.uk/publications/quarterlybulletin/threecenturiesofdata.xls>; from 1949 based on data from *Quarterly National Accounts* series ABMI and IHYP (National Statistics).

Figure 23.2 Long-term growth in integrated DAD/DAS and IS/MP framework

Over the long term, the rise in the potential level of output shifts the DAD and DAS curves and the IS and MP curves rightwards by the same amount. Long-term growth is accompanied by both a stable inflation rate at the targeted level and the natural real rate of interest.

DAS curve. The rate of growth in potential output is then the rate at which the curve shifts rightwards.

We can use Figure 23.2 to illustrate the process of long-run growth through a simplified version of our integrated macroeconomic framework introduced in the previous chapter. It combines the DAD/DAS and IS/MP models. The relationship between the labour market and long-term growth is discussed as we go through the chapter.

Does a rise in potential real income result in a fall in the natural rate of unemployment?

Assume initially that the economy is at equilibrium characterised by output (real national income) at the potential level (Y_{p1}), inflation at the target rate (π^*) and the interest rate at the natural rate (r^*). Now assume that potential output rises from Y_{p1} to Y_{p2} . We will look at how this might happen later in the chapter.

The DAD/DAS model (Figure 23.2(a))

The DAS curve moves rightwards – say to DAS_2 . The size of the shift reflects the increase in the economy's productive capabilities. If the extra capacity is used, this also has the effect of increasing the real national income of the country; people are now able to make more purchases. There is also likely to be a rightward shift in the DAD curve. If the extra real income generated by the increase in potential output generates an equivalent amount of additional real spending, the DAD curve will shift to DAD_2 . (This would be when Say's law is operative: see page 494.) In such a case, actual output would increase by the same amount as potential output: i.e. $Y_{p2} - Y_{p1}$.

If, however, the rise in potential output did not translate into sufficient extra spending, the DAD curve would not shift sufficiently to the right to give a new equilibrium at Y_{p2} – a negative output gap would emerge. In such a case, discretionary fiscal and/or monetary policy may be required to shift the DAD curve to DAD_2 .

Generally, however, over a time span of several years, periods of deficient demand are likely to be matched by periods of excess demand. In the long run, therefore, rightward shifts in the DAS curve would be matched by equivalent rightward shifts in the DAD curve. In other words, in the long run, economies tend towards equilibrium at the potential level of national income as markets and expectations adjust.

The IS/MP model (Figure 23.2(b))

In this model, the MP curve also shifts rightwards by the increase in potential output (i.e. from MP_1 to MP_2). This occurs because, with more productive capacity, the rate of inflation is now lower at any level of output. Hence, the central bank can now set a lower real rate of interest at any particular level of output than previously.

Meanwhile, if the extra capacity generates extra demand, the IS curve will shift to the right too. In periods of negative or positive output gaps, however, the shift in the IS curve is likely to fall short of or exceed the rightward shift in the MP curve. Over time, however, the rightward shift in the IS curve is likely to match the rightward shift in the MP curve as markets clear and expectations adjust.

Explain the mechanisms whereby the DAD and IS curves will shift by the same amount as the DAS and MP curves in the long run.

Figure 23.3 Long-term output growth (real GDP, 1960 = 100)

Growth over the decades

Despite economic volatility, most countries have experienced long-term economic growth. Figure 23.3 shows the path of real GDP (output) in six developed economies, including the UK, from 1960. As you can see, the fluctuations in output appear relatively minor compared with the long-term growth in output.

Such growth cannot be explained by a closing of the gap between actual and potential output: by an expansion of aggregate demand leading to a fuller use of resources. Instead, the explanation lies on the supply side. Countries' economic *capacity* has increased.

Comparing the growth performance of different countries

An increase in economic capacity is reflected in a growth in the average output per head of the population (per capita). Table 23.1 shows the average *annual* rate of growth in output per capita and output per employed person for several *developed* countries since the 1960s, alongside that for output (real GDP). The effect of even very small differences can have a significant effect when looked at over many years.

As you can see from Table 23.1, there has been a considerable difference in the rates of growth experienced by the different countries. Such differences have implications for the longer-term living standards of countries' populations. However, if economic growth is to give an indication of an increase in living standards, it has to be measured per head of the population.

Table 23.1 Average annual percentage growth rates, 1961–2018

	Real GDP	Real GDP per capita	Real GDP per worker
Australia	3.5	1.9	1.6
Canada	3.1	1.9	1.2
France	2.8	2.1	2.3
Germany	2.4	2.1	1.9
Ireland	4.7	3.8	3.5
Italy	2.4	2.1	2.2
Japan	3.8	3.2	3.2
Netherlands	2.7	2.0	1.9
New Zealand	2.7	1.5	1.1
Norway	3.1	2.4	2.0
Spain	3.4	2.6	2.7
UK	2.4	1.9	1.8
USA	3.0	2.0	1.6

Notes: (i) Figures from 2017 based on forecasts; (ii) German figures based on West Germany only up to 1991.

Source: Based on data from AMECO database (European Commission, DGECFIN).

Table 23.2 considers the average annual growth rates from 1993 to 2018, both overall and per capita, for a wider range of countries than we have so far considered. Canada and America had faster absolute growth rates than the UK, but after taking into account their more rapid increase in populations, they experienced a slightly lower per capita growth rate. Russia and South Korea, with a decline in their populations, experienced higher growth per capita than absolute growth.

Table 23.2 Average annual growth rates 1993–2018 at constant prices: total and per capita

	Real GDP	Real GDP per capita
Australia	3.3	1.8
Brazil	2.5	1.3
Canada	2.5	1.4
China	9.4	8.7

UK	2.1	1.6
USA	2.5	1.5

Note: Figures from 2016 based on forecasts.

Source: Authors' calculations based on data from *World Economic Outlook Database*, October 2016 (International Monetary Fund).

In general, GDP per capita in the richer developed countries have grown at a slower rate than the less rich ones. The result has been a narrowing of the gap. For example, in 1950 GDP per head in the USA (in purchasing-power standard terms) was 2.5 times that in West Germany and 20 times that in Japan. By 2018, GDP per head in the USA was estimated to be only 19 per cent higher than that in Germany and 49 per cent higher than that in Japan.

This *convergence in GDP per head*, however, has not been universal across the world. Although countries like Brazil, China, India and many other Asian countries have grown very rapidly, and in recent years some of the poorer African countries too, there remain others, often blighted by war or corruption or rapid population growth rates, where real GDP per capita has grown at pitifully slow rates, and in some cases has even declined. We examine the causes of low growth in developing countries in sections 26.3 to 26.5.

Although recent generations have come to expect economic growth, it is a relatively new phenomenon. For most of the last 2000 years, countries have experienced virtually static output per head over the long term. Economic growth has become significant only once countries have undergone an industrial revolution, and it is only with the technological advances of the twentieth and now the twenty-first centuries that long-term growth rates of 2 per cent or more have been achieved.

The causes of economic growth

The sources of economic growth can be grouped into two broad categories:

- An increase in the *quantity* of factors. Here we would include an increase in the workforce or the average number of hours that people work, an increase in raw materials (e.g. discoveries of oil) and an increase in capital. Of these,

TC 14
p458

Definition

Convergence in GDP per head The tendency for less rich developed countries to catch up with richer ones. Convergence does not apply to many of the poorer developing countries, however; the gap between them and richer countries has tended to widen.

*LOOKING AT THE MATHS

Since 1961, the UK economy has grown on average by 2.4 per cent per annum. This means that it has doubled in size roughly every 29 years. Over the same period, the Australian economy has grown by an average of 3.5 per cent per annum. As a result, its economy has doubled in size roughly every 20 years.

But how do we work out these numbers of years? To do this we use logarithms. To find the number of years, n , that it takes an economy to grow by a factor x (e.g. 2 in the case of a doubling), we divide the log of x by the log of the factor by which the economy is growing each year, g (so $g = 1.024$ for 2.4% and $g = 1.035$ for 3.5%):

$$n = \frac{\log x}{\log g}$$

We can use our calculators to find the logs. Thus, in the case of the UK:

$$n = \frac{\log x}{\log g} = \frac{\log 2}{\log 1.024} = 29.2$$

and in the case of Australia:

$$n = \frac{\log x}{\log g} = \frac{\log 2}{\log 1.035} = 20.1$$

In practice, these figures are only approximate as the two countries' growth rates varied from year to year.

How long would it take an economy, like China, growing at an annual rate of close to 10 per cent to (a) double in size; (b) triple in size?

for most countries, it is an increase in the capital stock, brought about by investment, that is the most important source of growth. The amount of capital per worker – the capital/labour ratio (K/L) – has increased over time and has resulted in a greater output per worker (Y/L).

- An increase in the *productivity* of factors. Here we would include an increase in the skills of workers, a more efficient organisation of inputs by management and more productive capital equipment. Most significant here is technological progress. Developments of computer technology, of new techniques in engineering, of lighter,

stronger and cheaper materials, of digital technology in communications and of more efficient motors have all contributed to a massive increase in the productivity of capital. Machines today can produce much more output than machines in the past and cost the same to manufacture.

In the next two sections, we will examine these two sources of growth and focus first on capital accumulation (an increase in the *quantity* of capital) and then on technological progress (an increase in the *productivity* of factors).

Section summary

1. Economies are inherently volatile in the short run. But most countries experience growth over the long term. The determinants of long-term economic growth lie primarily on the supply side. Long-term growth is therefore consistent with continuous rightwards shifts of the AS or DAS curves.
2. Most developed countries have experienced average annual rates of economic growth of 2 per cent or more over the last 50 years, but there have been considerable differences between countries.
3. The income gap between developed countries has tended to narrow as the less rich ones have grown faster than the richer ones. Some of the poorest countries of the world, however, have experienced very low rates of growth, with the result that the gap between them and richer countries has widened.
4. The determinants of economic growth can be put into two broad categories: an increase in the quantity of factors and an increase in the productivity of factors.

23.2 ECONOMIC GROWTH WITHOUT TECHNOLOGICAL PROGRESS

Capital accumulation

An increase in capital per worker will generally increase output. In other words, the more equipment that is used by people at work, the more they are likely to produce. But to increase capital requires investment, and that investment requires resources – resources that could have been used for producing consumer goods. Thus more investment means diverting resources away from producing finished goods into producing machines, buildings and other capital equipment. This is the opportunity cost of investment.

If we take a simple circular flow of income model, with saving as the only withdrawal and investment as the only injection, then saving will be equal to investment ($S = I$). An increase in saving, therefore, will enable more investment and more output for the future. Thus sacrifices today, in terms of more saving and less consumption, will mean more output and hence possibly more consumption for the future.

A model of economic growth

A country's percentage rate of economic growth (g) depends crucially on two factors:

- The amount of extra capital that is required to produce an extra unit of output per year: i.e. the marginal capital/

output ratio (k). The greater the marginal capital/output ratio, the lower will be the output per year that results from a given amount of investment.

- The percentage of national income that a country saves (s). The higher this percentage, the greater the amount of investment that can be financed.

There is a simple formula that relates the rate of economic growth to these two factors. It is known as the **Harrod-Domar model** (after the two economists, Sir Roy Harrod and Evsey Domar, who independently developed the model). The formula is:

$$g = s/k$$

Thus if a country saved 10 per cent of its national income ($s = 10\%$), and if £4 of additional capital were required to produce £1 of extra output per annum ($k = 4$), then the rate of economic growth would be $10\%/4 = 2.5$ per cent.

Definition

Harrod-Domar model A model that relates a country's rate of economic growth to the proportion of national income saved and the ratio of capital to output.

What would be the rate of economic growth if 20 per cent of national income were saved and invested and the marginal capital/output ratio was $\frac{5}{2}$?

However, we need to make two qualifications to this simple model.

Declining marginal efficiency of capital. The first relates to the marginal capital/output ratio (k). Since the ratio measures how much additional capital is needed to produce one more unit of output it reflects the effectiveness of additional capital. In fact, the ratio is the inverse of the *marginal efficiency of capital* (see page 305).

We can define the nation's marginal efficiency of capital (*MEC*) as the annual extra output (ΔY) yielded by an increase in the capital stock, relative to the cost of that extra capital (ΔK).

$$MEC = \frac{\Delta Y}{\Delta K} = \frac{\Delta Y}{I}$$

Thus if £4 of extra capital yielded an additional annual income of £1, the marginal efficiency of capital would be $\frac{1}{4}$. Since the marginal capital/output ratio (k) is $1/MEC$, then k must equal 4.

The marginal efficiency of capital is likely to decline (and the marginal capital/output ratio to increase) as the amount of capital per worker increases. This is because of diminishing returns to capital.

Increasing replacement investment. The second qualification is that a proportion of investment has to be used for replacing worn-out or obsolete equipment. The problem here is that the larger the capital stock, the greater the proportion of investment that will be needed for replacement purposes, and the smaller the proportion that can be used for increasing the size of the capital stock.

Growth to a long-run equilibrium level of national income

Let us now incorporate these two qualifications into a model of growth. This is known as the neoclassical or 'Solow' growth model, after the MIT economics professor and Nobel Prize winner, Robert Solow. In this model, we are assuming for simplicity that the size of the workforce is constant. Any increase in the capital stock, therefore, means an increase in the average amount of capital per worker.

The model is illustrated in Figure 23.4. The size of the capital stock (K) is measured on the horizontal axis; the level of national output (Y) is measured on the vertical axis.

We start by looking at the effects of a growth in the capital stock on national output (i.e. on real national income (Y)). This is shown by the green output curve. As the capital stock increases, so output increases, but at a diminishing rate (the curve gets less and less steep). The reason for this is the law of diminishing returns: in this case, diminishing returns to capital. For example, if, in an office, you start equipping workers with computers, at first output will increase very rapidly. But as more and more workers have their own

Figure 23.4 Steady-state output

computer rather than having to share, so the rate of increase in output slows down. When everyone has their own, output is likely to be at a maximum. Any additional computers (of the same specification) will remain unused.

Increased output will mean increased saving and hence increased investment (the amount depending on the level of i). This is shown by the blue investment (I) curve. In this simple model, the vertical distance between the Y and I curves represents consumption ($C = Y - I$).

The magenta (D) line shows the amount of depreciation of capital that takes place, and hence the amount of replacement investment required. The bigger the capital stock, the larger the amount of replacement investment required.

Assume initially that the size of the capital stock is K_0 . This will generate an output of Y_0 (point a). This output, in turn, will generate saving and investment of I_0 , but of this, D_0 will have to be used for replacement purposes. The difference ($b - c$) will be available to increase the size of the capital stock. The capital stock will thus increase up to K_1 (point g). At this point, all investment will be required for replacement purposes. Output will therefore cease growing. Y_1 represents the *steady-state level of national income*.

Effect of an increase in the saving rate

In the simple model, $g = s/k$ (or $g = s \times MEC$), an increase in the saving rate (s) will increase the growth rate (g). When we take into account diminishing returns to capital and depreciation, however, an increase in the saving rate will lead to only a temporary increase in output, and to no long-term *growth* at all!

Definition

Steady-state level of national income The long-run equilibrium level of national income. The level at which all investment is used to maintain the existing capital stock at its current level.

* LOOKING AT THE MATHS

Steady-state equilibrium in the Solow growth model is achieved where investment (I) equals depreciation (D).

Investment is assumed to be a given fraction (s) of the level of national income Y , where national income is a function of the total capital stock (K): $Y = f(K)$. Thus

$$\begin{aligned} I &= sY \\ &= s \times f(K) \end{aligned} \quad (1)$$

Depreciation in the model is assumed to be a fixed proportion (d) of the capital stock (K). Thus

$$D = dK \quad (2)$$

In steady-state equilibrium, given that $I = D$, from equations (1) and (2) we can write

$$s \times f(K) = dK$$

Thus

$$K = \frac{s \times f(K)}{d}$$

Thus if we know the production function ($Y = f(K)$), the saving rate (s) and the depreciation rate (d), we can solve for the steady-state equilibrium value of K and hence also for Y . Maths Case 23.1 on the student website gives a worked example of this.

BOX 23.1 GETTING INTENSIVE WITH CAPITAL

How quickly does it grow?

In this box we take a look at two issues relating to capital. First, we consider what counts as capital in a country's national accounts. Second, we compare the growth of the capital stock in a sample of developed economies and then see how this compares with their rates of economic growth.

What is capital?

In a country's national accounts, capital consists of non-financial *fixed assets*. It does not include goods and services transformed or used up in the course of production; these are known as *intermediate goods and services*. Furthermore, it does not relate directly to the stock of human capital: the skills and attributes embodied in individuals that affect production (see Box 23.3).

A country's stock of fixed assets can be valued at its replacement cost, regardless of its age: this is its gross value. It can also be valued at its written-down value known as its net value. The net value takes into account the *consumption of capital* which occurs through wear and tear (depreciation) or when capital becomes naturally obsolescent.

The table shows that the estimated net capital stock of the UK in 2015 was £4.35 trillion. This is considerably less than the estimate of human capital of £19.9 trillion (see Box 23.3). To put this into context, this is 2.3 times the value of (annual) GDP.

The table shows that there are five broad categories of fixed assets. The largest of these by value is *dwellings*, which includes houses, bungalows and flats. Residential housing yields rental incomes for landlords and, more generally, provides all of us with important consumption services, most notably shelter.

The second largest component by value is *other buildings and structures*. This includes buildings, other than residential dwellings, and most civil engineering and construction work. It includes structures such as factories, schools and hospitals and the country's railway track.

The third largest component is *ICT and other machinery equipment*. It includes telecommunications equipment, computer hardware, office machinery and hardware as well as weapon systems equipment.

UK net capital stock

Type	2015			average real annual change, %	
	£ billions	% of fixed assets	% of GDP	1996–2015	2009–2015
Dwellings (excluding land)	1 785.0	41.0	95.3	1.3	0.4
Other buildings and structures	1 592.6	36.6	85.0	2.1	1.6
ICT, other machinery and equipment	672.4	15.4	35.9	2.9	1.1
Intellectual property products	197.5	4.5	10.5	−2.0	−2.0
Transport equipment	99.8	2.3	5.3	1.8	3.0
Cultivated biological resources	6.6	0.2	0.4	0.7	4.4
All fixed assets	4 353.9	100.0	232.5	1.9	1.0

Source: Based on data from *Capital Stocks, Consumption of Fixed Capital, 2016* and *Quarterly National Accounts* (series YBHA) (National Statistics).

The fourth largest is *intellectual property products*. These include intangible fixed assets such as R&D, mineral exploration, software and databases, and original literary and artistic works.

Next by value is *transport equipment*. This includes equipment for moving people and objects such lorries for haulage, buses, railway rolling stock and civil aircraft.

The smallest component is *cultivated biological resources*. This includes livestock for breeding, vineyards, orchards and forests.

The final two columns of the table look at the annual growth in the stock of capital. The first of these shows that, on average, from 1996 to 2015 the volume of the UK capital stock increased by 1.9 per cent per year. This was largely driven by growth in 'ICT, other machinery and equipment' and in 'other buildings and

This is illustrated in Figure 23.5. If the saving rate increases, the investment curve will shift upwards. This is shown by a shift from I_1 to I_2 . Investment is now above that which is necessary to maintain the capital stock at K_1 . The capital stock will grow, therefore, and so will national income. But this growth is only temporary. Once the capital stock has risen to K_2 , all the new higher level of investment will be absorbed in replacing capital ($I = D$ at point n). National income stops rising. Y_2 represents the new steady-state national income.

Does this mean, therefore, that there is no long-term gain from an increase in the saving rate? There is a gain, to the extent that income per worker is now higher (remember that

we are assuming a constant labour force), and this higher income will be received not just once, but every year from now on as long as the saving rate remains at the new higher level. There is no increase in the long-term *growth rate*, however. To achieve that, we would have to look to the other determinants of growth.

Human capital and education

The analysis of Figures 23.4 and 23.5 need not be confined to the stock of *physical* capital: machines, buildings, tools, etc. It can also apply to *human capital*. Human capital, as we saw in Chapter 10, refers to the skills and expertise of workers that have been acquired through education and

structures'. Since 2009, the annual growth rate has fallen to just 1 per cent per year.

How quickly does capital grow? An international comparison

In models of economic growth an important measure of how much capital is being used is the amount of capital per person employed (per worker). This is also known as *capital intensity*. In the chart we plot the ratio of capital per worker in 2018 to that in 1960 (x-axis) against the ratio of output (real GDP) per worker in 2015 to that in 1960 (y-axis) in a selection of developed countries.

For each country we observe an increase in capital intensity, although the rates of capital accumulation differ quite significantly. The data show that the UK ranks relatively low in terms of capital accumulation. In the UK the capital stock per

worker is 2.3 times higher in 2018 than in 1960. This compares with, for example, Japan, where it is 5.6 times higher, or France, where it is 3.7 times higher.

We would expect that the higher the level of capital per worker, the greater will be the level of output per worker. This is largely borne out in the chart. However, while there is a strong statistical association between capital accumulation and economic growth, there are other factors that impact on long-term growth. Three of these are technological progress, *human capital* and the efficiency with which capital is deployed. We examine these later in this chapter.

1. How does human capital (the skills and expertise of the workforce) fit into a national account's definition of capital?
2. Does the composition of a country's capital affect its long-run economic growth?

Note: Figures from 2017 are forecasts.

Source: Based on data from AMECO database (European Commission).

Figure 23.5 Effect of an increase in the rate of saving and investment

training. If part of saving is used for investment in education and training, then the productivity of workers will rise, and so will output.

In Figures 23.4 and 23.5, therefore, the horizontal axis measures both physical and human capital. An increase in either has the effect of increasing the steady-state level of national income. In Boxes 23.1 and 23.3 we consider both how physical and human capital respectively are treated in countries' national accounts and at their rates of accumulation.

? *If there were a gradual increase in the saving rate over time, would this lead to sustained economic growth?*

An optimum rate of saving?

If an increase in the saving rate does at least lead to a higher level of output, is there an *optimum* level of saving? Clearly we would need to define 'optimum'. One definition would be where *consumption* per head is maximised.

Assuming a fixed population and a fixed workforce, higher saving will do two things. First, it will directly decrease consumption, since what is saved is not directly spent. Second, as we have seen, it will lead to higher output and hence higher income. So, with a higher saving rate, consumption will be a smaller proportion, but of a higher income. This implies that there will be some optimum saving rate at which consumption is maximised. This is illustrated in Figure 23.6.

If the saving rate is zero, the capital stock will be zero. Output and consumption will thus be zero (point *a*). As saving rises above zero, so the capital stock will grow, as will output and consumption. At the other extreme, if the saving rate were 100 per cent, although the capital stock would be high, all of the nation's income would go on maintaining that capital stock: there would be no consumption (point *b*). A saving rate somewhere between 0 and 100 per cent, therefore, will give the maximum consumption. In

Figure 23.6 An optimum saving rate

Figure 23.6, this is a rate of s^* , giving a level of consumption of C^* (point *m*). This is sometimes known as the *golden-rule saving rate*.

Evidence suggests that all countries have saving rates below the golden-rule level. Thus increases in saving rates would result in increases in consumption.

? *If this is true, why do people not increase their rate of saving?*

An increase in the workforce

An increase in the workforce, or in the number of hours worked by the existing workforce, will have the effect of shifting both the *Y* and *I* lines upwards in Figures 23.4 and 23.5. In other words, if a given amount of capital is used by more workers or for longer periods, output and hence saving and investment will increase. As more labour hours are used with any given amount of capital, diminishing returns to labour will set in. Output will grow, but at a diminishing rate. The marginal and average product of labour will fall (see Figure 6.1 on page 152). Thus although national output has risen (the new steady-state income is higher), the output per labour hour is less.

The effect on GDP per head of the population

If the rise in total hours worked is the result of an increased *participation rate* (i.e. a greater proportion of the population

Definition

Golden-rule saving rate The rate of saving that maximises the level of long-run consumption.

Participation rate The percentage of the working-age population that is part of the workforce.

wishing to work) or of people working longer hours, then GDP per capita will be higher, even though output per hour worked will be lower. If, however, the increased hours worked are the result of an increased *population*, with no increase in the participation rate or number of hours worked per worker, then, because of diminishing returns to labour, output per head of the population will have gone down: GDP per capita will be lower.

1. If there were a higher participation rate and GDP per capita rose, would output per worker also have risen?
2. If people worked longer hours and, as a result, GDP per capita rose, how would you assess whether the country was 'better off'?

Section summary

1. An increased saving rate will lead to higher investment and hence to an increase in the capital stock. This, in turn, will lead to a higher level of national income.
2. A larger capital stock, however, will require a higher level of replacement investment. Once this has risen to absorb all the extra investment, national income will stop rising: growth will cease. A steady-state level of national income has been achieved. An increased saving rate will therefore lead only to a rise in output, not to a long-term rise in the rate of growth.
3. An optimum rate of saving could be defined as one where consumption per head is maximised. This is sometimes known as the 'golden-rule saving rate'.
4. An increase in the workforce will lead to higher total output, but unless accompanied by an increase in the capital stock, it will generally lead to a reduction in output per worker.

23.3 ECONOMIC GROWTH WITH TECHNOLOGICAL PROGRESS

The effect of technological progress on output

Technological progress has the effect of increasing the output from a given amount of investment. This is shown in Figure 23.7. Initial investment and income curves are I_1 and Y_1 ; steady-state income is at a level of Y_1 (point f). A technological advance has the effect of shifting the Y line upwards, say to Y_2 . The higher income curve leads to a higher investment curve (for a given rate of saving). This is shown by curve I_2 . The new long-term equilibrium capital stock is thus K_2 , and the new steady-state level of income is Y_2 (point p).

If there is a 'one-off' technological advance, the effect is the one we have just illustrated. Income rises to a higher level, but does not go on rising once the new steady-state level has been reached. But technological progress marches on over time. New inventions are made; new processes are discovered; old ones are improved. In terms of Figure 23.7, the Y curve goes on shifting upwards over time.

The faster the rate of technological progress, the faster will the Y curve shift upwards and the higher will be the rate of economic growth. This is illustrated in Figure 23.8, which shows the increase in output over time. The faster the rate of technological progress, the higher the rate of growth of output.

Maths Case 23.2 on the student website explores the algebra of technological progress.

If, however, there is an increase in both labour *and* capital, GDP per capita need not fall, even with the same number of hours worked per head. There are likely to be constant returns to scale. For example, if country A has double the population and double the capital stock of country B, its GDP is likely to be approximately double, and its GDP per head approximately the same.

What should be clear from the above analysis is that, without technological progress or some other means of increasing output from a given quantity of inputs, long-term growth cannot be sustained.

Figure 23.7 Effect of a technological advance

The effect of an increase in the saving rate with a given rate of technological progress

Figure 23.9 shows the combined effects of an increased saving rate and continuing technological progress. The rate of technological progress gives the slope of the

BOX 23.2 LABOUR PRODUCTIVITY

How effective is UK labour?

A country's potential output depends on the productivity of its factors of production. There are two common ways of measuring labour productivity. The first is *output per worker*. This is the most straightforward measure to calculate. All that is required is a measure of total output and employment.

A second measure is *output per hour worked*. This has the advantage that it is not influenced by the *number* of hours worked. So for an economy like the UK, with a very high percentage of part-time workers on the one hand, and long average hours worked by full-time employees on the other, such a measure would be more accurate in gauging worker efficiency.

Both measures focus solely on the productivity of labour. In order to account directly for the productivity of capital we need to consider the growth in *total factor productivity (TFP)*. This measure analyses output relative to the amount of factors used. Changes in total factor productivity over time provide a good indicator of technical progress.

International comparisons of labour productivity

Charts (a) and (b) show comparative productivity levels of various countries and the G7 using GDP per hour worked. Chart (a) shows countries' productivity relative to the UK. As you can see, GDP per hour worked is lower in the UK than the other countries with the exception of Japan. For example, in 2016, compared with the UK, output per hour was 34.5 per cent higher in Germany, 29 per cent higher in France and 28 per cent higher in the USA.

Compared with the rest of the G7 countries, UK output per worker was 18 per cent lower, which means that the productivity gap remains at an historic high. A major explanation of lower productivity in the UK is the fact that for decades it has invested a smaller proportion of its national income than most other industrialised nations. Nevertheless, until 2006 the gap had been narrowing with the rest of the G7. This was because UK productivity, although lower than in many other countries, was growing faster. This can be seen in chart (b). Part of the reason for this was the inflow of investment from abroad.

Chart (c) compares labour productivity across both measures. Workers in the USA and the UK work longer hours than those in France and Germany. Thus whereas *output per hour worked* in the USA is on par with that in France and Germany, *output per person employed* in the USA is about 23 per cent higher than in France and 27 per cent higher than in Germany.

The evidence points to UK labour productivity being *lower* than that in the USA, France and Germany on both measures but higher than that in Japan.

In understanding the growth in labour productivity it is generally agreed that we need to focus on three issues: physical capital (see Box 23.1), human capital (see Box 23.3) and innovation and technological progress. The significance of these for the UK productivity gap is considered further in Case Study 23.2 on the student website.

(a) Productivity in selected economies relative to the UK (GDP per hour worked)

steady-state growth path. This is the growth path for any given saving rate. The saving rate determines the *position* (as opposed to slope) of the curve. Assume that the economy is on steady-state growth path 1. Then, at time t_1 , there is an increase in the saving rate. This has the effect of increasing output and the economy will move towards

Definition

What could explain the differences in productivity between the five countries in chart (c), and why do the differences vary according to which of the two measures is used?

steady-state growth path 2. But the full effect does not take place immediately, since new capital equipment takes time to plan and install and then to generate additional income, part of which will be used for more investment. Thus the actual growth path will follow the green line, gradually converging on steady-state growth path 2.

Endogenous growth theory

It should be clear from what we have argued that an increase in technological progress is essential if a country wants to achieve faster rates of growth in the long term. But is this purely in the lap of the scientists and engineers? In the Solow growth model that we have been considering up

Figure 23.8 Effect of technological progress on growth rates

to now, this is the type of assumption made. In other words, technological progress is simply a 'given': it is exogenously determined.

Whilst the neoclassical model identifies the importance of technological progress for enduring growth, it does not offer governments actual policy prescriptions. What can be done to speed up the rate of innovation? Can governments adopt policies that encourage scientific breakthroughs and technological developments? An *endogenous growth model* attempts to answer such questions this by incorporating technological advancement *within* the model.

What is endogenous about endogenous growth theory?

Endogenous growth models stress the importance of research and development, education and training and fostering innovation. Hence, policy makers are interested in

Figure 23.9 Effect of an increase in the saving rate, with a given rate of technological progress

appropriate policies that might, for example, make their country a world leader in innovation and technological advancement, especially if this helps to sustain higher long-run rates of economic growth, and so higher standards of living.

In such models, a major determinant of technological progress is the size and composition of the capital stock. As economies accumulate capital, they are likely to devote more resources to the development and maintenance of capital goods industries. In other words, they are likely to have a larger sector devoted to producing and developing capital goods. This, in turn, can raise the rate of technological progress and enable further capital accumulation. A virtuous circle is created. Consequently, rather than looking at capital accumulation and technological progress as separate sources of long-term economic growth, the two are arguably interdependent.

Investment in research and development can be encouraged through the use of patents and copyrights. These provide some protection to firms, enabling them to capture more of the benefits from their own ideas and thus providing them with an incentive to create and innovate. Furthermore, the striving for profit or the pursuit of competitive advantage over rival firms, through the design of either innovative products and services or the most cost-efficient production processes, are incentives that can drive this innovation and creativity.

But there are limits to the ability of firms to exclude other firms from prospering from their own ideas, such as the development of products, processes and people. The virtuous circle is thus reinforced by externalities: the spill-over of ideas from one firm to another. New ideas cannot be put back into the metaphorical bottle once its lid is off.

A model of endogenous technological progress

Endogenous growth models argue two things. The first is that technological progress is *dependent* on various economic factors such as the rate of investment in research and development. This could be included as an element in the investment (I) term, i.e.

$$I = I_n + I_c$$

where I_n is investment in research and development of new technology (it could also include investment in training) and

Definition

Endogenous growth models Models where the rate of growth depends on the rate of technological progress and diffusion, both of which depend on institutions, incentives and the role of government.

I_c is investment in capital that uses current technology. The greater the value of I_n/I_c , the faster will the Y curve shift upwards in Figure 23.4 (see page 719) and the steeper will be the steady-state growth path in Figure 23.9. Any policy, then, that increases the proportion of national income being devoted to R&D and training will increase the long-run rate of economic growth.

The second factor is the responsiveness of national income to new technologies ($\Delta Y/I_n$). This will depend in part on the extent to which innovations spill over to other firms, which duplicate or adapt them, thereby adding to the increase in national income (ΔY). The greater the value of $\Delta Y/I_n$, the greater will be the rate of economic growth: the steeper will be the steady-state growth path.

The values of I_n and $\Delta Y/I_n$ are thought to depend on structural and institutional factors within the economy and on the role of government. These include:

- attitudes of business, such as their inclination to take risk;
- willingness of financial institutions to lend support to investment opportunities;
- tax incentives and government grants, for instance support for R&D;
- a research infrastructure (e.g. laboratories and the number and skills of researchers);
- the degree of competition to develop new products and processes and/or to reduce costs;
- the magnitude of external spillovers from the generation of new products, processes and techniques;
- the stock of human capital.

As we have seen, endogenous growth models try to explain how the economy's production function shifts upwards over time. In some cases the production function may also become steeper. In other words, a given rise in the capital stock will cause a larger rise in national income. The reason is that the benefits of the output from investment are not confined just to the firms doing the investing. Rather, some benefits spill over to other firms. For example, firms may be able to duplicate or develop other firms' ideas. Consequently, these spillovers may positively impact on the overall marginal product of capital.

* LOOKING AT THE MATHS

The above endogenous growth model can be expressed algebraically as follows:

$$\Delta Y/Y = v(I_n/Y)$$

This states that the rate of economic growth ($\Delta Y/Y$) depends on the proportion of national income devoted to R&D and training (I_n/Y) by an amount v .

The higher the value of I_n/Y and the higher the value of v , the steeper will be the steady-state growth path.

Do all investment projects generate significant spillovers?

Policy implications

If there is a virtuous circle arising from firms investing and innovating, how can governments encourage this? Many economists argue that this requires supply-side policies. Examples include policies to influence research and development, education and training, industrial organisation and work practices – in other words, policies to affect aggregate supply directly.

There is less agreement, however, as to whether these policies should focus on delivering market solutions or involve greater state intervention. We look at this debate in the final sections of this chapter.

But encouraging investment does not just depend on effective supply-side policies. It also depends on the stability of the macroeconomic environment. It is not easy to plan ahead in times of great economic uncertainty. In the years following the financial crisis of 2007–8, uncertainty led to lower levels of investment and innovation in many countries. In the UK, for example, investment in the period 1997 to 2006 averaged 18.2 per cent of GDP; in the period 2009 to 2016, it averaged 16.3 per cent. The result was that productivity and potential income grew at a slower rate. In the decade following the financial crisis, annual productivity growth in advanced economies dropped to 0.3 per cent – down from around 1 per cent in the years before the crisis. If productivity growth had continued at 1 per cent, overall GDP in advanced economies would be some 5 per cent higher than it is today.¹

By contrast, the less the volatility in output (real GDP), the greater will be the confidence of business to innovate and invest and the higher will be the growth in potential income.

The idea that economic shocks can have persistent or enduring effects on the path of potential output has become a feature of many macroeconomic models (see section 16.6). These shocks can originate from both the demand and supply sides. Either way, we need to understand the mechanisms by which such shocks are propagated and their significance for longer-term growth.

Some economists, however, argue that, given the inherent volatility of economies, governments *should* be more proactive. For example, imperfections in the financial system which result in credit cycles can have marked effects on flows of investment, including spending on research and development. They argue that governments have a role to play in helping to stabilise aggregate demand so as to support and encourage firms to invest and increase potential output.

¹ See Christine Lagarde (Managing Director, International Monetary Fund), 'Reinvigorating productivity growth', *IMF Speeches*, 3 April 2017.

BOX 23.3 UK HUMAN CAPITAL

Estimating the capabilities of the labour force

The OECD (2001) defines human capital as the 'knowledge, skills, competencies and attributes embodied in individuals that facilitate the creation of personal, social and economic well-being'.¹ Hence, trends in human capital have implications for a range of economic-related issues, including economic growth, unemployment, life satisfaction, the inequality of income, wealth and opportunity and also for social cohesiveness. But how do we go about measuring human capital?

Measuring human capital

In estimating an individual's human capital, a common approach is to estimate the present value of an individual's *remaining lifetime labour income*. This can be done for representative individuals in categories defined by gender, age and educational attainment. An assumption is then made about the working life of individuals. In compiling the UK estimates it is assumed that the remaining lifetime labour income of individuals aged 65 and over is zero. Then an approach known as backwards recursion is applied.

Backwards recursion involves first estimating the remaining lifetime labour income of someone aged 64 with a particular gender, age and educational level. The remaining lifetime income in this case is simply their current labour income. For someone aged 63 it is their current labour income plus the present value of the remaining lifetime income of someone aged 64 with the same gender, age and educational level. This continues back to someone aged 16. In calculating the remaining lifetime labour income of representative individuals account is also taken of the probability that their level of educational attainment may rise and with it their expected future earnings.

Further working assumptions are necessary to complete the calculations. Two of the most important are: the rate of

labour productivity growth is 2 per cent per annum and the discount rate is 3.5 per cent per annum, as recommended by HM Treasury's *Green Book* (2003) when undertaking appraisal and evaluation studies in central government.

Two measures of the stock of human capital are estimated. The first is for *employed human capital*. It is based on estimating the lifetime labour income of those in employment. The second is *full human capital*. It includes the human capital of the unemployed. This assumes that the human capital of those currently unemployed should be valued at the remaining lifetime labour income of employed individuals with the same characteristics (gender, age and educational attainment). It ignores any so-called scarring effects from being unemployed, such as the depreciation of job-specific or transferable skills. Such effects are likely to increase with the duration of unemployment.

Estimates of human capital

The chart shows estimates of employed and full human capital in the UK since 2004. Both follow broadly similar patterns. Between 2004 and 2007, prior to the financial crisis, the stock of human capital increased by an average of 2.7 per cent per annum. Employed and full human capital fell in each year from 2009 to 2013. The fall in full human capital was, however, a little less pronounced because of the impact of rising unemployment on the employed human capital estimates.

On the back of a resumption of real wage growth and a rise in employment, the value of the stock of human capital, particularly employed human capital, began growing from 2014. In 2015 human capital values grew by over 4 per cent, with full human capital stock reaching £19.9 trillion (10.6 times GDP) and employed human capital £19.2 trillion (10.3 times GDP).

Section summary

1. A higher long-term rate of growth will normally require a faster rate of technological progress.
2. The rate of technological progress determines the slope of the steady-state growth path (i.e. the rate of steady-state growth). If there is a rise in the saving rate, this will shift the steady-state growth path upwards (parallel) and the actual growth path will gradually move from the lower to the higher path.
3. Endogenous growth theory argues that the rate of technological progress and its rate of diffusion depend on economic institutions and incentives. Supply-side policy could be used to alter these.

In Box 23.1 we saw that the net value of the UK's physical capital was £4.35 trillion (2.3 times GDP). Therefore, in 2015, the value of the stock of human capital was estimated to be around 4.6 times higher than the stock of physical capital.

We can also analyse the *distribution* of human capital by a particular characteristic, such as educational attainment. In 2015, it is estimated that 37.3 per cent of UK employed human capital was embodied in the 28.0 per cent of the population who have a degree (or equivalent). In contrast, only 5.1 per cent of employed human capital was embodied in

the 8.8 per cent of the working-age population with no formal qualifications.

1. Are human capital and physical capital substitutes or complements?
2. What characteristics might policy makers choose to focus on when analysing the distribution of human capital?

23.4 APPROACHES TO SUPPLY-SIDE POLICY

Macroeconomic objectives and supply-side policies

Long-term growth

Supply-side policies are policies designed to increase the quantity and/or productivity of the inputs used in production. If effective, such policies will increase potential output

Definition

Supply-side policies Government policies that attempt to influence aggregate supply directly, rather than through aggregate demand.

and thus, as we saw in section 23.1, shift the *AS* or *DAS* curves to the right. The more effective these policies are, the faster will potential output grow over time and the faster will the *AS* and *DAS* curves shift rightwards.

As we saw earlier in the chapter, an important influence on the pace of long-term growth is technological progress. Supply-side policies may therefore be directed at encouraging research and development. Specific measures might include increasing incentives for firms to take advantage of new ideas and innovations by investing in new capital, new production processes and perhaps organisational structures. But they will also need workers and managers with the tools, skills and flexibility to take full advantage of these innovations.

Thus supply-side policies to encourage economic growth are likely to focus not just on research and development, but also on education and training, infrastructure, industrial organisation, work practices and the whole range of incentives that may be necessary to make the best use of new ideas and techniques.

? *Why do Keynesians argue that, even in the long run, demand-side policies will still be required if faster growth in aggregate supply is to be achieved?*

Employment and unemployment

The cure for demand-deficient unemployment may lie on the demand side, but other types of unemployment require supply-side solutions.

Equilibrium unemployment – frictional, structural, etc. – is caused by rigidities or imperfections in the market. There is a mismatching of aggregate supply and demand, and vacancies are not filled despite the existence of unemployment. The problem is that labour is not sufficiently mobile, either occupationally or geographically, to respond to changes in the job market. Labour supply for particular jobs is too inelastic.

Supply-side policies aim to influence labour supply by helping workers to be more responsive to changes in job opportunities. They may also aim to make employers more adaptable and willing to operate within existing labour constraints. Alternatively, they may seek to reduce the monopoly power of unions to drive real wages above the equilibrium.

Successful supply-side policies that reduce equilibrium unemployment and increase employment and human capital also increase potential output. A rising stock of employed human capital (see Box 23.3) can contribute to the development of new products, processes and techniques and hence to the development of higher-quality capital. As we saw in the analysis of endogenous growth theories, there is also the potential that knowledge spillovers hasten progress. These spillovers are a form of externality with some of the benefits captured or consumed by others. In other words, these new ideas can then be developed by others.

Inflation

If inflation is caused by cost-push pressures, supply-side policy can help to reduce it in three ways:

- By reducing the power of unions and/or firms (for example, by the use of anti-monopoly legislation) and thereby encouraging more competition in the supply of labour and/or goods.
- By preventing people from exercising that power by some form of prices and incomes policy. (Such policies were used in the 1970s: see Case Study 23.7 on the student website.)
- By encouraging increases in productivity through retraining, or by investment grants to firms, or by tax incentives, etc.

The new classical approach

New classical economists argue that demand-side policy (by which they mean monetary policy) can only control inflation; it cannot affect growth and employment. Supply-side policy is the appropriate policy to increase output and reduce the level of unemployment.

New classical economists advocate policies to ‘free up’ the market: policies that encourage private enterprise, or provide incentives and reward initiative. Section 23.5 examines these *market-orientated supply-side policies*.

This part of the new classical agenda has much in common with the *neo-Austrian/libertarian school* (see Box 12.7). The argument here is that a free market, with the absolute minimum of government interference, will provide the dynamic environment where entrepreneurs will be willing to take risks and develop new products and new techniques.

The neo-Austrians go further. They also argue that the prospect of monopoly profits is often what provides a major motivation for firms to take risks. The search to achieve market advantages through new products and new techniques is just as important a part of competition, they argue, as competition in the market for existing goods. Thus private property rights are a key element in neo-Austrian thought: the right to keep the fruits of innovation and investment, with minimum taxation.

Definition

Market-orientated supply-side policies Policies to increase aggregate supply by freeing up the market.

Neo-Austrian/libertarian school A school of thought that advocates maximum liberty for economic agents to pursue their own interests and to own property.

The Keynesian approach

Modern Keynesians do not just advocate the management of demand. They also advocate supply-side policies, but generally of a more **interventionist** nature (e.g. training schemes, or policies to encourage firms to set up in areas of high unemployment).

The appropriate balance between demand- and supply-side policies depends on the degree of slack in the economy. In a recession, the immediate policy requirement is to increase aggregate *demand* rather than aggregate supply. Over the long term, however, supply-side policies will be needed to increase potential output and to reduce equilibrium (structural and frictional) unemployment.

Does this mean that Keynesians would advocate using supply-side policies only at times of full employment?

'Third Way' supply-side policies

During the early years of the Labour government in the UK from 1997 under Tony Blair, there was much discussion of a 'Third Way' between the unfettered market system advocated by many of those on the right and the interventionist approach advocated by those on the left. The Third Way borrows from the right in advocating incentives, low taxes and free movements of capital. It also borrows from the left in advocating means whereby governments can provide support for individuals in need while improving economic performance by investing in the country's infrastructure, such as its transport and telecommunication systems, and in its social capital, such as schools, libraries and hospitals.

Its main thrust is the concept of helping people to help themselves. Thus unemployment policies should be focused on helping the unemployed become employable, with

unemployment benefits linked to the obligation actively to look for work. Growth policies should be a mixture of strengthening market incentives and keeping taxes low, regulation to encourage more competition and prevent monopoly abuse, and providing improved infrastructure and improved education and training.

To some extent, this approach has been continued by subsequent UK governments through the 2010s, albeit with somewhat more emphasis on freeing up the market.

The link between demand-side and supply-side policies

Policies can have both demand-side and supply-side effects. For example, many supply-side policies involve increased government expenditure, whether on retraining schemes, on research and development projects, or on industrial relocation. They will therefore cause a rise in aggregate demand (unless accompanied by a rise in taxes). Similarly, supply-side policies of tax cuts designed to increase incentives will increase aggregate demand (unless accompanied by a cut in government expenditure). It is thus important to consider the consequences for demand when planning various supply-side policies.

Likewise, demand management policies often have supply-side effects. If a cut in interest rates boosts investment, there will be a multiplied rise in national income: a demand-side effect. But that rise in investment will also create increased productive capacity: a supply-side effect.

Definition

Interventionist supply-side policies Policies to increase aggregate supply by government intervention to counteract the deficiencies of the market.

Section summary

1. Supply-side policies, if successful, will shift the AS and DAS curves to the right, and possibly shift the Phillips curve downwards/to the left.
2. An important role for supply-side policies is to help increase productivity and, in particular, promote more rapid technological progress and its adoption by business. By doing so, this can raise the long-term rate of economic growth.
3. Demand-side policies (fiscal and monetary) may be suitable for controlling demand-pull inflation or demand-deficient unemployment, but supply-side policies will be needed to control the other types of inflation and unemployment.
4. New classical and neo-Austrian economists favour market-orientated supply-side policies. Keynesians tend to favour interventionist supply-side policies. The Third Way advocates carefully targeted government intervention, regulation, welfare and education programmes to encourage people better to help themselves and markets to work more effectively.
5. Supply-side policies often have demand-side effects, and demand-side policies often have supply-side effects. It is important for governments to take these secondary effects into account when working out their economic strategy.

23.5 SUPPLY-SIDE POLICIES IN PRACTICE: MARKET-ORIENTATED POLICIES

Market-orientated policies in the 1980s

Radical market-orientated supply-side policies were first adopted in the early 1980s by the Thatcher government in the UK and the Reagan administration in the USA. The essence of these policies was to encourage and reward individual enterprise and initiative, and to reduce the role of government; to put more reliance on market forces and competition, and less on government intervention and regulation. The policies were thus associated with the following:

- Reducing government expenditure so as to release more resources for the private sector.
- Reducing taxes so as to increase incentives.
- Reducing the monopoly power of trade unions so as to encourage greater flexibility in both wages and working practices and to allow labour markets to clear.

- Reducing the automatic entitlement to certain welfare benefits so as to encourage greater self-reliance.
- Reducing red tape and other impediments to investment and risk-taking.
- Encouraging competition through policies of deregulation and privatisation.
- Abolishing exchange controls and other impediments to the free movement of capital.

Such policies were increasingly copied by other governments around the world. Today most countries have adopted some or all of the above measures.

Government spending

The desire by many governments to cut government expenditure is not just to reduce the size of deficits and hence

BOX 23.4 THE SUPPLY-SIDE REVOLUTION IN THE USA

CASE STUDIES AND APPLICATIONS

'Reaganomics' and beyond

In both the UK and the USA, the 1980s proved to be years of radical political and economic change. Traditional economic and political practices were replaced by new and often controversial policies, although in theory many of the ideas advocated were based on old principles of laissez-faire capitalism.

In the USA, the era of 'Reaganomics' began in January 1981 when Ronald Reagan became President. With this new administration came a radical shift in policy aimed at directly tackling the supply side of the economy. This policy strategy involved four key strands:

- A reduction in the growth of Federal (central government) spending.
- A reduction in individual and corporate tax rates.
- A reduction in Federal regulations over private enterprise.
- A reduction in inflation through tight monetary policy.

On all four points, President Reagan was to achieve a degree of success. Federal spending growth was reduced even though military spending rocketed. Tax rates fell dramatically. Deregulation was speeded up. Inflation at first was stabilised and then fell sharply.

These supply-side measures were hailed as a great success by Republicans, and followers in both the UK and the USA were quick to advocate an even bigger reduction in the government's role.

Critics remained sceptical and pointed to the costs of Reaganomics. Huge budget deficits plagued the Reagan administration and the Bush Snr, Clinton and Bush Jnr

administrations that followed. The massive tax cuts were not matched by an equivalent cut in public expenditure; nor did they produce a sufficiently high rate of economic growth, through which additional tax revenues were to balance the budget. In the 1980s, 'civilian' or welfare spending was cut repeatedly in preference to the huge military budget. This led to increasing social hardship.

And such hardship still existed under George W. Bush. Indeed, with the onset of the credit crunch, things were to get worse as many poor people lost their houses. The emphasis had remained on cutting welfare and tightening requirements to receive state assistance. Critics claim that, even though the numbers on welfare might have fallen over the years, individuals and families remained in poverty, being forced to work for poverty wages as welfare support dwindled. The revolution was far from complete and its benefits to all social groups have been far from even.

The financial crisis of the late 2000s and the subsequent need for fiscal consolidation led to much debate, not only in the USA, about the form the fiscal consolidation should take and, more generally, about the role the state should play in modern economies. Whether, in such circumstances, current or future administrations will succeed in providing greater support for the poor without jeopardising the 'supply-side revolution' remains to be seen.

Are market-orientated supply-side policies incompatible with policies to redistribute national income more equally?

reduce the growth of money supply; it is also an essential ingredient of their supply-side strategy.

The public sector is portrayed as more bureaucratic and less efficient than the private sector. What is more, it is claimed that a growing proportion of public money has been spent on administration and other 'non-productive' activities, rather than on the direct provision of goods and services.

Two things are needed, it is argued: (a) a more efficient use of resources within the public sector and (b) a reduction in the size of the public sector. This would allow private investment to increase with no overall rise in aggregate demand. Thus the supply-side benefits of higher investment could be achieved without the demand-side costs of higher inflation.

In practice governments have found it very difficult to cut their share of expenditure in GDP. However, many countries were faced with trying to do this after the financial crisis and global economic slowdown of the late 2000s (see Figure 23.10). Governments found that this means making difficult choices, particularly concerning the level of services and the provision of infrastructure.

? Why might a recovering economy (and hence a fall in government expenditure on social security benefits) make the government feel even more concerned to make discretionary cuts in government expenditure?

Taxes and the labour market

Over time, governments in many countries have cut the marginal rate of income tax. Here we consider the case of the UK.

In 1979, the standard marginal rate of income tax was 33 per cent, with higher rates rising to 83 per cent. By 2008 the standard rate was 20 per cent and the higher rate was 40 per cent. From 2010, an additional 50 per cent tax rate was implemented for incomes in excess of £150 000, largely as a means of plugging the deficit in the public finances. This was subsequently reduced to 45 per cent from 2013.

Cuts in the marginal rate of income tax are claimed to have five beneficial effects: people work longer hours; more people wish to work; people work more enthusiastically; employment rises; unemployment falls. These are big claims. Are they true?

People work longer hours

A cut in the marginal rate of income tax has a *substitution effect* inducing people to work more and also an *income effect* causing people to work less. (At this point, you should review the arguments about the incentive effects of tax cuts: see pages 336–40.) Evidence suggests that the two effects will roughly cancel each other out. Anyway, for many people there is no such choice in the short run. There is no chance of doing overtime or working a shorter week. In the long run, there may be some flexibility in that people can change jobs.

More people wish to work

This applies largely to second income earners in a family, mainly women. A rise in after-tax wages may encourage more women to look for jobs. It may now be worth the cost in terms of transport, childcare, family disruption, etc. The effects of a 1 or 2 per cent cut in income tax rates, however, are likely to be negligible. A more significant effect may be

Figure 23.10 General government expenditure (% of GDP)

Notes: Data from 2017 based on forecasts.

Source: Based on data from *World Economic Outlook Database* (IMF) and *AMECO* database (European Commission).

achieved by raising tax allowances. Part-time workers, especially, could end up paying no taxes. Of course, if unemployment is already high, the government will not want to increase the labour force.

People work more enthusiastically

There is little evidence to test this claim. The argument, however, is that people will be more conscientious and will work harder if they can keep more of their pay.

Employment rises

If wages are flexible, total employment will rise. This is illustrated in Figure 23.11. The N curve shows the total labour force. The AS_L curve shows the number of people who are actually qualified and willing to do the specific jobs they are offered at each (after-tax) wage rate. Equilibrium is where the aggregate demand for labour (AD_L) is equal to the labour cost to the employer (i.e. the pre-tax wage rate). Assume an initial income tax per worker of $a - b$. The equilibrium employment will be Q_1 . Workers receive an after-tax wage W_1 and thus supply Q_1 labour. Employers' labour cost is the pre-tax wage lc_1 . At this wage, they demand Q_1 labour.

If the income tax per worker now falls to $c - d$, equilibrium employment will rise to Q_2 . Firms will employ more workers because their labour costs have fallen to lc_2 . More workers will take up jobs because their after-tax wages have risen to W_2 .

Unemployment falls

One of the causes of natural (equilibrium) unemployment highlighted by new classical economists is the cushioning provided by unemployment benefit. If income tax rates are cut, there will be a bigger difference between after-tax wage rates and unemployment benefit. More people will be motivated to 'get on their bikes' and look for work.

In Figure 23.11, the horizontal gap between N and AS_L represents equilibrium unemployment. With a cut in

income tax per worker from $a - b$ to $c - d$, equilibrium unemployment will fall from $e - b$ to $f - d$.

What would happen to the AS_L curve and the level of unemployment if unemployment benefits were increased?

Does this mean that there were no positive incentive effects from the 1979–97 Conservative government's tax measures?

To the extent that tax cuts do succeed in increasing take-home pay, there is a danger of 'sucking in' imports. In the UK, there is a high income elasticity of demand for imports. Extra consumer incomes may be spent on foreign-made electronic goods, foreign cars, holidays abroad and so on. Tax cuts can therefore have a serious effect on the current account of the balance of payments.

Taxes, business and investment

A number of financial incentives can be given to encourage investment. Selective intervention in the form of grants for specific industries or firms is best classified as an interventionist policy and will be examined in section 23.6. Market-orientated policies seek to reduce the general level of taxation on profits, or to give greater tax relief to investment.

A cut in taxes on business profits. A cut in corporation tax (the tax on business profits) will increase after-tax profits. This will leave more funds for ploughing back into investment. Also, the higher after-tax return on investment will encourage more investment to take place. In 1983, the main rate of corporation tax in the UK stood at 52 per cent. A series of reductions have taken place since then. By 2011 the main rate had been halved to 26 per cent; by 2017 it had fallen to 19 per cent; by 2020 the rate is due to have fallen to 17 per cent.

The UK government hopes that such low corporation tax rates will make the country an attractive destination for business investment. However, the danger of countries cutting taxes to make them more internationally competitive is that it is a prisoners' dilemma game. Countries cannot all have lower taxes than each other! You may simply end up with global taxes being lower and governments receiving less tax

Figure 23.11 Effect of a tax cut on total unemployment

² The rate was cut to 15 per cent in December 2008 for 13 months as part of the government's fiscal stimulus package.

revenue. Governments thus have to make a judgement as to whether or not cutting taxes will stimulate other countries to do the same.

Tax relief or other incentives for investment. Another approach to increase investment is through the use of allowances or R&D expenditure credits. Investment allowances enable firms to offset the cost of investment against their pre-tax profit, thereby reducing their tax liability. R&D expenditure credits operate by providing firms with cash payments for a proportion of their R&D expenditure which, although subject to tax, nonetheless increase their net profit.

Successive governments have applied such R&D incentives. For example, in the UK small and medium-sized enterprises (SMEs) can offset multiple research and development costs against corporation tax. Since April 2015, the rate of relief for small and medium-sized enterprises was 230 per cent: taxable profits are reduced by £230 for every £100 of R&D expenditure. Meanwhile, from April 2016 larger companies can claim a taxable credit worth 11 per cent of R&D expenditures.

Since April 2013, firms have been subject to a lower rate of corporation tax on profits earned from their patented inventions and certain other innovations. The idea is that firms will be provided with financial support to innovate where this results in their acquiring patents. Patents provide protection for intellectual property rights. Firms are liable to corporation tax on the profits attributable to qualifying patents at a reduced rate of 10 per cent.

Reducing the power of labour

In Figure 23.12, if the power of unions to push wage rates up to W_1 were removed, then (assuming no change in the demand curve for labour) wage rates would fall to W_e . Disequilibrium unemployment ($Q_2 - Q_1$) would disappear. Employment would rise from Q_1 to Q_e .

Equilibrium unemployment, however, will rise somewhat as the gap between gross and effective labour supply widens. With the reduction in wage rates, some people may now prefer to remain on unemployment benefits.

If labour costs to employers are reduced, their profits will probably rise. This could encourage and enable more investment and hence economic growth. If the monopoly power of labour is reduced, then cost-push inflation will also be reduced.

The Thatcher government took a number of measures to weaken the power of labour. These included restrictions on union closed shops, restrictions on secondary picketing, financial assistance for union ballots, and enforced secret ballots on strike proposals (see Chapter 10). It also set a lead in resisting strikes in the public sector.

As labour markets have become more flexible, with increased part-time working and short-term and zero-hour contracts, and as the process of globalisation has exposed more companies to international competition, so this has further eroded the power of labour in many sectors of the economy.

? *Is the number of working days lost through disputes a good indication of (a) union power; (b) union militancy?*

A danger in driving down wages through increased competition in the labour market is that it reduces the incentive for firms to increase labour productivity. One cause of the UK's significantly lower output per hour than its major competitors (see chart (c) in Box 23.2) is that hourly wages are lower in many industries.

Reducing welfare

New classical economists claim that a major cause of unemployment is the small difference between the welfare benefits of the unemployed and the take-home pay of the employed. This causes voluntary unemployment (i.e. frictional unemployment). People are caught in a 'poverty trap': if they take a job, they lose their benefits (see pages 342–3).

A dramatic solution to this problem would be to cut unemployment benefits. Unlike policies to encourage investment, this supply-side policy would have a very rapid effect. It would shift the effective labour supply curve to the right. In Figure 23.13, equilibrium unemployment would fall from $a - b$ to $c - d$ if real wage rates were flexible downwards; or from $a - b$ to $a - e$ if they were not flexible. In the case of non-flexible real wage rates, the reduction in equilibrium unemployment would be offset by a rise in disequilibrium unemployment ($e - b$).

Because workers would now be prepared to accept a lower wage, the average length of job search by the unemployed would be reduced. In Figure 23.14, the average duration of unemployment would fall from T_1 to T_2 .

? *Would a cut in benefits affect the W_e curve? If so, with what effect?*

Figure 23.13 The effects of a cut in benefits on the number unemployed

Figure 23.14 The effects of a cut in benefits on the average duration of unemployment

A major problem is that with changing requirements for labour skills, many of the redundant workers from the older industries are simply not qualified for new jobs that are created. What is more, the longer people are unemployed, the more demoralised they become. Employers would probably be prepared to pay only very low wage rates to such workers. To persuade these unemployed people to take these low-paid jobs, the welfare benefits would have to be slashed. A 'market' solution to the problem, therefore, may be a very cruel solution. A fairer solution would be an interventionist policy: a policy of retraining labour.

Another alternative is to make the payment of unemployment benefits conditional on the recipient making a concerted effort to find a job. In the jobseeker's allowance scheme introduced in the UK in 1996, claimants must be available for, and actively seeking, work and must sign a 'Claimant Commitment', which sets out the types of work the person is willing to do, and their plan to find work. Payment can be refused if the claimant refuses to accept the offer of a job.

Policies to encourage competition

If the government can encourage more competition, this should have the effect of increasing national output and reducing inflation. Five major types of policy have been pursued under this heading.

Privatisation

If privatisation simply involves the transfer of a natural monopoly to private hands (as with the water companies), the scope for increased competition is limited. However, where there is genuine scope for competition (e.g. in the supply of gas and electricity), privatisation can lead to increased efficiency, more consumer choice and lower prices (but see Box 14.4 on page 438).

Alternatively, privatisation can involve the introduction of private services into the public sector (e.g. private contractors providing cleaning services in hospitals, or refuse collection for local authorities). Private contractors may compete against each other for the franchise. This may well lower the cost of provision of these services, but the quality of provision may also suffer unless closely monitored. The effects on unemployment are uncertain. Private contractors may offer lower wages and thus may use more labour. But if they are trying to supply the service at minimum cost, they may employ less labour.

Deregulation

This involves the removal of monopoly rights. In 1979, the UK's National Bus Corporation lost its monopoly of long-distance coach haulage. Private operators were now allowed to compete. This substantially reduced coach fares on a number of routes. In 1986, competition was allowed in providing local bus services (see Case Study 23.5 on the student website).

An example in the private sector was the so-called 'Big Bang' on the Stock Exchange in 1986. Under this, the monopoly power of 'jobbers' to deal in stocks and shares on the Stock Exchange was abolished. In addition, stockbrokers now compete with each other in the commission rates that they charge, and online share dealing has become commonplace.

Introducing market relationships into the public sector

This is where the government tries to get different departments or elements within a particular part of the public sector to 'trade' with each other, so as to encourage competition and efficiency. The best-known examples are within health and education.

One example is the UK's National Health Service. In 2003, the government introduced a system of 'foundation trusts'. Hospitals can apply for foundation trust status. If successful, they are given much greater financial autonomy in terms of purchasing, employment and investment decisions. Applications are judged by Monitor, the independent health regulator. By April 2017, there were 155 NHS foundation trusts. Critics argue that funds have been diverted to foundation hospitals away from the less well-performing hospitals where greater funding could help that performance. In the 2012 Health and Social Care Act the government proposed that in due course all NHS hospitals become foundation trusts.

As far as general practice is concerned, groups of GP practices are formed into Clinical Commissioning Groups (CCGs). These are responsible for arranging most of the NHS services within their boundaries. A key principle of the system is to give GPs a choice of 'providers' with the hope of reducing costs and driving up standards.

Public-private partnerships

Public-private partnerships (PPS) are a way of funding public expenditure with private capital. In the UK the *Private Finance Initiative* (PFI), as it was known, began in 1992. The PFI meant that a private company, after a competitive tender, would be contracted by a government department or local authority to finance and build a project, such as a new road or a prison. The government then pays the company to maintain and/or run it, or simply rents the assets from the company. The public sector thus becomes a purchaser of services rather than a direct provider itself.

Critics claim that PFI projects have resulted in low quality of provision and that cost control has often been poor, resulting in a higher burden for the taxpayer in the long

term. What is more, many of the projects have turned out to be highly profitable, suggesting that the terms of the original contracts were too lax.

In 2012, the UK government published reforms to the PFI process following concerns about the quality of provision and the costs being incurred. The public sector now takes stakes of up to 49 per cent in new private finance projects (PF2 projects). PF2 projects no longer include 'soft services', such as cleaning and catering. The benefits and costs of PFI and PF2 are explored in Case 23.4 on the student website.

Free trade and free capital movements

The opening up of international trade and investment is central to a market-orientated supply-side policy. One of the first measures of the Thatcher government (in October 1979) was to remove all exchange controls, thereby permitting the free inflow and outflow of capital, both long term and short term. Most other industrialised countries also removed or relaxed exchange controls during the 1980s and early 1990s.

The Single European Act of 1987, which came into force in 1993, was another example of international liberalisation. As we shall see in section 24.4, it created a 'single market' in the EU: a market without barriers to the movement of goods, services, capital and labour.

Critics have claimed that in the short term industries may be forced to close by the competition from cheaper imported products, which can have a major impact on employment in the areas affected. A major election promise of the Trump campaign was that 'putting America first' would involve a move away from free trade and giving specific protection to US industries, such as vehicles and steel. We examine the arguments for and against protection in section 24.2.

Section summary

1. Market-orientated supply-side policies aim to increase the rate of growth of aggregate supply by encouraging private enterprise and the freer play of market forces.
2. Reducing government expenditure as a proportion of GDP is a major element of such policies.
3. Tax cuts can be used to encourage more people to take up jobs, and to encourage people to work longer hours and more enthusiastically. They can be used to reduce equilibrium unemployment and encourage employers to take on more workers. Likewise, tax cuts for businesses or increased investment allowances may encourage higher investment. The effects of tax cuts depend on how people respond to incentives. For example, people will work longer hours only if the substitution effect outweighs the income effect.
4. Reducing the power of trade unions by legislation could reduce disequilibrium unemployment and cost-push inflation. It could also lead to a redistribution of income to profits, which could increase investment and growth (but possibly lead to greater inequality).
5. A reduction in welfare benefits, especially those related to unemployment, will encourage workers to accept jobs at lower wages and thus decrease equilibrium unemployment.
6. Various policies can be introduced to increase competition. These include privatisation, deregulation, introducing market relationships into the public sector, public-private partnerships and freer international trade and capital movements.

23.6 SUPPLY-SIDE POLICIES IN PRACTICE: INTERVENTIONIST POLICIES

The case for intervention

Many interventionist policies come under the general heading of **industrial policy**: the government taking an active role to support investment in industry and to halt the decline of the manufacturing sector (see Box 23.3). The basis of the case for government intervention is that the free market is likely to provide too little research and development, training and investment.

As we saw in section 23.3, there are potentially large external benefits from research and development. Hence, the social rate of return on investment may be much higher than the private rate of return. Investment that is privately unprofitable for a firm may therefore still be economically desirable for the nation.

Similarly, investment in training may continue yielding benefits to society that are lost to the firms providing the training when the workers leave.

Investment often involves risks. Firms may be unwilling to take those risks, since the costs of possible failure may be too high. When looked at nationally, however, the benefits of investment might well have substantially outweighed the costs, and thus it would have been socially desirable for firms to have taken the risk. Successes would have outweighed failures.

For decades, the UK has had a lower level of investment relative to GDP than other industrialised countries. This is illustrated in Table 23.3. It could be argued, therefore, that there is a particularly strong case in the UK for government intervention to encourage investment.

Table 23.3 Gross capital formation (investment), % of GDP

	1980s	1990s	2000s	2010s	1980–2019
Australia	27.0	24.9	26.8	26.1	26.2

Imperfections in the capital market

Imperfections in the capital market may result in investment not being financed, even though it is privately profitable. Banks in the UK, unlike banks in France, Germany and Japan, have not traditionally been a source of finance for long-term investment by firms.

Similarly, if firms rely on raising finance by the issue of new shares, this makes them very dependent on the stock market performance of their shares, which depends on current profitability and expected profitability in the near future, not on long-term profitability. Shareholders, who are mainly financial institutions, tend to demand too high a dividend rate from the companies in which they invest. This, in part, is due to competition between financial institutions to attract savers to buy their savings packages. The result is that there is less profit left over for ploughing back into investment. The fear of takeovers (the competition for corporate control) again makes managers overconcerned to keep shareholders happy. Finally, floating successful companies on the Stock Exchange provides a large windfall gain to the original owners. This encourages entrepreneurs to *set up* companies, but discourages them from making *long-term* commitments to them. This has all led to the UK disease of 'short-termism': the obsession with short-term profits and the neglect of investment that yields profits only after a number of years.

Finally, in the case of ailing firms, if the government does not help finance a rescue investment programme, there may be substantial social costs from job losses. The avoidance of these social costs may make the investment socially, if not privately, profitable.

 How would the radical right reply to these arguments?

Examples of interventionist supply-side policy

Nationalisation

This is the most extreme form of intervention, and one that most countries have in the past rejected, given the worldwide trend of privatisation. Nevertheless, many countries have stopped short of privatising certain key transport and power industries, such as the railways and electricity

Definition

Industrial policies Policies to encourage industrial investment and greater industrial efficiency.

BOX 23.5

A NEW APPROACH TO INDUSTRIAL POLICY

EXPLORING ECONOMICS

Industrial policy attempts to increase investment and halt or slow the shrinking of the industrial sector. As with many other areas of economic policy, industrial policy throughout most of the world has undergone a radical reorientation in recent years. The government's role has shifted from one of direct intervention in the form of subsidies and protecting industry from competition, to one of focusing upon the external business environment and the conditions that influence its competitiveness.

The reasons for such a change are both philosophical and structural:

- The rise of the political right in the 1980s led to a shift away from interventionist and towards market-based supply-side policy.
- Growing government debt, and a desire to curb public expenditure, acted as a key incentive to reduce the state's role in industrial affairs. This was argued to be one of the driving forces behind the European privatisation process since the 1980s.
- Industry, during the 1980s, became progressively more global in its outlook. As such, its investment decisions were increasingly being determined by external environmental factors, especially the technology, productivity and labour costs of its international competitors.

The new approach to industrial policy, being widely adopted by many advanced countries, is to focus on improving those factors that shape a nation's competitiveness. This involves shifting away from particular sectors to targeting what are referred to as 'framework conditions for industry'.

Policies include the following:

- The promotion of investment in physical and human capital. Human capital in particular, and the existence of a sound skills base, are seen as crucial for attracting global business and ensuring long-run economic growth.
- A reduction in non-wage employment costs, such as employers' social security and pension contributions. Many governments see these costs as too high and as a severe limitation on competitiveness and employment creation.
- The promotion of innovation and the encouragement of greater levels of R&D.
- Support for small and medium-sized enterprises. SMEs have received particular attention due to their crucial role in enhancing innovation, creating employment and contributing to skills development, especially in high-tech areas.
- The improvement of infrastructure. This includes both physical transport, such as roads and railways, and information highways.
- The protection of intellectual property by more effective use of patents and copyright. By reinforcing the law in these areas it is hoped to encourage firms to develop new products and commit themselves to research.

These policies, if they are to be truly effective, are likely to require co-ordination and integration, since they represent a radical departure from traditional industrial policy.

1. *In what senses could these new policies be described as (a) non-interventionist; (b) interventionist?*
2. *Does globalisation, and in particular the global perspective of multinational corporations, make industrial policy in the form of selective subsidies and tax relief more or less likely?*

generation. Having these industries under public ownership may result in higher investment than if they were under private ownership. Thus French governments have invested heavily in the state-owned railway system. This has resulted in fast, efficient rail services, with obvious benefits to rail users and the economy generally.

Nationalisation may also be a suitable solution for rescuing vital industries suffering extreme market turbulence. This was the case in 2008 with many banks. With the credit crunch, overexposure to risky investments in securitised sub-prime debt, inadequate levels of capital, declining confidence and plummeting share prices, many banks were taken into full or partial public ownership. In the UK, Northern Rock and Bradford & Bingley were fully nationalised, while the government took a temporary majority shareholding in the Royal Bank of Scotland and Lloyds Banking Group.

Direct provision

Improvements in infrastructure – such as a better motorway system – can be of direct benefit to industry. Alternatively, the government could provide factories or equipment to

specific firms. Following the financial crisis and the economic volatility that followed, the IMF, OECD and other international organisations began calling for greater international expenditure on infrastructure as a way of increasing not only potential output but also aggregate demand.

Funding research and development (R&D)

To increase a country's research and development, the government could fund universities or other research institutes through various grants, perhaps allocated by research councils. Alternatively, it could provide grants or tax relief to private firms to carry out R&D.

As we saw in section 23.5, the UK uses the tax system to encourage research and development (R&D). Despite this, UK gross expenditure on R&D as a percentage of GDP has been significantly lower than that of its main economic rivals (see Figure 23.15). This has contributed to a productivity gap between the UK and other G7 countries (see Box 23.2).

The UK's poor R&D record has occurred even though a sizeable number of UK-based companies are among the world's largest R&D spending companies, albeit within a

Figure 23.15 Gross expenditure on R&D (% of GDP)

Note: OECD = 35 members (as of April 2017) of the Organisation for Economic Co-operation and Development.
 Source: *Gross Domestic Spending on R&D* (OECD, 2017).

narrow range of industries, such as pharmaceuticals, finance and aerospace. In part, this reflects the limited R&D expenditure by government. But, it also reflects the low R&D intensity across the private sector. In other words, total R&D expenditure by British firms has often been low *relative* to the income generated by sales.

Training and education

It is generally recognised by economists and politicians alike that improvements in training and education can yield significant supply-side gains. Indeed, the UK's failure to invest as much in training as many of its major competitors is seen as a key explanation for the persistent productivity gap with many other advanced countries.

The government may set up training schemes, or encourage educational institutions to make their courses more vocationally relevant, or introduce new vocational qualifications. Alternatively, the government can provide grants or tax relief to firms which themselves provide training schemes.

Education and training in the UK. From April 2017 in England, the Education and Skills Funding Agency (ESFA) took over responsibility for funding education and training for children, young people and adults. Hence, as well as the funding of education for pupils aged 5 to 16 it has responsibility for overseeing education and training for those aged 16 to 19 and apprenticeships and adult education.

As part of the government's strategy to support apprenticeships, the Apprenticeship Levy was introduced from April 2017. This saw employers with an annual wage bill of £3 million or more having to pay a levy of 0.5 per cent towards the funding of apprenticeships. Employers in

England can then use funds in their apprenticeship accounts to pay for apprenticeship training and assessment with the payment dependent, in part, on the level of the apprenticeship: i.e. the equivalent educational level. For smaller employers the government will pay up to 90 per cent of their training and assessment costs, although in the case of companies with fewer than 50 employees 100 per cent of these costs are paid for if the apprentices are aged between 16 and 18.

Figure 23.16 shows the steady expansion in the number of starts on government-funded apprenticeships in England between 2006/7 and 2009/10, followed by a more significant expansion in the early 2010s before then levelling off at around 500 000 per annum. While each age group has seen an increase in the number of apprenticeships, the growth in the number of learners aged 25 and over starting apprenticeships has been particularly rapid.

Nonetheless, the recent growth in apprenticeships has to be seen in the context of the relatively low starting point compared with other countries. The National Audit Office in 2012 identified that only 5 per cent of employers in England (2010) were offering apprenticeships compared with 24 per cent in Germany (2008) and 30 per cent in Australia (2009).

Alternative approaches to training in the UK, Germany, France and the USA are examined in Case 23.10 on the student website.

Advice, information and collaboration

The government may engage in discussions with private firms in order to find ways to improve efficiency and innovation. It may bring firms together to exchange information and create a climate of greater certainty or it may bring

Figure 23.16 Total government-funded apprenticeship starts, England

Source: Based on data from FE Data Library: Apprenticeships (Department for Education, 2017).

firms and unions together to try to create greater industrial harmony. It can provide various information services to firms: technical assistance, the results of public research, information on markets, etc.

Local Enterprise Partnerships (LEPs) are an example of partnerships created between local government and businesses in England. LEPs began in 2011 and their aim is to promote local economic development. As well as facilitating the flow of information between public and private organisations, LEPs agree on local strategic economic objectives. They can seek funds from central government through 'Local Growth Deals' or co-ordinate the establishment of enterprise zones (see below) to meet these objectives.

? What are the advantages and disadvantages of local collaborations, such as LEPs, as compared to geographically larger collaborations?

Regional and urban policy

Causes of regional imbalance

In addition to adopting supply-side measures that focus on the economy as a whole, governments may decide to target specific regions of the economy. Certain parts of the country suffer from lower economic growth and higher unemployment than others. These can be broad regions, such as the North East of England or Calabria in southern Italy, or much smaller areas, such as parts of inner cities. These regional and urban problems normally result from structural problems – the main one being the decline of certain industries, such as mining or heavy manufacturing

industry, which had previously been concentrated in those areas.

When an area declines, there will be a downward **regional multiplier effect**. The decline in demand and loss of jobs lead to less money being spent in the local community; transport and other service industries lose custom. The whole region becomes more depressed.

In addition, labour may be geographically immobile. The regional pattern of industrial location may change more rapidly than the labour market can adjust to it. Thus jobs may be lost in the depressed areas more rapidly than people can migrate from them. Unemployment rises. Even when people do leave the area, this can compound the downward multiplier effect as spending further declines.

If the capital market functioned well, this could help to arrest the decline. If wages were lower and land were cheaper in the depressed areas, capital would be attracted there. In practice, capital, like labour, is often relatively immobile. Existing capital stock is highly immobile. Buildings and most

Definition

Regional multiplier effects When a change in injections into or withdrawals from a particular region causes a multiplied change in income in that region. The regional multiplier (k_r) is given by $1/mpw_r$, where the import component of mpw_r consists of imports into that region either from abroad or from other regions of the economy.

machinery cannot be moved to where the unemployed are! New capital is much more mobile. But there may be insufficient new investment, especially during a recession, to halt regional decline, and investors may be put off by the depressed and run-down nature of the area, the lack of suitably qualified labour and lack of infrastructure.

Policy approaches

Policies targeted at specific regions (or sectors) tend to be more interventionist in nature. Interventionist policies involve encouraging firms to move. Such policies include the following.

Subsidies and tax concessions in the depressed regions. Businesses could be given general subsidies, such as grants to move, or reduced rates of corporation tax. Alternatively, grants or subsidies could be specifically targeted at increasing employment (e.g. reduced employers' national insurance contributions) or at encouraging investment (e.g. investment grants or other measures to reduce the costs of capital).

The provision of facilities in depressed regions. The government or local authorities could provide facilities, such as land and buildings at concessionary, or even zero, rents to incoming firms; or spend money on improving the infrastructure of the area (roads and communications, technical colleges, etc.).

The siting of government offices in the depressed regions. The government could move some of its own departments out of the capital and locate them in areas of high unemployment. The siting of the vehicle licensing centre in Swansea is an example.

Recent regional policy for England draws heavily on the first two of these. As we saw earlier, Local Enterprise Partnership (LEPs) have been a key mechanism used by the government in bringing together local authorities, firms and organisations. Subsequently, LEPs have been used to drive forward the development of Enterprise Zones. First established in 2012, these zones are specific geographic locations where firms can benefit from reduced planning restrictions, tax breaks and improved infrastructure, including access to superfast broadband. The number of zones has grown from 24 in 2012 to 48 in April 2017.

Many of the Enterprise Zones encourage clustering: businesses in the same sector grouping together. The hope is that they can mutually benefit from external economies of scale (see page 187) such as co-operation and technological developments.

To benefit from clustering effects, the zones typically focus on specific sectors, such as automotive and transport (e.g. the MIRA technology park near Hinckley, Leicestershire), renewable energy (e.g. the Humber Enterprise Zone) or science and innovation (e.g. Loughborough and Leicester Enterprise Zone).

The danger of such an approach, particularly given the relatively small geographic areas of many LEPs and Enterprise Zones, is that they may merely divert investment away from other areas rather than resulting in *additional* investment.

Case Study 23.14 on the student website is an extended case study of regional and urban policy in both the UK and the EU.

How might clustering effects be incorporated into endogenous growth theories?

Section summary

1. Those in favour of interventionist industrial policy point to failings of the market, such as the externalities involved in investment and training, the imperfections in the capital market and the short-term perspective of decision makers.
2. Interventionist supply-side policy can take the form of grants for investment and research and development, advice and persuasion, the direct provision of infrastructure and the provision, funding or encouragement of various training schemes.
3. Regional and local disparities arise from a changing pattern of industrial production. With many of the older industries concentrated in certain parts of the country and especially in the inner cities, and with an acceleration in the rate of industrial change, so the gap between rich and poor areas has widened.
4. Regional disparities may persist because of capital and labour immobility and regional multiplier effects.
5. Policies targeted at specific regions or sectors tend to be interventionist in their approach. These include subsidies, tax concessions and the provision of facilities in depressed regions.

BOX 23.6

UNEMPLOYMENT AND SUPPLY-SIDE POLICIES

CASE STUDIES AND APPLICATIONS

Two approaches

Countries have had varying degrees of success in reducing unemployment through appropriate supply-side policies.

In 2006, the OECD put countries into four groups according to their policies towards labour markets. The first two groups have been successful in cutting unemployment. The other two have not.

The first group, labelled 'mainly English-speaking' by the OECD (Japan, South Korea and Switzerland are honorary Anglophones), tends to have weaker job protection, less generous unemployment benefits and thinner tax wedges than the average. Its employment rate is comfortably higher than the OECD average; its jobless rate [5.3 per cent] is comfortably lower [than the OECD average of 7.5 per cent]. In the second, 'northern European' group (Scandinavia, the Netherlands, Austria and Ireland), taxes and unemployment benefits are high and workers hard to fire. Yet the average employment rate is a little higher than the first group's and the unemployment rate a little lower [4.8 per cent].

There are two reasons why the second group can match the first. Their product markets are, like those of the first group, fairly loosely regulated, making the whole economy more dynamic. And they spend much more on schemes intended to ensure that the unemployed try hard to find work: in return for high benefits, they must accept that their search for a job will be closely watched and that

some work-seeking programmes may be compulsory. That high unemployment benefits are a disincentive to seek work is not in doubt; but it seems that a sufficiently diligent and well-funded employment service can offset their effects. . . .

Countries in the third group – mainly southern European ones, plus France and Germany – tend to pay high benefits too. But they have not offset these with labour-market programmes on the scale of the second group, and their product markets are more protected. [Unemployment in this group averages 9.0 per cent.]

In the last group, which includes the Czech Republic, Poland and Slovakia, benefits are low. But workers are not especially easy to fire; little is spent on pushing the jobless into work; and product markets are more regulated than in any other group. [Unemployment in this group averages 15.1 per cent.]¹

1. How would you classify the approaches of the first two groups in terms of whether they are 'market-orientated' or 'interventionist'?
2. Is there an even more effective approach to reducing unemployment that uses elements of each?

¹ 'Intricate workings', *The Economist*, 17 June 2006.

END OF CHAPTER QUESTIONS

1. For what reasons do countries experience very different long-run rates of economic growth from each other?
2. Why do developed countries experience a degree of convergence over time? Would you expect there to be total convergence of GDP per head?
3. If increased investment (using current technology) does not lead to increased long-run economic growth, does it bring any benefits?
4. What determines the rate of depreciation of capital? What would happen if the rate of depreciation fell?
5. What is meant by the 'steady-state economic growth path'? What determines its slope?
6. What is the significance of the term 'endogenous' in endogenous growth theory? What, according to this theory, determines the long-run rate of economic growth?
7. Under what circumstances would a higher rate of investment lead to a higher rate of economic growth?
8. What determines the rate of growth in total factor productivity?
9. What policy prescriptions do the neoclassical and endogenous growth theories offer policy makers who are looking to raise their country's long-run growth rate?
10. For what possible reasons may a country experience a persistently faster rate of economic growth than another?
11. What is the relationship between 'successful' supply-side policies and unemployment in (i) the short run and (ii) the long run, according to (a) Keynesian and (b) monetarist assumptions?
12. Why might market-orientated supply-side policies have undesirable side effects on aggregate demand?
13. What type of tax cuts are likely to create the greatest (a) incentives, (b) disincentives to effort?
14. Is deindustrialisation necessarily undesirable?
15. In what ways can interventionist industrial policy work *with* the market, rather than against it? What are the arguments for and against such policy?
16. What are the arguments for and against relying entirely on *discretionary* regional and urban policy?
17. Select a European country other than the UK and compare its regional and urban policy with that of the UK.

|-----------|---|------------|
| 24 | International Trade | 746 |
| 25 | The Balance of Payments and Exchange Rates | 786 |
| 26 | Economies in an Interdependent World | 823 |

'Globalisation' is a word frequently used nowadays. It captures one of the key features of economics today: that it is global in nature. International trade and international financial flows have often grown at exceedingly rapid rates in recent decades. The result is that economies around the globe are highly interconnected so that what happens in one country can have profound effects on others.

In Chapter 24 we focus on international trade, looking at the benefits it brings, but also at the costs that can be incurred. This is important when analysing the calls, by some, for greater protectionism. Are people right to fear international competition? The chapter concludes by reflecting on the potential longer-term implications for the UK from the vote in 2016 to leave the European Union.

With the growth in international trade and financial flows Chapter 25 focuses on the potential for countries to be more vulnerable to balance of payments problems and exchange rate fluctuations. It analyses the relationships between a country's balance of payments and its exchange rate.

Chapter 26 looks at particular aspects of global and regional interdependence. In this context, it analyses the euro and how economic and monetary union (EMU) operates, whether the adoption of the euro by 19 EU countries has been of benefit to them and reflects on the future of the euro. Chapter 26 concludes by looking at the poorest countries of the world, whose development depends so much on the economic policies of the rich.

Long-term growth, trade and Brexit	781

Without international trade we would all be much poorer. There would be some items like pineapples, coffee, cotton clothes, foreign holidays and uranium that we would simply have to go without. Then there would be other items like wine and spacecraft that we could produce only very inefficiently. International trade has the potential to benefit all participating countries. This chapter explains why.

Totally free trade, however, may bring problems to countries or to groups of people within those countries. Many people argue strongly for restrictions on trade. Textile workers see their jobs threatened by cheap imported cloth. Car manufacturers worry about falling sales as customers switch to Japanese or other East Asian models. But are people justified in fearing international competition, or are they merely trying to protect some vested interest at the expense of everyone else? Section 24.2 examines these arguments and also looks at world attitudes towards trade restrictions.

A step on the road to freer trade is for countries to enter free trade agreements with just a limited number of other countries. Examples include the EU and more recently the North American Free Trade Association (NAFTA – the USA, Canada and Mexico). We consider such ‘preferential trading systems’ in section 24.3. Then, in section 24.4, we look in more detail at the EU and the development of the ‘single European market’. We finish by considering some of the possible economic implications for the UK from the vote in 2016 to leave the European Union. The focus here is on the supply-side effects of the UK’s new trading relationship with the EU and the rest of the world.

This chapter may be studied after Chapter 12 or Chapter 14 if you prefer.

24.1 THE ADVANTAGES OF TRADE

The growth of world trade

Trade values

In 1960 the (nominal) value of world merchandise exports (i.e. the exports of goods) was estimated at \$130 billion. By 2016 this had grown to over \$16 trillion. Figure 24.1 helps to put this into perspective by showing both the value of world merchandise exports and their value as a percentage of GDP. From just under 10 per cent in 1960, by 2008 they had grown to 25.5 per cent of GDP. Indeed, from 1960 to 2008 the value of world trade had typically grown at more than twice the rate of the value of world output. However, since the financial crisis of 2007–8, this trend has been reversed. By 2016, world merchandise exports had fallen to 21 per cent of world GDP.

Another way of looking at world trade is through the sum of both exports *and* imports. This is commonly used to capture the openness of economies. Table 24.1 shows total merchandise trade as a percentage of GDP for various countries. As you can see, in all cases the proportion was higher in the 2010s than in 1960s, and in some cases considerably higher.

? Which countries' merchandise trade had fallen as a percentage of GDP between the 2000s and the period from 2010 to 2015? Explain why.

So far our focus has been on the trade of goods. But countries trade services too. Commercial services include manufacturing services on physical inputs (e.g. oil refining,

Table 24.1 Merchandise trade, percentage of GDP

New Zealand	32.2	40.2	43.7	43.3	44.6	42.3
UK	31.0	38.7	39.3	37.1	37.0	42.2
USA	6.9	11.7	14.4	16.8	19.7	22.9
World	17.7	26.5	30.9	32.9	43.5	48.4

Note: Merchandise trade as a share of GDP is the sum of merchandise exports and imports divided by the value of GDP, all in current US dollars.

Source: World Bank (series TG.VAL.TOTL.GD.ZS).

assembly of electronics and packing), maintenance and repair, transport, construction, insurance and financial services, telecommunications and private health and education services. In 2016 the global value of exports of commercial services was \$4.9 trillion, the equivalent of 6.5 per cent of GDP. This was an increase from just \$191 billion or 3 per cent of GDP in 1976.

Figure 24.1 World merchandise exports, \$ billions and % of world GDP

Table 24.2 Trade in commercial services, percentage of GDP

	1980s	1990s	2000s	2010–15
USA	3.5	4.7	5.3	6.8
UK	10.7	11.2	16.2	19.3
China	2.2	5.9	7.7	5.9
Germany	8.7	8.6	12.7	15.5
France	10.8	11.2	13.4	16.9
Netherlands	19.3	21.6	27.2	34.3
World	7.3	8.4	10.7	12.3

Note: Trade in commercial services as a share of GDP is the sum of exports and imports in commercial services divided by the value of GDP, all in current US dollars.

Source: World Bank (series BG.GSR.NFSV.GD.ZS).

Table 24.2 shows the sum of exports and imports in commercial services as a percentage of GDP in various countries since the 1980s – these countries were the largest exporters by value of commercial service in 2015. Though the flows are much smaller than those of merchandise goods, we still observe a significant increase in international flows of commercial services over the whole period and, with the exception of China, the percentages were higher in the period 2010 to 2015 than in the 2000s.

Trade volumes

The dollar value of recorded global trade is affected by changes in prices and exchange rates as well as the volumes traded. Therefore, by adjusting the dollar value of trade flows for changes in export and import prices we are able to estimate the change in the *volumes* of goods being traded.

Figure 24.2 shows the growth in the value and volume of world merchandise exports from 1980. Over the period as a whole the value of merchandise exports grew at annual rate of 4.6 per cent. After accounting for changes in the prices of countries' exports, the volume of exports is estimated to have grown by 1.7 per cent per year.

The chart also shows the actual year-to-year changes in the values and volumes of merchandise exports. There are some significant differences between the change in values and volumes. Take, for example, 2015 when the value of merchandise exports fell by around 13.5 per cent. In contrast, the volume of exports rose by 2.5 per cent. The difference is largely attributable to the large fall in commodity prices in 2015 with, for example, global energy prices falling by as much as 45 per cent.

From Figure 24.2 we can see the significant negative impact of the global financial crisis at the end of the 2000s on the volume of merchandise exports. In 2009, the volume of worldwide merchandise exports fell by approximately 12 per cent (while their value declined by 23 per cent). This was the biggest contraction in global trade since the Second World War. Despite the initial rebound in 2010 the average rate of growth in the volume of exports from 2011 to 2016 was only 2.8 per cent compared to the 5.3 per cent average experienced from 1981 to 2007. This was partly attributable to weaker global economic growth: the world economy grew by 2.5 per cent per annum from 2011 to 2016 compared with 3.1 per cent from 1981 to 2007. Notably, larger developing economies, such as China, saw their growth weaken and in some cases, such as Brazil, economies went into recession.

? *If the volume of merchandise exports falls by less than their value what can be infer about what has happened to the prices of merchandise exports'?*

Figure 24.2 Growth in world merchandise exports by value and volume

Figure 24.3 Share of world merchandise exports, by value (2015)

Sources: Based on data in *Time Series on International Trade* (WTO, 2017).

Trading nations

Developed economies have until recently dominated world trade. In 2016, they accounted (by value) for 54 per cent of world merchandise exports and 57 per cent of world merchandise imports (see Figure 24.3). Their share of world trade, however, has tended to decline over time. Thirty years earlier, they accounted for nearly 80 per cent of merchandise exports and imports (see Box 24.1). The reason for this changing global pattern in trade is that many of the countries with the most rapid *growth* in exports can now be found in the developing world.

The growth in merchandise exports from the group of developing nations collectively known as the BRICS¹ (Brazil, Russia, India, China and South Africa) has been especially rapid. Between them they accounted for just 5.4 per cent of the value of world exports in 1994. In 2016

they accounted for 18.2 per cent of world exports (see Figure 24.4). More recently, other countries, such as Mexico, Turkey, Cambodia and Vietnam, have joined the ranks of rapidly growing 'newly industrialised' developing countries.

Box 24.1 looks in more detail at the leading trading nations and at the countries with which they trade.

Figure 24.4 Share of total world merchandise exports (%) by the BRICS

Source: Based on data from *Time Series on International Trade*, statistics database (SDB), (WTO).

¹ Sometimes the term is used to refer just to the first four countries. When South Africa is excluded, the term is written BRICs rather than BRICS.

BOX 24.1 TRADING PLACES

Patterns and trends in world trade

Note: data exclude Hong Kong re-exports; CIS = Commonwealth of Independent States (former Soviet republics).
Source: Based on data from *WTO Merchandise Trade Values Annual Dataset*, (WTO).

The past three decades have seen rapid changes in the composition of world trade flows. We have seen, for example, the rising importance of the BRICS and, in particular, of China (see Figure 24.4). More generally, the dominance of world trade by the developed nations has weakened. The chart shows the value of world exports since 1992 originating from developed countries, developing countries and the Commonwealth of Independent States (former Soviet republics).

In 1992, the percentage of world merchandise exports originating from developed countries was 73 per cent. In 2016, the percentage had fallen to 54 per cent, though this reflected a rebound after the ratio fell just below the 50 per

cent mark, for the first time, in the period from 2012 to 2014.

Table (a) shows the world's top five merchandise exporters and importers by value for 2015. It also shows trade figures for the UK. The four largest exporting nations are also the four largest importers of goods and services.

Trade partners

But who do countries trade with? Table (b) looks at the trading partners of the world's leading trading countries. The table shows that trading blocs (see section 24.3) and geography matter. For instance, in the case of Germany over one-half of its trade is with other EU countries. Similarly,

Specialisation as the basis for trade

Why do countries trade with each other, and what do they gain from it? The reasons for international trade are really only an extension of the reasons for trade *within* a nation. Rather than people trying to be self-sufficient and do everything for themselves, it makes sense to specialise.

Firms specialise in producing certain goods. This allows them to gain economies of scale and to exploit their entrepreneurial and management skills and the skills of their labour force. It also allows them to benefit from their particular location and from the ownership of any particular capital equipment or other assets they might possess. With the revenues firms earn, they buy in the inputs they need from other firms and the labour they require. Firms thus trade with each other.

Countries also specialise. They produce more than they need of certain goods. What is not consumed domestically is exported. The revenues earned from the exports are used to import goods that are not produced in sufficient amounts at home.

Why does the USA not specialise as much as General Motors or Texaco? Why does the UK not specialise as much as Tesco? Is the answer to these questions similar to the answer to the questions 'Why does the USA not specialise as much as Luxembourg?' and 'Why does Tesco or Unilever not specialise as much as the local butcher?'

But which goods should a country specialise in? What should it export and what should it import? The answer is that it should specialise in those goods in which it has a *comparative advantage*. Let us examine what this means.

(a) Top trading countries by value and world share, 2015

Rank	Exporters	\$ billion	Share	Rank	Importers	\$ billion	Share

Source: Trade profiles, Statistics database (WTO).

one-third of the value of the USA's exports and one-quarter of its imports can be attributed to Canada and Mexico, members of the North American Free Trade Association (NAFTA) (see page 774).

Does the fact that world trade has increased at a much faster rate than world GDP (at least up until the financial crisis) highlight the limitations of trade as a driver of economic growth?

The law of comparative advantage

Countries have different endowments of factors of production. They differ in population density, labour skills, climate, raw materials, capital equipment, etc. These differences tend to persist because factors are relatively immobile between countries. Obviously land and climate are totally immobile, but even with labour and capital there are more restrictions on their international movement than on their movement within countries. Thus the ability to supply goods differs between countries.

What this means is that the relative cost of producing goods varies from country to country. For example, one country may be able to produce one fridge for the same cost as 6 tonnes of wheat or 3 MP4 players, whereas another country may be able to produce one fridge for the same cost

as only 3 tonnes of wheat but 4 MP4 players. It is these differences in relative costs that form the basis of trade.

KT 2
p10

At this stage, we need to distinguish between *absolute advantage* and *comparative advantage*.

Absolute advantage

When one country can produce a good with less resources than another country, it is said to have an *absolute advantage* in that good. If France can produce grapes with less resources than the UK, and the UK can produce barley

Definition

Absolute advantage A country has an absolute advantage over another in the production of a good if it can produce it with less resources than the other country.

with less resources than France, then France has an absolute advantage in grapes and the UK an absolute advantage in barley. Production of both grapes and barley will be maximised by each country specialising and then trading with the other country. Both will gain.

Comparative advantage

The above seems obvious, but trade between two countries can still be beneficial even if one country could produce *all* goods with less resources than the other, providing the *relative* efficiency with which goods can be produced differs between the two countries.

Take the case of a developed country that is absolutely more efficient than a less developed country at producing both wheat and cloth. Assume that with a given amount of resources (labour, land and capital) the alternatives shown in Table 24.3 can be produced in each country.

Despite the developed country having an absolute advantage in both wheat and cloth, the less developed country (LDC) has a *comparative advantage* in wheat, and the developed country has a comparative advantage in cloth.

This is because wheat is relatively cheaper in the LDC: only 1 square metre of cloth has to be sacrificed to produce 2 kilos of wheat, whereas 8 square metres of cloth would have to be sacrificed in the developed country to produce 4 kilos of wheat (i.e. 2 square metres of cloth for every 1 kilo of wheat). In other words, the opportunity cost of wheat is four times higher in the developed country (8/4 compared with 1/2).

On the other hand, cloth is relatively cheaper in the developed country. Here the opportunity cost of producing 8 square metres of cloth is only 4 kilos of wheat, whereas in the LDC 1 square metre of cloth costs 2 kilos of wheat. Thus the opportunity cost of cloth is four times higher in the LDC (2/1 compared with 4/8).

? Draw up a similar table to Table 24.3, only this time assume that the figures are: LDC 6 wheat or 2 cloth; DC 8 wheat or 20 cloth. What are the opportunity cost ratios now?

To summarise: countries have a comparative advantage in those goods that can be produced at a lower opportunity cost than in other countries.

If countries are to gain from trade, they should export those goods in which they have a comparative advantage and import those goods in which they have a comparative disadvantage. From this we can state a *law of comparative advantage*.

KEY
IDEA
38

The law of comparative advantage. Provided opportunity costs of various goods differ in two countries, both of them can gain from mutual trade if they specialise in producing (and exporting) those goods that have relatively low opportunity costs compared with the other country.

Table 24.3 Production possibilities for two countries

		Kilos of wheat	or	Square metres of cloth
Less developed country	Either	2	or	1
Developed country	Either	4	or	8

See Case Study 24.1 on the student website for Ricardo's original statement of the law in 1817.

But why do they gain if they specialise according to this law? And just what will that gain be? We will consider these questions next.

The gains from trade based on comparative advantage

Before trade, unless markets are very imperfect, the prices of the two goods are likely to reflect their opportunity costs. For example, in Table 24.3, since the less developed country can produce 2 kilos of wheat for 1 square metre of cloth, the *price* of 2 kilos of wheat will roughly equal the price of 1 square metre of cloth.

Assume, then, that the pre-trade exchange ratios of wheat for cloth are as follows:

LDC : 2 wheat for 1 cloth
Developed country : 1 wheat for 2 cloth (i.e. 4 for 8)

Both countries will now gain from trade, provided the exchange ratio is somewhere between 2:1 and 1:2. Assume, for the sake of argument, that it is 1:1, that 1 wheat trades internationally for 1 cloth. How will each country gain?

The LDC gains by exporting wheat and importing cloth. At an exchange ratio of 1:1, it now only has to give up 1 kilo of wheat to obtain a square metre of cloth, whereas before trade it had to give up 2 kilos of wheat.

The developed country gains by exporting cloth and importing wheat. Again at an exchange ratio of 1:1, it now has to give up only 1 square metre of cloth to obtain 1 kilo of wheat, whereas before it had to give up 2 square metres of cloth.

Thus both countries have gained from trade.

Definitions

Comparative advantage A country has a comparative advantage over another in the production of a good if it can produce it at a lower opportunity cost: i.e. if it has to forgo less of other goods in order to produce it.

Law of comparative advantage Trade can benefit all countries if they specialise in the goods in which they have a comparative advantage.

The actual exchange ratios will depend on the relative prices of wheat and cloth after trade takes place. These prices will depend on total demand for and supply of the two goods. It may be that the trade exchange ratio is nearer to the pre-trade exchange ratio of one country than the other. Thus the gains to the two countries need not be equal. (We will examine these issues below.)

1. Show how each country could gain from trade if the LDC could produce (before trade) 3 wheat for 1 cloth and the developed country could produce (before trade) 2 wheat for 5 cloth, and if the exchange ratio (with trade) was 1 wheat for 2 cloth. Would they both still gain if the exchange ratio was (a) 1 wheat for 1 cloth; (b) 1 wheat for 3 cloth?
2. In question 1, which country gained the most from a trade exchange ratio of 1 wheat for 2 cloth?

Simple graphical analysis of comparative advantage and the gains from trade: constant opportunity cost

The gains from trade can be shown graphically using production possibility curves. Let us continue with the example of the developed and less developed countries that we looked at in Table 24.3, where both countries produce just two goods: wheat and cloth.

Table 24.4 Pre-trade production possibilities

	Less developed country		Developed country	
	Wheat (million kg)	Cloth (million m ²)	Wheat (million kg)	Cloth (million m ²)
A	1000	0	g	500
B	800	100	h	400
C	600	200	i	300
D	400	300	j	200
E	200	400	k	100
F	0	500	l	0

For simplicity, assume that the pre-trade opportunity costs of cloth in terms of wheat in the two countries do not vary with output: i.e. there are *constant opportunity costs* of cloth in terms of wheat of 2/1 in the LDC and 1/2 in the developed country. Let us assume that the pre-trade production possibilities are as shown in Table 24.4.²

² Note that, for simplicity, it is assumed that the size of the two economies is similar. The LDC can still have an *absolute* disadvantage in both goods, however, because it may take many more resources to produce these goods. For example, it may have a very much larger population than the developed country and hence a very much lower output per person.

BOX 24.2 SHARING OUT THE JOBS

CASE STUDIES AND APPLICATIONS

A parable of comparative advantage

Imagine that you and a group of friends are fed up with the rat race and decide to set up a self-sufficient community. So you club together and use all your savings to buy an old run-down farmhouse with 30 acres of land and a few farm animals.

You decide to produce all your own food, make your own clothes, renovate the farmhouse, make all the furniture, provide all your own entertainment and set up a little shop to sell the things you make. This should bring in enough income to buy the few items you cannot make yourselves.

The day comes to move in, and that evening everyone gathers to decide how all the jobs are going to be allocated. You quickly decide that it would be foolish for all of you to try to do all the jobs. Obviously it will be more efficient to specialise. This does not necessarily mean that everyone is confined to doing only one job, but it does mean that each of you can concentrate on just a few tasks.

But who is to do which job? The answer would seem to be obvious: you pick the best person for the job. So you go down the list of tasks. Who is to take charge of the renovations? Pat has already renovated a cottage, and is brilliant at bricklaying, plastering, wiring and plumbing. So Pat would seem to be the ideal person. Who is to do the cooking? Everyone agrees on this. Pat makes the best cakes, the best quiches and the best Irish stew. So Pat is everyone's choice

for cook. And what about milking the sheep? 'Pat used to keep sheep', says Tarquin, 'and made wonderful feta cheese.' 'Good old Pat!' exclaims everyone.

It doesn't take long before it becomes obvious that 'clever-clogs' Pat is simply brilliant at everything, from planting winter wheat, to unblocking drains, to doing the accounts, to tie-dyeing. But it is soon realised that, if Pat has to do everything, nothing will get done. Even Chris, who has never done anything except market research, would be better employed milking the sheep than doing nothing at all.

So what's the best way of allocating the jobs so that the work gets done in the most efficient way? Sharon comes up with the solution. 'Everyone should make a list of all the jobs they could possibly do, and then put them in order from the one they are best at to the one they are worst at.'

So this is what everyone does. And then people are allocated the jobs they are *relatively* best at doing. Chris escapes milking the sheep and keeps the accounts instead. And Pat escapes with an eight-hour day!

If Pat took two minutes to milk the sheep and Tarquin took six, how could it ever be more efficient for Tarquin to do it?

p752

Figure 24.5 Effect of trade on consumption possibilities

For each 100 extra square metres of cloth that the LDC produces, it has to sacrifice 200 kilos of wheat. For each extra 100 kilos of wheat that the developed country produces, it has to sacrifice 200 square metres of cloth. Straight-line pre-trade production possibility 'curves' can thus be drawn for the two countries with slopes of (minus) $2/1$ and (minus) $1/2$ respectively. These lines illustrate the various total combinations of the two goods that can be produced and hence consumed. They are shown as the blue lines in Figure 24.5.

Assume that before trade the LDC produces (and consumes) at point *d*: namely, 400 million kilos of wheat and 300 million square metres of cloth; and that the developed country produces at point *l*: namely, 300 million kilos of wheat and 400 million square metres of cloth.

If they now trade, the LDC, having a comparative advantage in wheat, will specialise in it and produce at point *a*. It will produce 1000 million kilos of wheat and no cloth. The developed country will specialise in cloth and produce at point *l*. It will produce 1000 million square metres of cloth and no wheat.

For simplicity, let us assume that trade between the two countries takes place at an exchange ratio of 1:1 (i.e. 1 kilo of wheat for 1 square metre of cloth). This means that the two countries can now consume along the red lines in Figure 24.5: at, say, points *x* and *y* respectively. At point *x* the LDC consumes 600 million kilos of wheat (a gain of 200 million kilos over the pre-trade position) and 400 million square metres of cloth (a gain of 100 million square metres over the pre-trade position). At point *y* the developed country consumes 400 million kilos of wheat (a gain of 100 million kilos over the pre-trade position) and 600 million square metres of cloth (a gain of 200 million square metres over the pre-trade position). Thus trade has allowed both countries to increase their consumption of both goods.

To summarise: before trade, the countries could only consume along their production possibility curves (the blue lines); after trade, they can consume along the higher red lines.

Note that in this simple two-country model total production and consumption of the two countries for each of the two goods must be the same, since one country's exports are the other's imports. Thus if the LDC produces at point *a* and consumes at point *x*, the developed country, producing at point *l*, must consume at point *y*. The effects on trade of the two countries consuming at points *x* and *y* are shown in Table 24.5.

As complete specialisation has taken place in our example, the LDC now has to import all its cloth and the developed country has to import all its wheat. Thus, given the exchange ratio of 1:1, the LDC exports 400 million kilos of wheat in exchange for imports of 400 million square metres of cloth. (These imports and exports are also shown in Figure 24.5.)

The final two columns of Table 24.5 show that trade has increased the total production and consumption of the two countries.

1. Draw a diagram with the same two countries and with the same production possibilities and exchange ratio as in Figure 24.5. But this time show how much would be imported and exported for each country if, after trade, the LDC consumes 500 million kilos of wheat. Fill the figures in on a table like Table 24.5.
2. If the opportunity cost ratio of wheat for cloth is $1/2$ in the LDC, why is the slope of the production possibility curve $2/1$? Is the slope of the production possibility curve always the reciprocal of the opportunity cost ratio?
3. Show (graphically) that, if the (pre-trade) opportunity cost ratios of the two countries were the same, there would be no gain from trade – assuming that the production possibility curves were straight lines and did not shift as a result of trade.

Table 24.5 The production and consumption gains from trade

	Less developed country			Developed country			Total	
	Production	Consumption	Imports (-)/ Exports (+)	Production	Consumption	Imports (-)/ Exports (+)	Production	Consumption
No trade								
Wheat (million kg)	400	400	0	300	300	0	700	700
Cloth (million m ²)	300	300	0	400	400	0	700	700
With trade								
Wheat (million kg)	1000	600	+400	0	400	-400	1000	1000
Cloth (million m ²)	0	400	-400	1000	600	+400	1000	1000

International trade and its effect on factor prices

Countries tend to have a comparative advantage in goods that are *intensive in their abundant factor*. Canada has abundant land and hence it is cheap. Therefore Canada specialises in grain production since grains are land-intensive. South Asian countries have abundant supplies of labour with low wage rates, and hence specialise in clothing and other labour-intensive goods. Europe, Japan and the USA have relatively abundant and cheap capital, and hence specialise in capital-intensive manufactured goods.

Trade between such countries will tend to lead to greater equality in factor prices. For example, the demand for labour will rise in labour-abundant countries like India if they specialise in labour-intensive goods. This will push up wage rates in these low-wage countries, thereby helping to close the gap between their wage rates and those of the developed world. Without trade, wage rates would tend to be even lower.

Increasing opportunity costs and the limits to specialisation and trade

In practice, countries are likely to experience increasing opportunity costs (and hence have bowed-out production

possibility curves). The reason for this is that, as a country increasingly specialises in one good, it has to use resources that are less and less suited to its production and which were more suited to other goods. Thus ever-increasing amounts of the other goods have to be sacrificed. For example, as a country specialises more and more in grain production, it has to use land that is less and less suited to growing grain.

These increasing costs as a country becomes more and more specialised lead to the disappearance of its comparative cost advantage. When this happens, there will be no point in further specialisation. Thus whereas a country like Germany has a comparative advantage in capital-intensive manufactures, it does not produce only manufactures. It would make no sense not to use its fertile lands to produce food or its forests to produce timber. The opportunity costs of diverting all agricultural labour to industry would be very high.

Thus increasing opportunity costs limit the amount of a country's specialisation and hence the amount of its trade. There are also other limits to trade:

- Transport costs may outweigh any comparative advantage. A country may be able to produce bricks more cheaply than other countries, but their weight may make them too expensive to export.

BOX 24.3 TRADE AS EXPLOITATION?

EXPLORING ECONOMICS

Does free trade exploit cheap labour abroad?

People sometimes question the morality of buying imports from countries where workers are paid 'pittance' wages. 'Is it right', they ask, 'for us to support a system where workers are so exploited?' As is often the case with emotive issues, there is some truth and some misunderstanding in a point of view like this.

First the truth. If a country like the UK trades with a regime that denies human rights, and treats its workers very badly, we may thereby be helping to sustain a corrupt system. We might also be seen to be lending it moral support. In this sense, therefore, trade may not help the cause of the workers in these countries. It is arguments like these that were used to support the imposition of trade sanctions against South Africa in the days of apartheid.

Now the misunderstanding. If we buy goods from countries that pay low wages, we are *not* as a result contributing to their low-wage problem. Quite the reverse. If countries like India export textiles to the West, this will help to *increase* the wages of Indian workers. If India has a comparative advantage in labour-intensive goods, these goods will earn a better price by being exported than by being sold entirely in the domestic Indian market. Provided *some* of the extra revenues go to the workers, they will gain from trade.

Under what circumstances would a gain in revenues by exporting firms not lead to an increase in wage rates?

K1 2
p10K1 4
p14

- It may be the factors of production, rather than the goods, that move from country to country. Thus developed countries, rather than exporting finished goods to LDCs, may invest capital in LDCs to enable manufactures to be produced there. Also, labour may migrate from low-wage to high-wage countries.
- Governments may restrict trade (see section 24.2).

The terms of trade

What price will our exports fetch abroad? What will we have to pay for imports? The answer to these questions is given by the *terms of trade*.

To simplify matters, suppose there is only one exported good and only one imported good. In this case, the terms of trade are defined as P_x/P_m , where P_x is the price of the exported good and P_m is the price of the imported good. This is the reciprocal of the exchange ratio: for example, if 2x exchange for 1m (an exchange ratio of 2/1), the price of x will be half the price of m. The terms of trade will be 1/2.

- ?**
1. If 4x exchange for 3m, what are the terms of trade?
 2. If the terms of trade are 3, how many units of the imported good could I buy for the money earned by the sale of 1 unit of the exported good? What is the exchange ratio?

In the real world where countries have *many* exports and imports, the *terms of trade* are given by

$$\frac{\text{Average price of exports}}{\text{Average price of imports}}$$

expressed as an index, where price changes are measured against a base year in which the terms of trade are assumed to be 100. Thus if the average price of exports relative to the average price of imports has risen by 20 per cent since the base year, the terms of trade will now be 120. The terms of

trade for selected countries are shown in Figure 24.6 (with 2010 as the base year).

If the terms of trade rise (export prices rising relative to import prices), they are said to have 'improved', since fewer exports now have to be sold to purchase any given quantity of imports. Changes in the terms of trade are caused by changes in the demand for and supply of imports and exports, and by changes in the exchange rate.

? In Figure 24.6, which countries' terms of trade improved in the 2000s?

The terms of trade and comparative advantage

Assuming there are two goods, x and m, trade can be advantageous to a country as long as the terms of trade P_x/P_m are different from the opportunity cost ratios of the two goods, given by MC_x/MC_m . For example, if the terms of trade were greater than the opportunity cost ratio ($P_x/P_m > MC_x/MC_m$), it would benefit the country to produce more x for export in return for imports of m, since the relative value of producing x (P_x/P_m) is greater than the relative cost (MC_x/MC_m).

With increasing opportunity costs, however, increasing specialisation in x will lead to MC_x rising (and MC_m falling), until $P_x/P_m = MC_x/MC_m$. At this point, there can be no more gain from further specialisation and trade: the maximum gain has been achieved and comparative cost advantages have been exhausted.

Definition

Terms of trade The price index of exports divided by the price index of imports and then expressed as a percentage. This means that the terms of trade will be 100 in the base year.

Figure 24.6 Terms of trade for selected countries (2010 = 100)

Note: Data from 2017 are based on forecasts.
Source: Based on data in AMECO Database (European Commission, DGECFIN).

Figure 24.7 Determination of the price of an individual traded good

The determination of the terms of trade

When countries import and export many goods, the terms of trade will depend on the prices of all the various exports and imports. These prices will depend on the demand and supply of each traded good and their elasticities in the respective countries. Take the case of good g in which country A has a comparative advantage with respect to the rest of the world. This is illustrated in Figure 24.7.

Demand and supply curves of good g can be drawn for both country A and the rest of the world. (The upward-sloping supply curves imply increasing opportunity costs of production.) Before trade, country A has a low equilibrium price of P_1 and the rest of the world a high equilibrium price of P_2 . After trade, price will settle at P_3 in both countries (assuming no transport costs), where total demand by both country A and the rest of the world together equals total supply, and thus where the imports of g into the rest of the world ($d - c$) equal the exports from country A ($b - a$). The position of P_3 relative to P_1 and P_2 will depend on the elasticities of demand and supply.

A similar analysis can be conducted for all the other traded goods – both exports and imports of country A. The resulting prices will allow country A's terms of trade to be calculated.

? Draw a similar diagram to Figure 24.7 showing how the price of an individual good imported into country A is determined.

The analysis is complicated somewhat if different national currencies are involved, since the prices in each country will be expressed in its own currency. Thus to convert one country's prices to another currency will require knowledge of the rate of exchange: e.g. for the USA and the UK it might be $\$1.50 = \pounds 1$. But under a floating exchange rate system, the rate of exchange will depend in

part on the demand for and supply of imports and exports. If the rate of exchange depreciates – say, from $\$1.50 = \pounds 1$ to $\$1.25 = \pounds 1$ – the UK's terms of trade will worsen. Exports will earn less foreign currency per pound: e.g. $\pounds 1$ worth of exports will now be worth only $\$1.25$ rather than $\$1.50$. Imports, on the other hand, will be more expensive: e.g. $\$6$ worth of imports previously cost $\pounds 4$; they now cost $\pounds 4.80$.

? Why will exporters probably welcome a 'deterioration' in the terms of trade?

In a world of many countries and many goods, an individual country's imports and exports may have little effect on world prices. In the extreme case, the country may face prices totally dictated by the external world demand and supply. The country in this case is similar to an individual firm under perfect competition. The country is too small to influence world prices, and thus faces a horizontal demand curve for its exports and a horizontal supply curve for its imports. In foreign currency terms, therefore, the terms of trade are outside its control. Nevertheless, these terms of trade will probably be to its benefit, in the sense that the gains from trade will be virtually entirely received by this small country rather than the rest of the world. It is too small for its trade to depress the world price of its exports or drive up the price of its imports.

In general, a country's gains from trade will be greater the less elastic its own domestic demand and supply of tradable goods are, and the more elastic the demand and supply of other countries. You can see this by examining Figure 24.7. The less elastic the domestic demand and supply, the bigger will be the effect of trade on prices faced by that country. The more the trade price differs from the pre-trade price, the bigger the gain.

*Intermediate analysis of gains from trade

The analysis of section 12.1 (pages 353–5) can be used to demonstrate the welfare gains from trade and the limits to specialisation under conditions of increasing opportunity cost. A simple two-good model is used, and the pre-trade position is compared with the position with trade.

Pre-trade

Let us make the following simplifying assumptions:

- There are two goods, x and m.
- Country A has a comparative advantage in the production of good x.
- There are increasing opportunity costs in the production of both x and m. Thus the production possibility curve is bowed out.
- Social indifference curves can be drawn, each one showing the various combinations of x and m that give society in country A a particular level of utility.

Figure 24.8 shows the pre-trade position in country A. Production and consumption at P_1C_1 will give the highest possible utility. (All other points on the production possibility curve intersect with lower indifference curves.)

If there is perfect competition, production will indeed be at P_1C_1 . There are four steps in establishing this:

- The slope of the production possibility curve ($-\Delta m/\Delta x$) is the marginal rate of transformation (MRT), and equals MC_x/MC_m (see pages 354–5). For example, if the opportunity cost of producing 1 extra unit of x (Δx) was a sacrifice of 2 units of m ($-\Delta m$), then an extra unit of x would cost twice as much as an extra unit of m: i.e. $MC_x/MC_m = 2/1$, which is the slope of the production possibility curve, $-\Delta m/\Delta x$.
- The slope of each indifference curve ($-\Delta m/\Delta x$) is the marginal rate of substitution (MRS), and equals MU_x/MU_m . For example, if x had three times the

marginal utility of m ($MU_x/MU_m = 3$), consumers would be willing to give up 3m for 1x ($-\Delta m/\Delta x = 3$).

- Under perfect competition,

$$\frac{MC_x}{MC_m} = \frac{P_x}{P_m} = \frac{MU_x}{MU_m}$$

- Thus the domestic pre-trade price ratio P_x/P_m under perfect competition must equal the slope of the production possibility curve (MC_x/MC_m) and the slope of the social indifference curve (MU_x/MU_m). This is the case at P_1C_1 in Figure 24.8.

1. If production were at point a in Figure 24.8, describe the process whereby equilibrium at point P_1C_1 would be restored under perfect competition.
2. Why would production be unlikely to take place at P_1C_1 if competition were not perfect?

With trade

If country A has a comparative advantage in good x, the price of x relative to m is likely to be higher in the rest of the world than in country A: i.e. world $P_x/P_m >$ pre-trade domestic P_x/P_m . This is shown in Figure 24.9. The world price ratio is given by the slope of the line WW. With this new steeper world price ratio, the optimum production point will be P_2 where MRT (the slope of the production possibility curve) = world P_x/P_m (the slope of WW).

With production at P_2 , the country can by trading consume *anywhere* along this line WW. The optimum consumption point will be C_2 where MRS (the slope of the indifference curve) = world P_x/P_m (the slope of WW). Thus trade has allowed consumption to move from point C_1 on the lower indifference curve I_1 to point C_2 on the higher indifference curve I_2 . There has thus been a gain from trade. Perfect competition will ensure that this gain is realised, since production at P_2 and consumption at C_2 meet the equilibrium condition that

$$\frac{MC_x}{MC_m} = \frac{P_x}{P_m} = \frac{MU_x}{MU_m}$$

How much will be imported and how much will be exported? With production at P_2 and consumption at C_2 , country A will import $C_2 - D$ of good m in exchange for exports of $P_2 - D$ of good x.

Similar diagrams to Figure 24.9 can be drawn for other countries. Since they show equilibrium for both imports and exports on the *one* diagram, economists refer to them as **general equilibrium diagrams** (see page 355 for another example).

Figure 24.8 Equilibrium before trade

Definition

General equilibrium diagrams (in trade theory)

Indifference curve/production possibility curve diagrams that show a country's production and consumption of both imports and exports.

Figure 24.9 Equilibrium with trade

1. Draw a similar diagram to Figure 24.9, only this time assume that the two goods are good *a* measured on the vertical axis and good *b* measured on the horizontal axis. Assume that the country has a comparative advantage in good *a*. (Note that the world price ratio this time will be shallower than the domestic pre-trade price ratio.) Mark the level of exports of *a* and imports of *b*.
2. Is it possible to gain from trade if competition is not perfect?

Other reasons for gains from trade

Decreasing costs

Even if there are no initial comparative cost differences between two countries, it will still benefit both to specialise in industries where economies of scale (either internal or external) can be gained, and then to trade. Once the economies of scale begin to appear, comparative cost differences will also appear, and thus the countries will have gained a comparative advantage in these industries.

A similar argument applies to different models of the same product (e.g. different models of cars or electrical goods). Several countries, by specialising in just one or two models each, can gain the full economies of scale and hence a comparative advantage in their particular model(s). Then, through trade, consumers can gain from having a wider range from which to choose. Much of the specialisation that international trade permits is of this nature.

The decreasing cost reason for trade is particularly relevant for small countries where the domestic market is not large enough to support large-scale industries. Thus exports form a much higher percentage of GDP in small countries such as Singapore than in large countries such as the USA.

Would it be possible for a country with a comparative disadvantage in a given product at pre-trade levels of output to obtain a comparative advantage in it by specialising in its production and exporting it?

Differences in demand

Even with no comparative cost differences and no potential economies of scale, trade can benefit both countries if demand conditions differ.

If people in country A like beef more than lamb, and people in country B like lamb more than beef, then rather than A using resources better suited for lamb to produce beef and B using resources better suited for producing beef to produce lamb, it will benefit both to produce beef *and* lamb and to export the one they like less in return for the one they like more.

Increased competition

If a country trades, the competition from imports may stimulate greater efficiency at home. This extra competition may prevent domestic monopolies/oligopolies from charging high prices. It may stimulate greater research and development and the more rapid adoption of new technology, thereby increasing the economy's longer-term growth rate. It may lead to a greater variety of products being made available to consumers.

Trade as an 'engine of growth'

In a growing world economy, the demand for a country's exports is likely to grow, especially when these exports have a high income elasticity of demand. This provides a stimulus to growth in the exporting country.

Non-economic advantages

There may be political, social and cultural advantages to be gained by fostering trading links between countries.

The competitive advantage of nations

The theory of comparative advantage shows how countries can gain from trade, but why do countries have a comparative advantage in some goods rather than others?

One explanation is that it depends on the resources that countries have. If a country has plenty of land, then it makes sense to specialise in products that make use of this abundant resource. Thus Canada produces and exports wheat. If a country has a highly skilled workforce and an established research base, then it makes sense to specialise in high-tech products and export these. Thus Germany exports many highly sophisticated manufactured products. By contrast, many developing countries with plentiful but relatively low-skilled workers specialise in primary products or simple manufactured products.

In other words, countries should specialise in goods which make intensive use of their abundant resources. But this still does not give enough detail as to why countries specialise in the precise range of products that they do. Also, why do countries both export and import the *same* products? Why do many countries produce and export cars, but also import many cars?

According to Porter,³ there are four key determinants of why nations are highly competitive in certain products but less so in others.

Available resources. These include 'given' resources, such as raw materials, population and climate, but also specialised resources that have been developed by humans, such as the skills of the labour force, the amount and type of capital, the transport and communications infrastructure, and the science and technology base. These specialised resources vary in detail from one country to another and give them a competitive advantage in very specific products. Once an industry has started to develop, this may attract further research and development, capital investment and training, all of which are very specific to that industry. This then further builds the country's competitive advantage in that industry. Thus the highly developed engineering skills and equipment in Germany give it a competitive advantage in producing well-engineered cars.

Demand conditions in the home market. The more discerning customers are within the country, the more this will drive the development of each firm's products and the more competitive the firm will then become in international markets. The demand for IT solutions within the USA drove the development of the software industry and gave companies such as Microsoft, Intel and Google an international advantage.

Strategy, structure and rivalry of firms. Competition between firms is not just in terms of price. Competitive rivalry extends to all aspects of business strategy, from product design, to marketing, to internal organisation, to production efficiency, to logistics. The very particular competitive conditions within each industry can have a profound effect on the development of firms within that industry and determine whether or not they gain an international competitive advantage. Strategic investments and rivalry gave Japanese electronic companies an international competitive advantage.

Related and supporting industries. Firms are more likely to be successful internationally if there are well-developed supporting industries within the home economy. These may be industries providing specialist equipment or specialist consultancy, or they may simply be other parts of the main value chain, from suppliers of inputs to distributors of the firms' output. The more efficient this value chain, the greater the competitive advantage of firms within the industry.

The competitive advantage of nations is the ability of countries to compete in the market for exports and with potential importers to their country. The competitiveness of any one industry depends on the availability and quality of resources, demand conditions at home in that industry, the strategies and rivalry of firms within the industry and the quality of supporting industries and infrastructure. It also depends on government policies, and there is also an element of chance.

The above four determinants of competitive advantage are interlinked and influence each other. For example, the nature of related and supporting industries can influence a firm's strategic decision about whether to embark on a process of vertical integration or de-integration. Similarly, the nature of related and supporting industries depends on demand conditions in these industries and the availability of resources.

With each of the four determinants, competitive advantage can be stimulated by appropriate government supply-side policies, such as a supportive tax regime, investment in transport and communications infrastructure, investment in education and training, competition policy and sound macroeconomic management of the economy. Also, chance often has a large part to play. For example, any pharmaceutical company which discovers a cure for AIDS or for various types of cancer will give a significant competitive advantage to the country in which it is based.

3 Michael E. Porter, *The Competitive Advantage of Nations* (The Free Press, 1998).

Section summary

1. Countries can gain from trade if they specialise in producing those goods in which they have a comparative advantage: i.e. those goods that can be produced at relatively low opportunity costs. This is merely an extension of the argument that gains can be made from the specialisation and division of labour.
2. If two countries trade, then, provided that the trade price ratio of exports and imports is between the pre-trade price ratios of these goods in the two countries, both countries can gain. They can both consume *beyond* their production possibility curves.
3. With increasing opportunity costs there will be a limit to specialisation and trade. As a country increasingly specialises, its (marginal) comparative advantage will eventually disappear. Trade can also be limited by transport costs, factor movements and government intervention.
4. The terms of trade give the price of exports relative to the price of imports. Additional trade can be beneficial if the terms of trade (P_x/P_m) are greater than the relative marginal costs of exports and imports (MC_x/MC_m).
5. A country's terms of trade are determined by the demand and supply of imports and exports and their respective elasticities. This will determine the prices at which goods are traded and affect the rate of exchange. A country's gains from trade will be greater the less elastic its own

domestic demand and supply of tradable goods, and the more elastic the demand and supply of other countries.

- *6. Trade allows countries to achieve a higher level of utility by consuming on a higher social indifference curve. The maximum gain from trade is achieved by consuming at the point where the world price ratio is tangential to both the production possibility curve and a social indifference curve. This would be achieved under perfect competition.
- 7. Gains from trade also arise from decreasing costs (economies of scale), differences in demand between

countries, increased competition from trade and the transmission of growth from one country to another. There may also be non-economic advantages from trade.

- 8. Comparative advantage is related to competitive advantage. Countries tend to have a competitive advantage in those industries where specialist resources have been developed, where products have been developed in response to changing consumer demands, where business strategy is conducive and where there is a network of supporting industries and infrastructure.

24.2 ARGUMENTS FOR RESTRICTING TRADE

Most countries have not pursued a policy of totally free trade. Their politicians know that trade involves costs as well as benefits. In this section, we will attempt to identify what these costs are, and whether they are genuine reasons for restricting trade.

K1 2
p10

Although countries may sometimes contemplate having completely free trade, they usually limit their trade. However, they certainly do not ban it altogether. The sorts of questions that governments pose are (a) should they have freer or more restricted trade and (b) in which sectors should restrictions be tightened or relaxed? Ideally, countries should weigh up the marginal benefits against the marginal costs of altering restrictions, although just *what* benefits and costs should be taken into account, and what weighting should be attached to them, may be highly contentious. For example, should external costs and benefits be considered and should these include *global* externalities?

Methods of restricting trade

Tariffs (customs duties). These are taxes on imports and are usually *ad valorem tariffs*: i.e. a percentage of the price of the import. Tariffs that are used to restrict imports are most effective if demand is elastic (e.g. when there are close domestically produced substitutes). Tariffs can also be used as a means of raising revenue, but in this case they are more effective if demand is inelastic. They can in addition be used to raise the price of imported goods to prevent 'unfair' competition for domestic producers.

Quotas. These are limits imposed on the quantity of a good that can be imported. Quotas can be imposed by the government, or negotiated with other countries which agree 'voluntarily' to restrict the amount of exports to the first country.

Exchange controls. These include limits on how much foreign exchange can be made available to importers (financial quotas), or to citizens travelling abroad, or for investment. Alternatively, they may take the form of charges for the purchase of foreign currencies.

Import licensing. The imposition of exchange controls or quotas often involves requiring importers to obtain licences. This makes it easier for the government to enforce its restrictions.

Embargoes. These are total government bans on certain imports (e.g. drugs) or exports to certain countries (e.g. to enemies during war).

Administrative barriers. Regulations may be designed to exclude imports: examples include customs delays and excessive paperwork.

Procurement policies. This is where governments favour domestic producers when purchasing equipment (e.g. defence equipment).

Dumping. Alternatively, governments may favour domestic producers by subsidising their exports in a process known as *dumping*. The goods are 'dumped' at artificially low prices in the foreign market.

Arguments in favour of restricting trade

Economic arguments having some general validity

The infant industry argument. Some industries in a country may be in their infancy, but have a potential comparative advantage. This is particularly likely in developing countries. Such industries are too small yet to have gained economies of scale; their workers are inexperienced; they lack back-up facilities, such as communications networks and specialist suppliers. They may have only limited access to

TC 7
p81

Definitions

Ad valorem tariffs Tariffs levied as a percentage of the price of the import.

Dumping Where exports are sold at prices below marginal cost – often as a result of government subsidy.

BOX 24.4 FREE TRADE AND THE ENVIRONMENT

CASE STUDIES AND APPLICATIONS

Do whales, rainforests and the atmosphere gain from free trade?

International trade provides an outlet for hardwood from the rainforests, for tiger parts for medicines, for chemicals and other industrial products produced with little regard for safety or environmental standards, and for products produced using electricity generated from low-cost, high-sulphur, highly polluting coal.

The problem is that countries are likely to export goods that they can produce at a relatively low opportunity cost. But these opportunity costs are *private* costs. They do not take into account externalities. This is a powerful argument against free trade based on free-market prices.

Surely, though, the developed countries use taxes, legislation and other means to prevent the abuse of the environment? They may do, but this does not stop them importing products from countries that do not.

In reply, the advocates of free trade argue that it is up to each country to decide its own environmental standards. If a poor country produces a product in a cheap polluting way, the

gains from exporting it may more than offset the environmental damage done.

There is some strength in this argument provided (a) the government of that country has done a proper study of the costs and benefits involved, including the external costs; and (b) the externalities are confined to within the country's borders. Unfortunately, in many cases neither of these conditions holds. Much of the pollution generated from industrial production has global effects (e.g. global warming).

As countries such as China and India take an increasingly large share of world exports of industrial products (see Figure 24.4), so these problems are likely to grow. Both countries have much lower environmental protection standards than those in Europe and North America.

 *Should the world community welcome the use of tariffs and other forms of protection by the rich countries against imports of goods from developing countries that have little regard for the environment?*

finance for expansion. Without protection, these *infant industries* will not survive competition from abroad.

Protection from foreign competition, however, will allow them to expand and become more efficient. Once they have achieved a comparative advantage, the protection can then be removed to enable them to compete internationally.

Similar to the infant industry argument is the *senile industry argument*. This is where industries with a potential comparative advantage have been allowed to run down and can no longer compete effectively. They may have considerable potential, but be simply unable to make enough profit to afford the necessary investment without some temporary protection. This is one of the most powerful arguments used to justify the use of special protection for the automobile and steel industries in the USA.

 *How would you set about judging whether an industry had a genuine case for infant/senile industry protection?*

To reduce reliance on goods with little dynamic potential. Many developing countries have traditionally exported primaries: foodstuffs and raw materials. The world demand for these, however, is fairly income inelastic, and thus grows relatively slowly. In such cases, free trade is not an engine of growth. Instead, if it encourages countries' economies to become locked into a pattern of primary production, it may prevent them from expanding in sectors like manufacturing that have a higher income elasticity of demand. Since 2000, for example, the value of exports of manufactures has typically been in excess of 70 per cent of the value of all merchandise exports. There may thus be a valid argument for protecting or promoting manufacturing industry. (We explore these arguments in section 26.4.)

To prevent dumping and other unfair trade practices. A country may engage in dumping by subsidising its exports. The result is that prices may no longer reflect comparative costs. Thus the world would benefit from tariffs being imposed to counteract such practices.

 *Does the consumer in the importing country gain or lose from dumping?*

It can also be argued that there is a case for retaliating against countries that impose restrictions on your exports. In the *short* run, both countries are likely to be made worse off by a contraction in trade. But if the retaliation persuades the other country to remove its restrictions, it may have a longer-term benefit. In some cases, the mere threat of retaliation may be enough to get another country to remove its protection.

To prevent the establishment of a foreign-based monopoly. Competition from abroad, especially when it involves dumping or predatory pricing (see pages 246 and 761), could drive domestic producers out of business. The foreign company, now having a monopoly of the market, could charge high prices with a resulting misallocation of resources.

All of the above arguments suggest that governments should adopt a 'strategic' approach to trade. *Strategic trade theory* (see Box 24.5) argues that protecting certain industries allows a net gain *in the long run* from increased competition in the market. This argument has been used to justify the huge financial support given to the aircraft manufacturer Airbus, a consortium based in four European countries. The subsidies have allowed it to compete with Boeing, which would

otherwise have a monopoly in many types of passenger aircraft. Airlines and their passengers worldwide, it is argued, have benefited from the increased competition.

To spread the risks of fluctuating markets. A highly specialised economy – Zambia with copper, Cuba with sugar – is highly susceptible to world market fluctuations. Greater diversity and greater self-sufficiency can reduce these risks.

To reduce the influence of trade on consumer tastes. It is a mistake to assume that fixed consumer tastes dictate the pattern of production through trade. Multinational companies through their advertising and other forms of sales promotion may influence consumer tastes. Thus some restriction on trade may be justified in order to reduce this ‘producer sovereignty’.

In what ways may free trade have harmful cultural effects on developing countries?

Definitions

Infant industry An industry that has a potential comparative advantage, but which is as yet too underdeveloped to be able to realise this potential.

Strategic trade theory The theory that protecting/supporting certain industries can enable them to compete more effectively with large monopolistic rivals abroad. The effect of the protection is to increase long-run competition and may enable the protected firms to exploit a comparative advantage that they could not have done otherwise.

BOX 24.5

STRATEGIC TRADE THEORY

EXPLORING
ECONOMICS

An argument for protection?

Lester Thurow is professor of management and economics and former dean in the Sloan School of Management at the Massachusetts Institute of Technology (MIT), and an economics journalist and editor. He is also one of the USA's best-known and most articulate advocates of ‘managed trade’.

Thurow (and others) have been worried by the growing penetration of US markets by imports from Japan and Europe and also from China and many other developing countries. Their response is to call for a carefully worked-out strategy of protection for US industries.

The *strategic trade theory* that they support argues that the real world is complex. It is wrong, they claim, to rely on free trade and existing comparative advantage. Particular industries will require particular policies of protection or promotion tailored to their particular needs:

- Some industries will require protection against unfair competition from abroad – not just to protect the industries themselves, but also to protect the consumer from the oligopolistic power that the foreign companies will gain if they succeed in driving the domestic producers out of business.
- Other industries will need special support in the form of subsidies to enable them to modernise and compete effectively with imports.
- New industries may require protection to enable them to get established – to achieve economies of scale and build a comparative advantage.
- If a particular foreign country protects or promotes its *own* industries, it may be desirable to retaliate in order to persuade the country to change its mind.

The arguments of strategic trade theorists are criticised by economic liberals. If the USA is protected from cheap imports from Asia, they claim, all that will be achieved is a huge increase in consumer prices. The car, steel, telecommunications and electrical goods industries might

find their profits bolstered, but this is hardly likely to encourage them to be more efficient.

Another criticism of managed trade is the difficulty of identifying just which industries need protection, and how much and for how long. Governments do not have perfect knowledge. What is more, the political lobbyists from various interested groups are likely to use all sorts of tactics – legal or illegal – to persuade the government to look favourably on them. In the face of such pressure, will the government remain ‘objective’? No, say the liberals.

So how do the strategic trade theorists reply? If it works for China and Japan, they say, it can work for the USA. What is needed is a change in attitudes. Rather than industry looking on the government as either an enemy to be outwitted or a potential benefactor to be wooed, and government looking on industry as a source of votes or tax revenues, both sides should try to develop a partnership – a partnership from which the whole country can gain.

But whether sensible, constructive managed trade is possible given the political context in which decisions would need to be made is a highly debatable point. ‘Sensible’ managed trade, say the liberals, is just pie in the sky. However, with the election of Donald Trump, who has vowed to ‘put America first’, calls for specific protection of certain industries in the USA may receive a more sympathetic hearing than from previous administrations. But whether increased protection will help to increase efficiency and regain comparative advantage remains to be seen.

Airbus, a consortium based in four European countries, has received massive support from the four governments, in order to enable it to compete with Boeing, which until the rise of Airbus had dominated the world market for aircraft. To what extent are (a) air travellers; (b) citizens of the four countries likely to have gained or lost from this protection? (See Case Study 24.8 on the student website.)

To prevent the importation of harmful goods. A country may want to ban or severely curtail the importation of things such as drugs, pornographic literature and live animals.

To take account of externalities. Free trade will tend to reflect private costs. Both imports and exports, however, can involve externalities. The mining of many minerals for export may damage the health of miners; the production of chemicals for export may involve pollution; the importation of juggernaut lorries may lead to structural damage to houses; shipping involves large amounts of CO₂ emissions (some 3 to 5 per cent of total world emissions) (see Box 24.4).

In recent years some politicians and green groups have called for the imposition of 'carbon tariffs'. The rate of tariff would reflect the amount of carbon emitted in the production of the good being imported. Such tariffs would be hard to implement, however. Assessing and valuing the carbon emitted would be very difficult and could lead to arbitrary tariff rates. Also, domestic goods would have to be subject to similar taxes.

Economic arguments having some validity for specific groups or countries

The arguments considered so far are of general validity: restricting trade for such reasons could be of net benefit to the world. There are other arguments, however, that are used by individual governments for restricting trade, where their country will gain, but at the expense of other countries, such that there will be a net loss to the world. Such arguments include the following.

The exploitation of market power. If a country, or a group of countries, has market power in the supply of exports (e.g. South Africa with diamonds, OPEC with oil) or market power in the demand for imports (e.g. the USA or other large, wealthy countries), it can exploit this power by intervening in trade.

Let us first take the case of a country, or a group of countries acting as a cartel, which has monopoly power in the sale of a particular export: for example, West African countries in the sale of cocoa. But let us assume that there are many individual producers that are therefore price takers and are thus not in a position to exploit the country's overall market power. In Figure 24.10, these price-taking firms will collectively produce at point *a* where $P = MC$. Market equilibrium is at a trade price of P_1 and an output of Q_1 .

The country's profit, however, would be maximised at point *b* where $MC = MR$, with output at the lower level of Q_2 . By imposing an export tax of $P_2 - P_3$, therefore, the country can maximise its gain from this export. Producers will receive P_3 and will therefore supply Q_2 . Market price will be P_2 .

1. How much would be the total tax revenue for the government?
2. Will the individual producers gain from the export tax?

Now let us take the case of a country that has *monopsony* power in the demand for an import. This is illustrated in

Figure 24.10 A country with a monopoly supply of an export

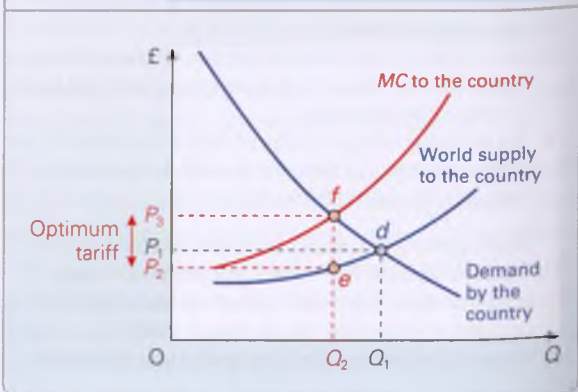

Figure 24.11. Without intervention, equilibrium will be at point *d* where demand equals supply. Q_1 would be purchased at a price of P_1 .

But the marginal cost of imports curve will be *above* the supply curve because, given the country's size, the purchase of additional imports would drive up their price. This means that the cost of additional imports would be the new higher price (given by the supply curve) *plus* the rise in expenditure on the imports that would previously have been purchased at a lower price. The country will maximise its gain from trade at point *f* by importing Q_2 , where demand equals marginal cost. Consumption can be reduced to Q_2 if the government imposes a tariff of $P_3 - P_2$. This is known as the **optimum tariff**. The country now only pays P_2 to importers. Consumers have to pay P_3 (i.e. P_2 plus the tariff).

Definition

Optimum tariff A tariff that reduces the level of imports to the point where marginal social cost equals marginal social benefit.

Figure 24.11 A country with a monopsony demand for an export

The country gains from such intervention, but only at the expense of the other countries with which it trades.

To protect declining industries. The human costs of sudden industrial closures can be very high. In areas heavily reliant on a declining industry, such as coal mining areas, or 'rust belt' towns in the USA or cities like Detroit, there can be huge costs to the individuals losing their jobs. Their lack of transferable skills may make them occupationally highly immobile. What is more, regional multiplier effects can compound the direct loss of income and consumption. In such circumstances, temporary protection may be warranted to allow industries that have lost comparative advantage to decline more slowly, or even to encourage inward investment in new more efficient technology (making senile industries new 'infants'). Such policies will be at the expense of the consumer, who will be denied access to cheaper foreign imports. Nevertheless, such arguments have gained huge support from populist movements in the USA and elsewhere and protection for such industries form part of President Trump's 'America first' policies.

To improve the balance of payments. Under certain special circumstances, when other methods of balance of

payments correction are unsuitable, there may be a case for resorting to tariffs (see Chapter 25).

'Non-economic' arguments

A country may be prepared to forgo the direct economic advantages of free trade – consumption at a lower opportunity cost – in order to achieve objectives that are often described as 'non-economic':

- It may wish to maintain a degree of self-sufficiency in case trade is cut off in times of war. This may apply particularly to the production of food and armaments.
- It may decide not to trade with certain countries with which it disagrees politically.
- It may wish to preserve traditional ways of life. Rural communities or communities based on old traditional industries may be destroyed by foreign competition.
- It may prefer to retain as diverse a society as possible, rather than one too narrowly based on certain industries.

Pursuing such objectives, however, involves costs. Preserving a traditional way of life, for example, may mean that consumers are denied access to cheaper goods from abroad. Society must therefore weigh up the benefits against the costs of such policies.

*BOX 24.6 THE OPTIMUM TARIFF OR EXPORT TAX

EXPLORING ECONOMICS

Using calculus

The size of the optimum export tax depends on the price elasticity of demand ($P\epsilon_d$). You can see this if you imagine rotating the demand and MR curves in Figure 24.10. The less elastic the demand curve, the bigger will be the optimum export tax. The formula for the optimum export tax rate is

$$t = 1/P\epsilon_d$$

The proof of this is as follows.

In Figure 24.10, the optimum tax rate is

$$(P_2 - P_3) \div P_2 \quad (1)$$

From the point of view of the country (as opposed to individual producers) this is simply

$$(P - MR) \div P \quad (2)$$

Remember from Box 2.6 (on page 64) that price elasticity of demand is given by

$$P\epsilon_d = \frac{-dQ}{dP} \times \frac{P}{Q} \quad (3)$$

Remember also, from Box 6.10 (on page 183), that

$$MR = \frac{dTR}{dQ} = \frac{d(P \cdot Q)}{dQ} \quad (4)$$

From the rules of calculus:

$$\frac{d(P \cdot Q)}{dQ} = \frac{dP \cdot Q + dQ \cdot P}{dQ} \quad (5)$$

$$\therefore P - MR = P - \frac{dP \cdot Q + dQ \cdot P}{dQ} \quad (6)$$

$$\frac{P}{P - MR} = \frac{P}{P - \frac{dP \cdot Q + dQ \cdot P}{dQ}} \quad (7)$$

$$= 1 - \frac{P}{P - \frac{dP \cdot Q + dQ \cdot P}{dQ}} \quad (8)$$

Again from the rules of calculus:

$$= 1 - \left(\frac{dQ \cdot P}{dP \cdot Q} + \frac{dQ \cdot P}{dQ \cdot P} \right) \quad (9)$$

$$= 1 - \frac{dQ \cdot P}{dP \cdot Q} - 1 \quad (10)$$

$$= \frac{-dQ \cdot P}{dP \cdot Q} = P\epsilon_d \quad (11)$$

\therefore from equations (2) and (11):

$$\frac{P - MR}{P} = \text{optimum tax rate} = \frac{1}{P\epsilon_d}$$

See if you can devise a similar proof to show that the optimal import tariff, where a country has monopsony power, is $1/P\epsilon_s$ (where $P\epsilon_s$ is the price elasticity of supply of the import).

? If economics is the study of choices of how to use scarce resources, can these other objectives be legitimately described as 'non-economic'?

Problems with protection

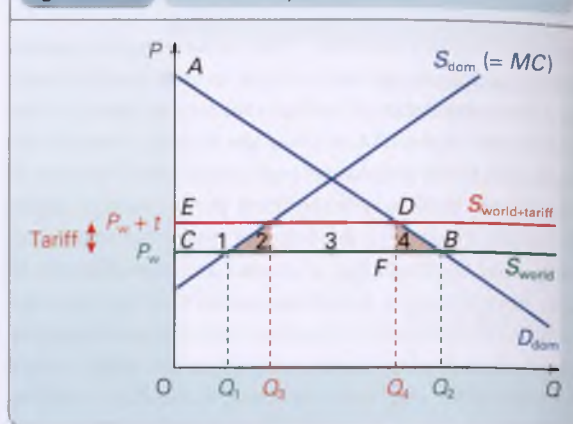

TC 1 Tariffs and other forms of protection impose a cost on society. This is illustrated in Figure 24.12. It illustrates the case of a good that is partly home produced and partly imported. Domestic demand and supply are given by D_{dom} and S_{dom} . It is assumed that firms in the country produce under perfect competition and that therefore the supply curve is the sum of the firms' marginal cost curves.

Let us assume that the country is too small to affect world prices: it is a price taker. The world price is given, at P_w , and world supply to the country (S_{world}) is perfectly elastic. At P_w , Q_2 is demanded, Q_1 is supplied by domestic suppliers and hence $Q_2 - Q_1$ is imported.

Now a tariff is imposed. This shifts up the world supply curve to the country by the amount of the tariff. Price rises to $P_w + t$. Domestic production increases to Q_3 , consumption falls to Q_4 , and hence imports fall to $Q_4 - Q_3$.

What are the costs of this tariff to the country? Consumers are having to pay a higher price, and hence consumer surplus falls from ABC to ADE . The cost to consumers in lost

Figure 24.12 The cost of protection

consumer surplus is thus $EDBC$ (i.e. areas 1 + 2 + 3 + 4). Part of this cost, however, is redistributed as a *benefit* to other sections in society. *Firms* face a higher price, and thus gain extra profits (area 1): where profit is given by the area between the price and the MC curve. The *government* receives extra revenue from the tariff payments (area 3): i.e. $Q_4 - Q_3 \times \text{tariff}$. These revenues can be used, for example, to reduce taxes.

BOX 24.7 GIVING TRADE A BAD NAME

EXPLORING ECONOMICS

Arguments that don't add up

'Why buy goods from abroad and deny jobs to workers in this country?'

This is typical of the concerns that many people have about an open trade policy. However, these concerns are often based on arguments that do not stand up to close inspection. Here are four of them.

'Imports should be reduced since they lower the standard of living.'

The money goes abroad rather than into the domestic economy. Imports are consumed and thus add directly to consumer welfare. Also, provided they are matched by exports, there is no net outflow of money. Trade, because of the law of comparative advantage, allows countries to increase their standard of living: to consume beyond their production possibility curve (see Figures 24.5 and 24.9).

'Protection is needed from cheap foreign labour.'

Importing cheap goods from, say, Indonesia, allows more goods to be consumed. The UK uses less resources by buying these goods through the production and sale of exports than by producing them at home. However, there will be a cost to certain UK workers whose jobs are lost through foreign competition.

'Protection reduces unemployment.'

At a microeconomic level, protecting industries from foreign competition may allow workers in those industries to retain their jobs. But if foreigners sell fewer goods to the UK, they will not be able to buy so many UK exports. Thus unemployment will rise in UK export industries. Overall unemployment, therefore, is little affected, and in the meantime the benefits from trade to consumers are reduced. Temporary protection given to declining industries, however, may help to reduce structural unemployment.

'Dumping is always a bad thing, and thus a country should restrict subsidised imports.'

Dumping may well reduce world economic welfare: it goes against the law of comparative advantage. The importing country, however, may well gain from dumping. Provided the dumping is not used to drive domestic producers out of business and establish a foreign monopoly, the consumer gains from lower prices. The losers are the taxpayers in the foreign country and the workers in competing industries in the home country.

Go through each of these five arguments and provide a reply to the criticisms of them.

But *part* of this cost is not recouped elsewhere. It is a net cost to society (areas 2 and 4).

Area 2 represents the extra costs of producing $Q_3 - Q_1$ at home, rather than importing it. If $Q_3 - Q_1$ were still imported, the country would only be paying S_{world} . By producing it at home, however, the costs are given by the domestic supply curve (=MC). The difference between MC and S_{world} (area 2) is thus the efficiency loss on the production side.

Area 4 represents the loss of consumer surplus by the reduction in consumption from Q_2 to Q_4 . Consumers have saved area FBQ_2Q_4 of expenditure, but have sacrificed area DBQ_2Q_4 of utility in so doing – a net loss of area 4.

The government should ideally weigh up such costs against any benefits that are gained from protection.

 In this model, where the country is a price taker and faces a horizontal supply curve (the small country assumption), is any of the cost of the tariff borne by the overseas suppliers?

Apart from these direct costs to the consumer, there are several other problems with protection. Some are direct effects of the protection; others follow from the reactions of other nations.

Protection as 'second best'. Many of the arguments for protection amount merely to arguments for some type of government intervention in the economy. Protection, however, may not be the best way of dealing with the problem, since protection may have undesirable side effects. There may be a more direct form of intervention that has no side effects. In such a case, protection will be no more than a second-best solution.

For example, using tariffs to protect old, inefficient industries from foreign competition may help prevent unemployment in those parts of the economy, but the consumer will suffer from higher prices. A better solution would be to subsidise retraining and investment in those areas of the country in *new, efficient* industries – industries with a comparative advantage. In this way, unemployment is avoided, but the consumer does not suffer.

Even if the *existing* industries were to be supported, it would still be better to do this by paying them subsidies than by putting tariffs on imports. This argument can be expressed in terms of Figure 24.12. As we have seen, a tariff imposes costs on the consumer of areas $1 + 2 + 3 + 4$. In the current example, area 2 may be a cost worth paying in order to increase domestic output to Q_3 , (and hence reduce unemployment). Areas 1 and 3, as argued above, are merely *redistributed* elsewhere (to firms and the government respectively). But this still leaves area 4. This is a side-effect cost not recouped elsewhere.

A *subsidy*, on the other hand, would not have involved this side-effect cost. In order to raise output to Q_3 , a rate of subsidy the same as the tariff rate would have to be given to producers. This would raise the amount they receive per unit

to $P_w + t$. They would choose to supply Q_3 . The price to the consumer, however, would *remain at the world price* P_w . There would thus be no cost to the consumer. The cost of the subsidy to the taxpayer would be areas $1 + 2$. Area 1 would be redistributed to firms as extra profit. Area 2, as argued above, may be worth paying to achieve the desirable output and employment consequences.

If the aim is to increase output, a *production* subsidy is the best policy. If the aim is to increase employment, an *employment* subsidy is the best policy. In either case, to use *protection* instead would be no more than second best, since it would involve side effects.

To conclude: the best policy is to tackle the problem directly. Unless the aim is specifically to reduce imports (rather than help domestic industry), protection is an indirect policy, and hence never more than second best.

-  1. What would be the 'first-best' solution to the problem of an infant industry not being able to compete with imports?
2. Protection to allow the exploitation of monopoly/monopsony power can be seen as a 'first-best' policy for the country concerned. Similarly, the use of tariffs to counteract externalities directly involved in the trade process (e.g. the environmental costs of an oil tanker disaster) could be seen to be a first-best policy. Explain why.

World multiplier effects. If the UK imposes tariffs or other restrictions, imports will be reduced. But these imports are other countries' exports. A reduction in their exports will reduce the level of injections into the 'rest-of-the-world' economy, and thus lead to a multiplied fall in rest-of-the-world income. Which in turn will lead to a reduction in demand for UK exports. This, therefore, tends to undo the benefits of the tariffs.

 What determines the size of this world multiplier effect?

Retaliation. If the USA imposes restrictions on, say, imports from the EU, then the EU may impose restrictions on imports from the USA. Any gain to US firms competing with EU imports is offset by a loss to US exporters. What is more, US consumers suffer, since the benefits from comparative advantage have been lost.

The increased use of tariffs and other restrictions can lead to a trade war: each country cutting back on imports from other countries. In the end, everyone loses.

Protection may allow firms to remain inefficient. By removing or reducing foreign competition, protection may reduce firms' incentive to reduce costs. Thus if protection is being given to an infant industry, the government must ensure that the lack of competition does not prevent it 'growing up'. Protection should not be excessive and should be removed as soon as possible.

Bureaucracy. If a government is to avoid giving excessive protection to firms, it should examine each case carefully. This can lead to large administrative costs.

Corruption. Some countries that have an extensive programme of protection suffer from corruption. Home producers want as much protection as possible. Importers want as much freedom as possible. It is very tempting for both groups to bribe officials to give them favourable treatment.

The World Trade Organization

After the Wall Street crash of 1929 (when prices on the US stock exchange plummeted), the world plunged into the Great Depression (see pages 495–9). Countries found their exports falling dramatically, and many suffered severe balance of payments difficulties. The response of many countries was to restrict imports by the use of tariffs and quotas.

Of course, this reduced other countries' exports, which encouraged them to resort to even greater protectionism. The net effect of the Depression and the rise in protectionism was a dramatic fall in world trade. The volume of world trade in manufactures fell by more than a third in the three years following the Wall Street crash. Clearly there was a net economic loss to the world from this decline in trade.

After the Second World War there was a general desire to reduce trade restrictions, so that all countries could gain the maximum benefits from trade. There was no desire to return to the beggar-my-neighbour policies of the 1930s.

In 1947, 23 countries got together and signed the General Agreement on Tariffs and Trade (GATT). By 2017, there were 164 members of its successor organisation, the World Trade Organization (WTO), which was formed in 1995. Between them, the members of the WTO account for around 98 per

BOX 24.8 THE DOHA DEVELOPMENT AGENDA

A new direction for the WTO?

Globalisation, based on the free play of comparative advantage, economies of scale and innovation, has produced a genuinely radical force, in the true sense of the word. It essentially amplifies and reinforces the strengths, but also the weaknesses, of market capitalism: its efficiency, its instability, and its inequality. If we want globalisation not only to be efficiency-boosting but also fair, we need more international rules and stronger multilateral institutions.¹

In November 1999, the members of the World Trade Organization met in Seattle in the USA. What ensued became known as the 'Battle of Seattle' (see Case Study 24.3 on the student website). Anti-globalisation protesters fought with police; the world's developing economies fell out with the world's developed economies; and the very future of the WTO was called into question. The WTO was accused of being a free trader's charter, in which the objective of free trade was allowed to ride roughshod over anything that might stand in its way. Whatever the issue – the environment, the plight of developing countries, the dominance of trade by multinationals – free trade was king.

At Seattle, both the protesters and developing countries argued that things had gone far enough. The WTO must redefine its role, they argued, to respect *all* stakeholders. More radical voices called for the organisation to be scrapped. As Pascal Lamy, the EU Trade Commissioner, made clear in the speech quoted above, rules had to be strengthened, and the WTO had to ensure that the gains from trade were fairer and more sustainable.

The rebuilding process of the WTO began in Doha, Qatar, in 2001. The meeting between the then 142 members of the WTO concluded with the decision to launch a new round of WTO trade talks, to be called the Doha Development Agenda (DDA). As with previous trade rounds, the talks were designed

to increase the liberalisation of trade. However, this time such a goal was to be tempered by a policy of strengthening assistance to developing economies.

At Doha it was agreed that the new trade talks would address questions such as:

- *Sustainable development and the environment.* In the past, international trade agreements always seemed to take precedence over international environmental agreements, even though they are legally equivalent. The hope this time was to achieve greater coherence between various areas of international policy making.
- *Trade and development.* The Doha round would attempt to address a number of issues of concern to developing countries as they become more integrated into the world's trading system. These included improving access to markets in developed countries and strengthening the special treatment that developing countries received, such as the ability to maintain higher rates of tariff protection.

Other areas identified for discussion include: greater liberalisation of agriculture; rules to govern foreign direct investment; the co-ordination of countries' competition policies; the use and abuse of patents on medicines; and the needs of developing countries.

The talks were originally scheduled for completion by January 2005, but this deadline was extended several times as new talks were arranged and failed to reach agreement. A particular sticking point was the unwillingness of rich countries, and the USA and the EU in particular, to make sufficient reductions in agricultural protection, given the pressure from their domestic farmers. The USA was unwilling to make substantial cuts in agricultural subsidies and the EU in agricultural tariffs.

cent of world trade. The aims of GATT, and now the WTO, have been to liberalise trade.

WTO rules

The WTO requires its members to operate according to various rules. These include the following:

- **Non-discrimination.** Under the ‘most favoured nations clause’, any trade concession that a country makes to one member must be granted to *all* signatories. The only exception is with free trade areas and customs unions (such as the EU). Here countries are permitted to abolish tariffs between themselves while still maintaining them with the rest of the world.
- **Reciprocity.** Any nation benefiting from a tariff reduction made by another country must reciprocate by making similar tariff reductions itself.
- **The general prohibition of quotas.**

- **Fair competition.** If unfair barriers are erected against a particular country, the WTO can sanction retaliatory action by that country. The country is not allowed, however, to take such action without permission.
- **Binding tariffs.** Countries cannot raise existing tariffs without negotiating with their trading partners.

Unlike the GATT, the WTO has the power to impose sanctions on countries breaking trade agreements. If there are disputes between member nations, these will be settled by the WTO, and if an offending country continues to impose trade restrictions, permission will be granted for other countries to retaliate.

For example, in March 2002, the Bush administration imposed tariffs on steel imports into the USA in order to protect the ailing US steel industry (see Case Study 24.6 on the student website). The EU and other countries referred the case to the WTO, which in December 2003 ruled that they

CASE STUDIES AND APPLICATIONS

There was also unwillingness on the part of large developing countries, such as India and Brazil, to reduce protection to their industrial and service sectors. What is more, there were large divergences in opinion between developing countries on how much they should reduce their own agricultural protection.

Breakdown of the talks

The talks seemed finally to have broken down at a meeting in Geneva in July 2008. Despite the willingness of developing countries to reduce industrial tariffs by more than 50 per cent, and that of the USA and the EU to make deep cuts in agricultural subsidies and tariffs, the talks foundered over the question of agricultural protection for developing countries. This was item 18 on a ‘to-do’ list of 20 items; items 1 to 17 had already been agreed. China and India wanted to protect poor farmers by retaining the ability to impose temporary tariffs on food imports in the event of a drop in food prices or a surge in imports. The USA objected. When neither side would budge, the talks collapsed.

Many commentators, however, argued that failure was no catastrophe. The gain from total liberalisation of trade would have boosted developing countries’ GDP by no more than 1 per cent. And anyway, tariffs were already at an all-time low, demonstrating the extent to which progress had already been made. But with the global economic downturn of 2008–9, there were worries that protectionism would begin to rise again. This was a classic prisoners’ dilemma (see pages 235–7 and 403–5). Policies that seemed to be in the interests of countries separately would be to the overall detriment of the world. The Nash equilibrium of such a ‘game’, therefore, is one where countries are generally worse off. As it turned out, the worries were largely unfounded – at least in the short term.

The Bali Package and the push to agreement

In December 2013, agreement was reached on a range of issues at the WTO’s Bali Ministerial Conference and these were adopted in November 2014 by the General Council. The agreement means a streamlining of trade to make it ‘easier, faster and cheaper’, with particular focus on the promotion of development, boosting the trade of the least developed countries and allowing developing countries more options for providing food security, as long as this does not distort international trade.

This was the first significant agreement of the round and goes some way to achieving around 25 per cent of the goals set for the Doha round.

Then in December 2015, at the Ministerial Conference in Nairobi, another historic agreement was made on various trade initiatives that should provide particular benefits to the WTO’s poorest members. This ‘Nairobi Package’ contains six Ministerial Decisions on agriculture, cotton and issues related to least developed countries, including a commitment to abolish export subsidies for farm exports.

While many issues remain outstanding, some progress has been made. However, many governments, including the USA, have indicated that this could well be the end of the road for the Doha round. Indeed, the Trump presidency may usher in a new wave of protectionism around the world, with populist movements blaming free trade for the decline of many traditional sectors, with a loss of jobs and increased social deprivation.

Does the process of globalisation mean that the role of the WTO is becoming less and less important?

1 ‘Global policy without democracy’ (speech by Pascal Lamy, EU Trade Commissioner, given in 2001).

were illegal. This ruling made it legitimate for the EU and other countries to impose retaliatory tariffs on US products. President Bush consequently announced that the steel tariffs would be abolished.

Could US action to protect its steel industry from foreign competition be justified in terms of the interests of the USA as a whole (as opposed to the steel industry in particular)?

The greater power of the WTO has persuaded many countries to bring their disputes to it. From January 1995 to April 2017 the WTO had considered, or was considering, 524 disputes (compared with 300 by GATT over the whole of its 48 years).

Trade rounds

Periodically, member countries have met to negotiate reductions in tariffs and other trade restrictions. There have been eight 'rounds' of such negotiations since the signing of GATT in 1947. The last major round to be completed was the Uruguay round, which began in Uruguay in 1986, continued at meetings around the world and culminated in a deal being signed in April 1994. By that time, the average tariff on manufactured products was 4 per cent and falling. In 1947 the figure was nearly 40 per cent. The Uruguay round agreement also involved a programme of phasing in substantial reductions in tariffs and other restrictions up to the year 2002 (see Case Study 24.2 on the student website).

Despite the reduction in tariffs, many countries have still tried to restrict trade by various other means, such as quotas and administrative barriers. Also, barriers have been particularly high on certain non-manufactures. Agricultural protection in particular has come in for sustained criticism by developing countries. High fixed prices and subsidies given

to farmers in the EU, the USA and other advanced countries mean that the industrialised world continues to export food to many developing countries that have a comparative advantage in food production! Farmers in developing countries often find it impossible to compete with subsidised food imports from the rich countries.

The most recent round of trade negotiations began in Doha, Qatar, in 2001 (see Box 24.8). The negotiations have focused on both trade liberalisation and measures to encourage development of poorer countries. In particular, the Doha Development Agenda, as it is called, is concerned with measures to make trade fairer so that its benefits are spread more evenly around the world. This would involve improved access for developing countries to markets in the rich world. The Agenda is also concerned with the environmental impacts of trade and development.

The negotiations were originally due to be completed in 2005, but, as Box 24.8 explains, deadlines continued to be missed. However, some progress was made at Ministerial Conference in 2013 and 2015. The Bali Package agreed in 2013 made commitments to streamline trade, boost trade among least developed countries and provide 'food security' for developing countries. The deal was proclaimed as the first substantial agreement since the WTO was formed in 1995. This was followed in 2015 by the 'Nairobi Package' which built on the Bali package by agreeing on actions in the areas of agriculture, cotton with particular relevance to the least developed countries. This included a commitment to begin to abolish export subsidies for farm exports. Nonetheless, considerable work remained in meeting the goals set in Doha. And with the rise in populist anti-globalisation movements and with the election of Donald Trump, it looks as if the Nairobi Package may be the high point of freer trade for some time to come.

Section summary

1. Countries use various methods to restrict trade, including tariffs, quotas, exchange controls, import licensing, export taxes, and legal and administrative barriers. Countries may also promote their own industries by subsidies.
2. Reasons for restricting trade that have some validity in a world context include the infant industry argument; the inflexibility of markets in responding to changing comparative advantage, dumping and other unfair trade practices; the danger of the establishment of a foreign-based monopoly; the problems of relying on exporting goods whose market is growing slowly or even declining; the need to spread the risks of fluctuating export prices; and the problems that free trade may adversely affect consumer tastes, may allow the importation of harmful goods and may not take account of externalities.
3. Often, however, the arguments for restricting trade are in the context of one country benefiting even though other countries may lose more. Countries may intervene in trade in order to exploit their monopoly/monopsony power. In the case of imports, the optimum tariff would be that which would reduce consumption to the level where price was equal to the country's marginal cost. In the case of exports, the optimum export tax would be that which reduced production to the level where the country's marginal revenue was equal to marginal cost. Other 'beggar-my-neighbour' arguments include the protection of declining industries and improving the balance of payments.
4. Finally, a country may have other objectives in restricting trade, such as remaining self-sufficient in certain strategic products, not trading with certain countries of which it disapproves, protecting traditional ways of life or simply retaining a non-specialised economy.
5. In general, trade brings benefits to countries, and protection to achieve one objective may be at a very high

opportunity cost. Other things being equal, there will be a net loss in welfare from restricting trade, with any gain in government revenue or profits to firms being outweighed by a loss in consumer surplus. Even if government intervention to protect certain parts of the economy is desirable, restricting trade is unlikely to be a first-best solution to the problem, since it involves side-effect costs. What is more, restricting trade may have adverse world multiplier effects; it may encourage retaliation; it may allow inefficient firms to remain inefficient; it may involve considerable bureaucracy and possibly even corruption.

6. Most countries of the world are members of the WTO and in theory are in favour of moves towards freer trade. The Uruguay round brought significant reductions in trade restrictions, both tariff and non-tariff.
7. The latest, the Doha round, focuses on trade liberalisation and aims to spread the benefits of trade across developing countries. It has yet to be concluded, but progress has been made since 2013. There is some doubt, however, as to whether any further progress will be made and whether the round, therefore, is effectively over.

24.3 PREFERENTIAL TRADING

The world economy has, over time, seen the formation of a series of trade blocs. These have often been based upon regional groupings of countries, such as the European Union (EU) or the North American Free Trade Agreement (NAFTA). Such trade blocs are examples of *preferential trading arrangements*. These arrangements involve trade restrictions with the rest of the world, and lower or zero restrictions between the members.

Although trade blocs clearly encourage trade between their members, many countries outside the blocs complain that they benefit the members at the expense of the rest of the world. For many developing economies, in need of access to the most prosperous nations in the world, this represents a significant check on their ability to grow and develop.

Types of preferential trading arrangement

There are three possible forms of such trading arrangements.

Free trade areas

A *free trade area* is where member countries remove tariffs and quotas between themselves, but retain whatever restrictions *each member chooses* with non-member countries. Some provision will have to be made to prevent imports from outside coming into the area via the country with the lowest external tariff.

Customs unions

A *customs union* is like a free trade area, but in addition members must adopt *common* external tariffs and quotas with non-member countries.

Common markets

A *common market* is where member countries operate as a *single* market. As with a customs union, there are no tariffs and quotas between member countries and there are

common external tariffs and quotas. But a common market goes further than this. A full common market includes the following features:

- *A common system of taxation.* In the case of a *perfect* common market, this will involve identical rates of tax in all member countries.
- *A common system of laws and regulations governing production, employment and trade.* For example, in a perfect common market, there would be a *single* set of laws governing issues such as product specification (e.g. permissible artificial additives to foods, or levels of exhaust emissions from cars), the employment and dismissal of labour, mergers and takeovers, and monopolies and restrictive practices.
- *Free movement of labour, capital and materials, and of goods and services.* In a perfect common market, this will involve a total absence of border controls between member states, the freedom of workers to work in any member country and the freedom of firms to expand into any member state.
- *The absence of special treatment by member governments of their own domestic industries.* Governments are large

Definitions

Preferential trading arrangements A trade agreement whereby trade between the signatories is freer than trade with the rest of the world.

Free trade area A group of countries with no trade barriers between themselves.

Customs union A free trade area with common external tariffs and quotas.

Common market A customs union where the member countries act as a single market with free movement of labour and capital, common taxes and common trade laws.

purchasers of goods and services. In a perfect common market, they should buy from whichever companies within the market offer the most competitive deal and not show favouritism towards domestic suppliers: they should operate a *common procurement policy*.

The definition of a common market is sometimes extended to include the following two features of *economic and monetary union*:

- A *fixed exchange rate between the member countries' currencies*. In the extreme case, this would involve a single currency for the whole market.
- *Common macroeconomic policies*. To some extent, this must follow from a fixed exchange rate, but in the extreme case it will involve a single macroeconomic management of the whole market, and hence the abolition of separate fiscal or monetary intervention by individual member states.

We will examine European economic and monetary union in section 26.2.

The direct effects of a customs union: trade creation and trade diversion

By joining a customs union (or free trade area), a country will find that its trade patterns change. Two such changes can be distinguished: trade creation and trade diversion.

Trade creation

Trade creation is where consumption shifts from a high-cost producer to a low-cost producer. The removal of trade barriers allows greater specialisation according to comparative advantage. Instead of consumers having to pay high prices for domestically produced goods in which the country has a comparative disadvantage, the goods can now be obtained more cheaply from other members of the customs union. In return, the country can export to them goods in which it has a comparative advantage.

For example, suppose that the most efficient producer in the world of good *x* is France. Assume that, before it joined the EU in 2004, Poland had to pay tariffs on good *x* from France. After joining the EU, however, it was then able to import good *x* from France without paying tariffs. There was a gain to Polish consumers. This gain is illustrated in Figure 24.13. Curves S_{Pol} and D_{Pol} show the domestic supply and demand curves in Poland. The diagram assumes for simplicity that Poland is a price taker as an importer of good *x* from France: the EU price is given.

The diagram shows that, before joining the EU, Poland had to pay the EU price *plus* the tariff (i.e. P_1). At P_1 Poland produced Q_2 , consumed Q_1 and thus imported $Q_1 - Q_2$. With the removal of tariffs, the price fell to P_2 . Consumption increased to Q_3 and production fell to Q_4 . Imports thus increased to $Q_3 - Q_4$. Trade had been created.

The gain in welfare from the removal of the tariff is also illustrated in Figure 24.13. A reduction in price from P_1 to P_2

Figure 24.13 Trade creation

leads to an increase in Polish consumer surplus of areas $1 + 2 + 3 + 4$. On the other hand, there is a loss in profits to domestic producers of good *x* of area 1 and a loss in tariff revenue to the government of area 3. There is still a net gain, however, of areas $2 + 4$.

The increased consumption of wine in the UK after joining the EU may be seen as trade creation.

Trade diversion

Trade diversion is where consumption shifts from a lower-cost producer outside the customs union to a higher-cost producer within the union.

Assume that the most efficient producer of good *y* in the world was Russia – outside the EU. Assume that, before membership, Poland paid a similar tariff on good *y* from any country, and thus imported the product from Russia rather than the EU.

After joining the EU, however, the removal of the tariff made the EU product cheaper, since the tariff remained on the Russian product. Consumption thus switched to a higher-cost producer. There was thus a net loss in world efficiency. As far as Poland was concerned, consumers still gained, since they were paying a lower price than before, but this time the loss in profits to Polish producers plus the loss

Definition

Trade creation Where a customs union leads to greater specialisation according to comparative advantage and thus a shift in production from higher-cost to lower-cost sources.

Trade diversion Where a customs union diverts consumption from goods produced at a lower cost outside the union to goods produced at a higher cost (but tariff-free) within the union.

in tariff revenue to the Polish government might have outweighed these gains, giving a net loss.

These benefits and costs are shown in Figure 24.14. For simplicity it assumes a constant Russian and EU price (i.e. that their supply curves to Poland are infinitely elastic). The domestic supply curve (S_{Pol}) is upward sloping, and is assumed to be equal to marginal cost.

Before joining the EU, Poland was importing good y from Russia at a price P_1 (i.e. the Russian price plus the tariff). Poland thus consumed Q_1 , produced Q_2 domestically and imported the remainder, $Q_1 - Q_2$. On joining the EU, it was now able to consume at the EU (tariff-free) price of P_2 . (Note that this is above the tariff-free Russian price, P_3 .) What are the gains and losses to Poland?

- Consumers' gain: Polish consumer surplus rises by areas 1 + 2 + 3 + 4.
- Producers' loss: Polish producer surplus (profit) falls by area 1.
- Government's loss: previously tariffs of areas 3 + 5 were paid. Now no tariffs are paid. The Polish government thus loses this revenue.

There is thus a net gain of areas 1 + 2 + 3 + 4 minus areas 1 + 3 + 5, i.e. areas 2 + 4 minus area 5. If, however, area 5 is bigger than area 2 + 4, there is a net loss.

When trade *diversion* takes place, therefore, there may still be a net gain, but there may be a net loss. It depends on circumstances.

Under which of the following circumstances is there likely to be a net gain from trade diversion? (Refer to Figure 24.14.)

- (a) A small difference between the EU price and the Russian pre-tariff price, and a large difference between the EU price and the Russian price with the tariff, or vice versa.
- (b) Elastic or inelastic Polish demand and supply curves.
- (c) The Polish demand and supply curves close together or far apart.

A customs union is more likely to lead to trade diversion rather than trade creation:

- When the union's external tariff is very high. Under these circumstances, the abolition of the tariff within the union is likely to lead to a large reduction in the price of goods imported from other members of the union.
- When there is a relatively small cost difference between goods produced within and outside the union. Here the abolition of even relatively low tariffs within the union will lead to internally produced goods becoming cheaper than externally produced goods.

Longer-term effects of a customs union

The problem with the above analysis is that it assumes *static* demand and supply curves: in other words, supply and demand curves that are unaffected by changes in trading patterns. In reality, if a country joins a customs union, the curves are likely to shift. Membership itself affects demand and supply – perhaps beneficially, perhaps adversely.

Longer-term advantages (economic) include the following:

- Increased market size may allow a country's firms to exploit (*internal*) *economies of scale*. This argument is more important for small countries, which have therefore more to gain from an enlargement of their markets.
- *External economies of scale*. Increased trade may lead to improvements in the infrastructure of the members of the customs union (better roads, railways, financial services, etc.). This in turn could bring bigger long-term benefits from trade between members, and from external trade too, by making the transport and handling of imports and exports cheaper.
- The bargaining power of the whole customs union with the rest of the world may allow member countries to gain *better terms of trade*. This, of course, will necessarily involve a degree of political co-operation between the members.
- *Increased competition* between member countries may stimulate efficiency, encourage investment and reduce monopoly power. Of course, a similar advantage could be gained by the simple removal of tariffs with any competing country.
- Integration may encourage a more rapid spread of technology.

Longer-term disadvantages (economic) include the following:

- *Resources may flow from a country* to more efficient members of the customs union, or to the geographical centre of the union (so as to minimise transport costs). This can be a major problem for a *common market* (where there is free movement of labour and capital). The country could become a depressed 'region' of the community, with adverse regional multiplier effects.

- If integration encourages greater co-operation between firms in member countries, it may also encourage *greater oligopolistic collusion*, thus keeping prices to the consumer higher. It may also encourage mergers and takeovers which would increase monopoly power.
- *Diseconomies of scale*. If the union leads to the development of very large companies, they may become bureaucratic and inefficient.
- The *costs of administering* the customs union may be high. This problem is likely to be worse, the greater the intervention in the affairs of individual members.

It is extremely difficult to assess these arguments. To decide whether membership has been beneficial to a country requires a prediction of what things would have been like if it had not joined. No *accurate* predictions of this sort can be made, and they can never be tested. Also, many of the advantages and disadvantages are very long term, and depend on future attitudes, institutions, policies and world events, which again cannot be predicted.

In addition, some of the advantages and disadvantages are distinctly political, such as 'greater political power' or 'loss of sovereignty'.

How would you set about assessing whether or not a country had made a net long-term gain by joining a customs union? What sort of evidence would you look for?

Preferential trading in practice

Preferential trading has the greatest potential to benefit countries whose domestic market is too small, taken on its own, to enable them to benefit from economies of scale, and where they face substantial barriers to their exports. Most developing countries fall into this category, and as a result many have attempted to form preferential trading arrangements.

Examples in Latin America and the Caribbean are the Latin American Integration Association (LAIA), the Andean Community, the Central American Integration System (SICA) and the Caribbean Community (CARICOM). In 1991, a Southern Common Market (MerCoSur) was formed, consisting of Argentina, Brazil, Paraguay and Uruguay. Venezuela joined in 2012. It has a common external tariff and most of its internal trade is free of tariffs.

The Association of South-East Asian Nations (ASEAN) was formed in 1967 when six nations (Brunei, Indonesia, Malaysia, the Philippines, Singapore and Thailand) agreed to work towards an ASEAN Free Trade Area (AFTA). ASEAN now has 10 members (the new countries being Vietnam, Laos, Myanmar and Cambodia) with a population of over 620 million people and is dedicated to increased economic co-operation within the region.

By 2010, virtually all tariffs between the six original members had been eliminated and both tariff and non-tariff barriers are falling quickly for both original and new members. The ASEAN Economic Community (AEC) was established in 2015, ahead of schedule.

In Africa, the Economic Community of West African States (ECOWAS) has been attempting to create a common market between its 15 members which has a combined population of around 350 million. The West African franc is used in eight of the countries and another six plan to introduce a common currency, the *eco*. However, the launch of this has been delayed several times and it is now not expected until at least 2020. The ultimate goal is to combine the two currency areas and adopt a single currency for all member states.

North American Free Trade Agreement (NAFTA)

Along with the EU, NAFTA is one of the two most powerful trading blocs in the world. It came into force in 1994 and consists of the USA, Canada and Mexico. These three countries agreed to abolish tariffs between themselves in the hope that increased trade and co-operation would follow. Tariffs between the USA and Canada were phased out by 1999, and tariffs between all three countries were eliminated as of 1 January 2008. Many non-tariff restrictions remain, although new ones are not permitted. However, the Trump administration has threatened to break this rule with the erection of new barriers against Mexican imports.

NAFTA members hope that, with a market similar in size to the EU, they will be able to rival the EU's economic power in world trade. NAFTA is, however, at most only a free trade area and not a common market. Unlike the EU, it does not seek to harmonise laws and regulations, except in very specific areas such as environmental management and labour standards. Member countries are permitted total legal independence, subject to the one proviso that they must treat firms of other member countries equally with their own firms – the principle of 'fair competition'. Nevertheless, NAFTA has encouraged a growth in trade between its members, most of which is trade creation rather than trade diversion.

Case Study 24.7 on the student website looks at the costs and benefits of NAFTA membership to the three countries involved.

Asia-Pacific Economic Co-operation forum (APEC)

The most significant move towards establishing a more widespread regional economic organisation in East Asia appeared with the creation of the Asia-Pacific Economic Co-operation (APEC) in 1989. APEC links 21 economies of the Pacific rim, including Asian, Australasian and North and South American countries (19 countries, plus Hong Kong and Taiwan). These countries account for over half of global GDP and almost half of the world's trade. At the 1994 meeting of APEC leaders, it resolved to create a free trade area across the Pacific by 2010 for the developed industrial countries, and by 2020 for the rest.

This preferential trading area is by no means as advanced as NAFTA and is unlikely to move beyond a free trade area. Within the region there exists a wide disparity across a range of economic and social indicators. Such disparities create a wide range of national interests and goals. Countries are

unlikely to share common economic problems or concerns. In addition, political differences and conflicts within the region are widespread, reducing the likelihood that any organisational agreement beyond a simple economic one would succeed. Nevertheless, freer trade has brought economic benefits to the countries involved.

The longest established and most comprehensive of preferential trading arrangements is the European Union. The next section is devoted to examining its evolution from a rather imperfect customs union to a common market (though still not perfect).

The Trans-Pacific Partnership

The Trans-Pacific Trade Partnership (TPP) is an agreement between 12 Pacific-rim countries – Australia, Brunei, Canada, Chile, Japan, Malaysia, Mexico, New Zealand, Peru, Singapore, the USA and Vietnam, but not China. It was signed by the 12 countries in February 2016, but has yet to be ratified by the countries' governments. On coming into office in January 2017, Donald Trump withdrew the USA from the agreement, making ratification of the agreement by the remaining countries difficult.

The agreement is more than a simple free trade agreement. In terms of trade it involves the removal of many non-tariff barriers as well as most tariff barriers. It also has elements of a single market. For example, it contains many robust and enforceable environmental protection, human rights and labour standards measures. It also allows for the free transfer of capital by investors in most circumstances.

However, it also established an 'investor-state dispute settlement' (ISDS) mechanism. This allows companies from any of the now 11 countries to sue governments of any other countries in the agreement for treaty violations, such as giving favourable treatment to domestic companies, the seizing of companies' assets or controls over the movement of capital. Critics of ISDS claim that it gives too much power to companies and may prevent governments from protecting their national environment or domestic workers and companies.

China, South Korea, Indonesia, the Philippines, Thailand and Colombia have expressed an interest in joining and it may be that these and the 11 members will find a way of progressing with the agreement without the USA. A key question is whether a growing international antipathy to trade deals will extend beyond the USA to current and prospective members.

Section summary

1. Countries may make a partial movement towards free trade by the adoption of a preferential trading system. This involves free trade between the members, but restrictions on trade with the rest of the world. Such a system can be either a simple free trade area, or a customs union (where there are common restrictions with the rest of the world), or a common market (where in addition there is free movement of capital and labour, and common taxes and trade laws).
2. A preferential trading area can lead to trade creation where production shifts to low-cost producers within the area, or to trade diversion where trade shifts away from lower-cost producers outside the area to higher-cost producers within the area.
3. There is a net welfare gain from trade creation: the gain in consumer surplus outweighs the loss of tariff revenue and the loss of profit to domestic producers. With trade diversion, however, these two losses may outweigh the gains to consumers: whether they do depends on the size of the tariffs and on the demand for and supply of the traded goods.
4. Preferential trading may bring dynamic advantages of increased external economies of scale, improved terms of trade from increased bargaining power with the rest of the world, increased efficiency from greater competition between member countries, and a more rapid spread of technology. On the other hand, it can lead to increased regional problems for members, greater oligopolistic collusion and various diseconomies of scale. There may also be large costs of administering the system.
5. There have been several attempts around the world to form preferential trading systems. The two most powerful are the European Union and the North American Free Trade Association (NAFTA).

24.4 THE EUROPEAN UNION

Historical background

The European Economic Community was formed by the signing of the Treaty of Rome in 1957 and came into operation on 1 January 1958.

The original six member countries of the EEC (Belgium, France, Italy, Luxembourg, the Netherlands and West

Germany) had already made a move towards integration with the formation of the European Coal and Steel Community in 1952. This had removed all restrictions on trade in coal, steel and iron ore between the six countries. The aim had been to gain economies of scale and allow more effective competition with the USA and other foreign producers.

The EEC extended this principle and aimed eventually to be a full common market with completely free trade between members in all products, and with completely free movement of labour, enterprise and capital.

All internal tariffs between the six members had been abolished and common external tariffs established by 1968. But this still only made the EEC a *customs union*, since a number of restrictions on internal trade remained (legal, administrative, fiscal, etc.). Nevertheless the aim was eventually to create a full common market.

In 1973 the UK, Denmark and Ireland became members. Greece joined in 1981, Spain and Portugal in 1986, and Sweden, Austria and Finland in 1995. In May 2004, a further 10 countries joined: Cyprus, the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia and Slovenia. Bulgaria and Romania joined in 2007. The last new member is Croatia, which joined in 2013. With the UK scheduled to leave the EU in 2019, there will then be 27 members.

Montenegro, Serbia and Turkey ('accession countries') are in negotiations to join and Albania and the former Yugoslav Republic of Macedonia have applied to join ('candidate countries'). However, with concerns throughout the EU with immigration, cultural assimilation and financial costs, it is doubtful that any of these countries will succeed in joining.

From customs union to common market

The EU is clearly a customs union. It has common external tariffs and no internal tariffs. But is it also a common market? For many years, there have been *certain* common economic policies.

Common Agricultural Policy (CAP). The Union has traditionally set common high prices for farm products. This has involved charging variable import duties to bring foreign food imports up to EU prices and intervention to buy up surpluses of food produced within the EU at these above-equilibrium prices (see section 3.4). Although the main method of support has shifted to providing subsidies (or 'income support') unrelated to current output, this still represents a *common* economic policy.

Regional policy. EU regional policy provides grants to firms and local authorities in relatively deprived regions of the Union (see Case Study 23.14 on the student website).

Competition policy. EU policy here has applied primarily to companies operating in more than one member state (see section 14.1). For example, Article 101 of the Treaty of Lisbon prohibits agreements between firms operating in more than one EU country (e.g. over pricing or sharing out markets) which adversely affect competition in trade between member states (see page 424–5).

Harmonisation of taxation. VAT is the standard form of indirect tax throughout the EU. However, there are substantial differences in VAT rates between member states, as there are with other tax rates.

What would be the economic effects of (a) different rates of VAT, (b) different rates of personal income tax and (c) different rates of company taxation between member states if there were no other barriers to trade or factor movements?

Social policy. In 1989 the European Commission presented a *social charter* to the heads of state. This spelt out a series of worker and social rights that should apply in all member states (see Case Study 24.9 on the student website). These rights were grouped under 12 headings covering areas such as the guarantee of decent levels of income for both the employed and the non-employed, freedom of movement of labour between member countries, freedom to belong to a trade union and equal treatment of men and women in the labour market. However, the charter was only a recommendation and each element had to be approved separately by the European Council of Ministers.

The social chapter of the Maastricht Treaty (1991) attempted to move the Community forward in implementing the details of the social charter in areas such as maximum hours, minimum working conditions, health and safety protection, information and consultation of workers, and equal opportunities.

Would the adoption of improved working conditions necessarily lead to higher labour costs per unit of output?

Despite these various common policies, in other respects the Community of the 1970s and 1980s was far from a true common market: there were all sorts of non-tariff barriers such as high taxes on wine by non-wine-producing countries, special regulations designed to favour domestic producers, governments giving contracts to domestic producers (e.g. for defence equipment), and so on.

The category often cited by businesses as being the most important single barrier was that of regulations and norms. In some cases, the regulations merely added to the costs of imports. But in the cases of many mechanical engineering and telecommunications products, technical and health and safety regulations sometimes ruled out foreign imports altogether.

Moves towards a single market

The Single European Act of 1986, which came into force in July 1987, sought to remove these barriers and to form a genuine common market by the end of 1992 (see Box 24.10).

One of the most crucial aspects of the Act was its acceptance of the principle of *mutual recognition*. This is the

Definition

Mutual recognition The EU principle that one country's rules and regulations must apply throughout the EU. If they conflict with those of another country, individuals and firms should be able to choose which to obey.

principle whereby if a firm or individual is permitted to do something under the rules and regulations of *one* EU country, it must also be permitted to do it in all other EU countries. This means that firms and individuals can choose the country's rules that are least constraining.

Mutual recognition also means that individual governments can no longer devise special rules and regulations that keep out competitors from other EU countries (see Box 24.9). Here was the answer to the dilemma of how to get all EU countries to agree to common sets of rules and regulations. All that was required was that they recognised the rules and regulations applying in each other's countries. However, there was a danger that governments would end up competing against each other to provide the lightest set of regulations in order to attract firms to invest in their country. This could be to the detriment of consumers and workers.

Thus *some* common sets of rules and regulations were still required. One other feature of the Single European Act helped here. This was the institution of *majority* voting in questions of harmonisation of rules and regulations. Previously, unanimous approval had been necessary. This had meant that an individual country could veto the dismantling of barriers. This new system of majority voting, however, does not currently apply to the harmonisation of taxes, although the European Commission continues to propose that majority voting be extended to taxation while recognising that 'there is no need for across the board harmonisation' of taxes.

The benefits and costs of the single market

It is difficult to quantify the benefits and costs of the single market, given that many occur over a long period, and it is hard to know to what extent the changes that are taking place are the direct result of the single market.

One study conducted in 1998 did, nevertheless, estimate the benefits in terms of increased consumption (see Table 24.6). This found that the benefits to the smaller, lower-income countries, such as Portugal and Greece, were the greatest. Such estimates, however, do depend crucially on the assumptions made and are thus open to substantial error.

Then in 2012, the European Commission published *20 Years of the European Single Market*. This stated that, 'The GDP of the EU27 was 2.13% – or €233 billion – higher in 2008 than it would have been without the Single Market. This can be equated to around €500 extra in income per EU citizen. Between 1992 and 2008, the Single Market helped to create 2.77 million new jobs.'

Even though the precise magnitude of the benefits is difficult to estimate, it is possible to identify the *types* of benefit that have resulted, many of which have been substantial.

Trade creation. The expansion of trade within the EU has reduced both prices and costs, as countries have been able to exploit their comparative advantage. Member countries have specialised further in those goods and services that they can produce at a comparatively low opportunity cost.

BOX 24.9 MUTUAL RECOGNITION: THE CASSIS DE DIJON CASE

CASE STUDIES AND APPLICATIONS

Or when is a liqueur not a liqueur?

Crème de Cassis is an alcoholic blackcurrant drink made by the French firm Cassis de Dijon. Added to white wine, it makes the drink kir. It is not just the French who like drinking kir; it is also, among others, the Germans. In this seemingly innocent fact lay the seeds for the dismantling of some of the most serious trade barriers in Europe!

The story starts back in 1978. The West German company Rewe Zentral AG wanted to import Cassis, but found that under West German law it could not. The problem was that Cassis does not contain enough alcohol to be classed as a liqueur, and it also fell outside any other category of alcoholic drink that was permitted by West German law.

But Rewe was not to be put off. It started legal proceedings in Europe to challenge the German law. The basis of Rewe's case was that this law discriminated against non-German companies. After much legal wrangling, the European Court of Justice in Luxembourg ruled that Germany had no right to prevent the importation of a product that was legitimately on sale in another member country (i.e. France). The only exceptions to this ruling would be if the product was barred for reasons of consumer protection, health or fair trade. None of these applied to Cassis, so the Germans can

now drink kir to their hearts' content without having to become smugglers.

But what of the implications of the case? These are enormous and were spelt out in the Single European Act: 'the Council may decide that provisions in force in a member state must be recognised as being equivalent to those applied by another'. In other words, individuals and firms can choose which country's sets of regulations suit them the best and then insist that they be applied in *all* member states.

'Mutual recognition' of each other's laws tends to lead to deregulation, as people choose those countries' laws that give them the greatest freedom. This appeals to economic and political liberals. Equally, it worries those who argue that regulations and laws on industrial standards have been instituted for a purpose, and should not be undone just because some other member country has not been wise enough to institute them itself.

How has the Cassis de Dijon ruling affected the balance of power in the EU between (a) individual states and the EU as a whole; (b) governments and the courts?

BOX 24.10

FEATURES OF THE SINGLE MARKET

CASE STUDIES AND APPLICATIONS

Since 1 January 1993 trade within the EU has operated very much like trade within a country. In theory, it should be no more difficult for a firm in Marseilles to sell its goods in Berlin than in Paris. At the same time, the single market allows free movement of labour and involves the use of common technical standards.

The features of the single market are summed up in two European Commission publications.¹ They are:

- Elimination of border controls on goods within the EU: no more long waits.
- Free movement of people across borders.
- Common security arrangements.
- No import taxes on goods bought in other member states for personal use.
- The right for everyone to live in another member state.
- Recognition of vocational qualifications in other member states: engineers, accountants, medical practitioners, teachers and other professionals able to practise throughout Europe.
- Technical standards brought into line, and product tests and certification agreed across the whole EU.
- Common commercial laws – making it attractive to form Europe-wide companies and to start joint ventures.
- Public contracts to supply equipment and services to state organisations now open to tenders across the EU.

So what does the single market mean for individuals and for businesses?

Individuals

Before 1993, if you were travelling in Europe you had a 'duty-free allowance'. This meant that you could only take goods up to the value of €600 across borders within the EU without having to pay VAT in the country into which you were importing them. Now you can take as many goods as you like from one EU country to another, provided they are for your own consumption. But to prevent fraud, member states may ask for evidence that the goods have been purchased for the traveller's own consumption if they exceed specified amounts.

Individuals have the right to live and work in any other member state. Qualifications obtained in one member state must be recognised by other member states.

Firms

Before 1993 all goods traded in the EU were subject to VAT at every internal border. This involved some 60 million customs clearance documents at a cost of some €70 per consignment.²

This has all now disappeared. Goods can cross from one member state to another without any border controls: in fact, the concepts of 'importing' and 'exporting' within the EU no longer officially exist. All goods sent from one EU country to another will be charged VAT only in the country of destination. They are exempt from VAT in the country where they are produced.

One of the important requirements for fair competition in the single market is the convergence of tax rates. Although income tax rates, corporate tax rates and excise duties still differ between member states, there has been some narrowing in the range of VAT rates. Higher rates of VAT on luxury goods were abolished and countries are allowed to have no more than two lower rates of at least 5 per cent on 'socially necessary' goods, such as food and water supply.

There is now a lower limit of 15 per cent on the standard rate of VAT. Actual rates in January 2017 nonetheless varied from 17 per cent in Luxembourg to 27 per cent in Hungary. However, during the early 2010s several countries, including the UK, Ireland, Greece and Portugal increased their standard rate of VAT as a means of reducing their budget deficits (see sections 22.2 and 22.4). One effect of this is that the vast majority of EU countries now have a standard rate of VAT between 20 and 25 per cent.

In what ways would competition be 'unfair' if VAT rates differed widely between member states?

1 *A Single Market for Goods* (Commission of the European Communities, 1993); *10 Key Points about the Single European Market* (Commission of the European Communities, 1992).

2 *A Single Market for Goods* (Commission of the European Communities, 1993).

Table 24.6 Gains from the single market

Countries	Extra consumption as % of GDP
France, Germany, UK, Italy	2–3
Denmark	2–5
Netherlands, Spain	3–4
Belgium, Luxembourg	4–5
Ireland	4–10
Greece	5–16
Portugal	19–20

Source: C. Allen, M. Gasiorek and A. Smith, 'The competition effects of the single market in Europe', *Economic Policy* (1998).

Reduction in the direct costs of barriers. This category includes administrative costs, border delays and technical regulations. Their abolition or harmonisation has led to substantial cost savings, shorter delivery times and a larger choice of suppliers.

Economies of scale. With industries based on a Europe-wide scale, many firms can now be large enough, and their plants large enough, to gain the full potential economies of scale (see Box 6.9 on pages 174–5). Yet the whole European market is large enough for there still to be adequate competition. Such gains have varied from industry to industry depending on the minimum efficient scale of a plant or

firm. Economies of scale have also been gained from mergers and other forms of industrial restructuring.

Greater competition. Increased competition between firms has led to lower costs, lower prices and a wider range of products available to consumers. This has been particularly so in newly liberalised service sectors such as transport, financial services, telecommunications and broadcasting. In the long run, greater competition can stimulate greater innovation, a greater flow of technical information and the reorganisation ('rationalisation') of production to increase efficiency.

Despite these gains, the single market has not received universal welcome within the EU. Its critics argue that, in a Europe of oligopolies, unequal ownership of resources, rapidly changing technologies and industrial practices, and factor immobility, the removal of internal barriers to trade has merely exaggerated the problems of inequality and economic power. More specifically, the following criticisms are made.

Radical economic change is costly. Substantial economic change is necessary to achieve the full economies of scale and efficiency gains from a single European market. These changes necessarily involve redundancies – from bankruptcies, takeovers, rationalisation and the introduction of new technology. The severity of this structural and technological unemployment depends on (a) the pace of economic change and (b) the mobility of labour – both occupational and geographical. Clearly, the more integrated markets become across the EU, the less the costs of *future* change.

Adverse regional multiplier effects. Firms are likely to locate as near as possible to the 'centre of gravity' of their markets and sources of supply. The geographical expansion of firms' markets to potentially encompass the whole of the EU can tend to attract capital and jobs away from the edges of the Union to its geographical centre.

In an ideal market situation, areas like the south of Italy or Portugal, should attract resources from other parts of the Union. Since they are relatively depressed areas, wage rates and land prices are lower. The resulting lower industrial costs should encourage firms to move into the areas. In practice, regional multiplier effects may worsen the problem (see page 741). As capital and labour (and especially young and skilled workers) leave the extremities of the Union, so these regions are likely to become more depressed. If, as a result, their infrastructure is neglected, they then become even less attractive to new investment.

Has the problem of adverse regional multiplier effects been made better or worse by the adoption of a single European currency? (This issue is explored in section 26.3.) (Clue: without a single currency, how would the devaluation of the drachma (the former Greek currency) have affected a depressed Greek economy?)

The development of monopoly/oligopoly power. The free movement of capital can encourage the development of giant

'Euro-firms' with substantial economic power. Indeed, recent years have seen some very large European mergers (see Box 9.4 on pages 262–3). This can lead to higher, not lower, prices and less choice for the consumer. It all depends on just how effective competition is, and how effective EU competition policy is in preventing monopolistic and collusive practices.

Trade diversion. Just as increased trade creation has been a potential advantage from completing the internal market, so trade diversion has been a possibility too. This is more likely if *external* barriers remain high (or are even increased) and internal barriers are *completely* abolished.

Is trade diversion more likely or less likely in the following cases? (a) European producers gain monopoly power in world trade. (b) Modern developments in technology and communications reduce the differences in production costs associated with different locations. (c) The development of the internal market produces substantial economies of scale in many industries.

Perhaps the biggest objection raised against the single European market is a political one: the loss of national sovereignty. Governments find it much more difficult to intervene at a microeconomic level in their own economies. This was one of the key arguments in the debate over the Britain's future within Europe in the run-up to the EU referendum in 2016 (see section 24.5).

Why may the newer members of the Union have the most to gain from the single market, but also the most to lose?

Completing the internal market

Despite the reduction in barriers, the internal market is still not 'complete'. In other words, various barriers to trade between member states still remain. Thus, in June 1997, an Action Plan was adopted by the European Council. Its aim was to ensure that all barriers were dismantled by the launch of the euro in January 1999.

In 1997, what is now known as Single Market Scoreboard was established to monitor the progress in dismantling trade barriers. This is now published annually and shows progress towards the total abandonment of any forms of internal trade restrictions (see Case Study 24.11 on the student website). It shows the percentage of EU Single Market Directives still to be transposed into national law. To counteract new barriers, the EU periodically issues new Directives. If this process is more rapid than that of the transposition of existing Directives into national law, the transposition deficit increases.

In addition to giving each country's 'transposition deficit', the Scoreboard identifies the number of infringements of the internal market that have taken place. The hope is that the 'naming and shaming' of countries will encourage them to make more rapid progress towards totally free trade within the EU.

In 1997, the average transposition deficit of member countries was 6.3 per cent. By 1999, this had fallen to 3.5 per cent and by 2016 to 0.7 per cent. However, by the beginning of 2017 it had risen 1.5 per cent. But this was largely due to an exceptional number of new directives waiting to be transposed and the deficit was expected to return to between 0.5 and 0.7 per cent. Despite this success, national governments have continued to introduce *new* technical standards, several of which have had the effect of erecting new barriers to trade. Also, infringements of single market rules by governments have not always been dealt with. The net result is that, although trade is much freer today than in the early 1990s, especially given the transparency of pricing with the euro, there still do exist various barriers, especially to the free movement of goods.

If there have been clear benefits from the single market programme, why do individual member governments still try to erect barriers, such as new technical standards?

The effect of the new member states

Given the very different nature of the economies of many of the new entrants to the EU, and their lower levels of GDP per head, their potential gain from membership has been substantial. The gains come through trade creation, increased competition, technological transfer and inward investment, both from other EU countries and from outside the EU.

A study in 2004 concluded that Poland's GDP would rise by 3.4 per cent and Hungary's by almost 7 per cent.⁴ Real

wages would rise, with those of unskilled workers rising faster than those of skilled workers, in accordance with these countries' comparative advantage. There would also be benefits for the existing 15 EU countries from increased trade and investment, as well as cheaper inputs, but these would be relatively minor in comparison to the gains to the new members.

A European Commission Report produced in April 2009, five years after the enlargement,⁵ found that the expansion had been a win-win situation for both old and new members. There had been significant improvements in the standard of living in new member states and they had benefited from modernisation of their economies and more stabilised institutions and laws. In addition, enterprises in old member states had enjoyed opportunities for new investment and exports, and there had been an overall increase in trade and competition between the member states.

When Lithuania adopted the euro in 2015 the number of countries using the euro had reached 19. Hence, in future years trade within the EU is likely to continue to grow as a proportion of GDP. We examine the benefits and costs of the single currency and the whole process of economic and monetary union in the EU in section 26.2.

Section summary

1. The European Union is a customs union in that it has common external tariffs and no internal ones. But virtually from the outset it has also had elements of a common market, particularly in the areas of agricultural policy, regional policy, monopoly and restrictive practice policy, and to some extent in the areas of tax harmonisation and social policy.
2. Nevertheless, there have been substantial non-tariff barriers to trade within the EU, such as different tax rates, various regulations over product quality, licensing, state procurement policies, educational qualification requirements, financial barriers, various regulations and norms, and subsidies or tax relief to domestic producers.
3. The Single European Act of 1987 sought to sweep away these restrictions and to establish a genuine free market within the EU: to establish a full common market. Benefits from completing the internal market have included trade creation, cost savings from no longer having to administer barriers, economies of scale for firms now able to operate on a Europe-wide scale, and greater competition leading to reduced costs and prices, greater flows of technical information and more innovation.
4. Critics of the single market point to various changes in industrial structure that have resulted, bringing problems of redundancies and closures. They also point to adverse regional multiplier effects as resources are attracted to the geographical centre of the EU, to possible problems of market power with the development of giant 'Euro-firms', and to the possibilities of trade diversion.
5. The actual costs and benefits of EU membership to the various countries vary with their particular economic circumstances – for example, the extent to which they gain from trade creation, or lose from adverse regional multiplier effects – and with their contributions to and receipts from the EU budget.
6. These cost and benefits in the future will depend on just how completely the barriers to trade are removed, on the extent of monetary union and on any further enlargements to the Union.

24.5 THE UK AND BREXIT

On 23 June 2016, the UK held a referendum on whether to remain a member of the EU. By a majority of 51.9 per cent to 48.1 per cent of the 72.1 per cent of the electorate who voted, Britain voted to leave the EU.

In the run-up to the vote there was heated debate on the merits and costs of membership and of leaving ('Brexit'). Although many of the arguments were concerned with sovereignty, security and other political factors, many of the arguments centred on whether there would be a net *economic* gain from either remaining or leaving.

However, as we have previously discussed, assessing the benefits of membership of customs unions and, in this case, of the EU is fraught with difficulties. Hence, forecasting the economic impact of the decision is difficult. The effects of either remaining or leaving were likely to be very different in the long run from the short run and, of course, long-run forecasts are highly unreliable as the economy is likely to be affected by so many unpredictable events.

Nonetheless, the tools of economics provide a framework in which we can discuss the *potential* economic benefits and costs of the UK's membership of the European Union as compared with the alternatives outside the EU.

Alternative trading arrangements

An analysis of the longer-term economic effects of the UK leaving the European Union depend on the nature of its future trading relationship with the EU. Three main possibilities were suggested.

The first was 'the Norwegian model', where Britain leaves the EU, but joins the European Economic Area (EEA), giving access to the single market, but removing regulation in some key areas, such as fisheries and home affairs.

The second possibility is the negotiation of bilateral agreements. These fall under three types:

- 'The Swiss model' where the UK negotiates a series of bilateral agreements with the EU, including selective or general access to the single market.
- 'The Canadian model' where the UK forms a comprehensive trade agreement with the EU to lower customs tariffs and other barriers to trade.
- 'The Turkish model' where the UK forms a customs union with the EU. In Turkey's case the agreement relates principally to manufactured goods.

At the extreme, the UK could make a complete break from the EU and simply use its membership of the WTO to make trade agreements. Table 24.7 summarises the possible alternative trading relationships between the UK and the EU.

Of these alternatives, the most likely seems a 'hard Brexit', which means leaving both the single market and the customs union. Indeed, in a speech in January 2017, the Prime Minister, Theresa May, stated that the UK 'cannot possibly'

remain in the single market, as that would mean 'not leaving the EU at all. So we do not seek membership of the Single market. Instead, we seek the greatest possible access to it through a new, comprehensive, bold and ambitious 'Free Trade Agreement'.⁶

After the triggering of Article 50 in March 2017 (which begins formal Brexit talks), the EU negotiators also made clear that leaving the EU means sacrificing the right of access to the single market and customs union. What is more, any trade deals between the UK and the EU could only be considered once the terms of the 'divorce' settlement had been finalised.

Long-term growth, trade and Brexit

The effects of the decision to leave the EU will take many years to become clear. Many of these effects will depend on the impact that the decision has for the UK's long-term rate of growth. In Chapter 23 we saw that long-term growth requires continuous increases in potential output. Hence, a longer-term analysis of the vote to leave can be expected to focus on its impact on the economy's productive potential.

The important point here is that for most countries it is important to consider their long-term growth and well-being within the context of a global economy with markedly greater levels of openness and trade flows than in the past.

Since the UK joined the EU in 1973 the openness of the UK economy has increased rapidly. Figure 24.15 shows the ratio of the total flow of imports and exports of goods and services to GDP since the 1970s. Over this period the ratio has doubled from 30 per cent to 60 per cent.

Adverse effects of Brexit

In its 2016 analysis of the possible long-term implications of Brexit, the UK Treasury argued that the country's openness to trade and investment had been a key factor behind the growth in the economy's potential output.⁷ Hence, maintaining this openness, it argued, would be important for long-term growth and so for raising living standards. Positive supply-side effects from openness might include:

- Increasing *market opportunities* which enable firms to exploit internal economies of scale (see pages 162–4 and 759).
- Increasing *competition* encourages firms to improve their productivity to maintain their market share and so encourages the adoption of new technologies and processes.
- *Technology transfer*. Technological know-how can be passed between firms in international supply chains,

⁶ Speech given by Theresa May at Lancaster House, 17 January 2017.

through internationally mobile workers or new international entrants.

The Treasury's analysis attempted to estimate the average impact on households of the UK leaving the EU by modelling the adverse impacts on the supply-side of the economy from lower levels of openness. To do so it considered three new relationships with the EU (see Table 24.7) and annual losses 15 years after leaving. With a Norwegian-type deal, households would be £2600 worse off each year; a Swiss deal would lead to a £4300 annual loss of GDP per household and a complete exit would create a household loss per annum of £5200. It found that tax receipts would be lower and that the overall benefit to the UK of being in the EU, relative to another arrangement, would be between 3.4 per cent and 9.5 per cent of GDP, depending on the exact 'new deal'.

The OECD suggested that Brexit would be like a tax, pushing up the costs and weakening the economy. Its analysis indicated that by 2020, GDP would be at least 3 per cent lower than it otherwise would have been, making households £2200 worse off. By 2030, these figures would be 5 per cent and £3200. It continues that:

In the longer term, structural impacts would take hold through the channels of capital, immigration and lower technical progress. In particular, labour productivity would be held back by a drop in foreign direct investment and a smaller pool of skills. The extent of forgone GDP would increase over time . . . The effects would be even larger in a more pessimistic scenario and remain negative even in the optimistic scenario.⁸

The OECD analysis points to the *structural change* the UK economy will experience. The growth in openness experienced by the UK economy has occurred within the context of EU membership. Membership has influenced the patterns

of trade and investment. It has provided the framework in which businesses have operated – for example, the development of supply chains across EU member countries. Structural changes accompanying Brexit, the OECD argued, would have negative supply-side effects.

Can we incorporate trade effects into endogenous growth models?

Opportunities from Brexit

Despite the pessimistic forecasts from the vast majority of economists about a British exit, there was a group of eight economists in favour of Brexit.⁹ They claimed that leaving the EU would lead to a stronger economy, with higher GDP, a faster growth in real wages, lower unemployment and a smaller gap between imports and exports. The main argument to support the claims was that the UK would be more able to pursue trade creation freed from various EU rules and regulations. In other words, there would be positive supply-side effects.

While disagreement about the impact on the UK's exit from the EU was to be expected, there was agreement that these effects would work primarily through their impact on the supply-side.

However, perhaps less clear was the likely *distributional* effects of the UK's exit. While openness and its associated movements in people, goods, services and capital impact on an economy's productive capabilities, there can be significant distributional effects too. Trade can impact on different sectors differently. Consequently, a more complete analysis of Brexit or of trading relationships more generally needs to take account of the possible distributional effects.

What particular sectors might a distributional analysis of the impact of trade consider?

Section summary

1. Following a referendum in June 2016 the UK voted to leave the European Union. The longer-term economic effects for the UK were expected to depend crucially on the nature of its future trading relationship with the EU.
2. Much of the economic analysis of Brexit has focused on the long-term implications for growth and living standards. Economic theory gives us a framework through which we can analyse the possible supply-side effects of Brexit.
3. Economists have largely argued that the decision to leave would result in negative supply-side effects. Brexit, they argue, would impede cross-border trade with its EU's partners and so reduce the UK's openness to trade and investment. This then adversely affects productivity growth and so living standards.
4. Some economists, however, have argued that outside of the EU the UK would be free of EU rules and regulations and would be able to create trade. The supply-side benefits would help to raise long-term growth and living standards.
5. Trade and the openness of economies has distributional effects. A more complete economic assessment of Brexit therefore requires that we take into account such effects.

END OF CHAPTER QUESTIONS

1. Imagine that two countries, Richland and Poorland, can produce just two goods, computers and coal. Assume that for a given amount of land and capital, the output of these two products requires the following constant amounts of labour:

	Richland	Poorland
1 computer	2	4
100 tonnes of coal	4	5

Assume that each country has 20 million workers.

- Draw the production possibility curves for the two countries (on two separate diagrams).
 - If there is no trade, and in each country 12 million workers produce computers and 8 million workers produce coal, how many computers and tonnes of coal will each country produce? What will be the total production of each product?
 - What is the opportunity cost of a computer in (i) Richland; (ii) Poorland?
 - What is the opportunity cost of 100 tonnes of coal in (i) Richland; (ii) Poorland?
 - Which country has a comparative advantage in which product?
 - Assuming that price equals marginal cost, which of the following would represent possible exchange ratios?
 - 1 computer for 40 tonnes of coal;
 - 2 computers for 140 tonnes of coal;
 - 1 computer for 100 tonnes of coal;
 - 1 computer for 60 tonnes of coal;
 - 4 computers for 360 tonnes of coal.
 - Assume that trade now takes place and that a computer exchanges for 65 tonnes of coal. Both countries specialise completely in the product in which they have a comparative advantage. How much does each country produce of its respective product?
 - The country producing computers sells 6 million domestically. How many does it export to the other country?
 - How much coal does the other country consume?
 - Construct a table like Table 24.4 to show the no-trade and with-trade positions of each country.
- If capital moves from developed to less developed countries, and labour moves from less developed to developed countries, what effects will these factor movements have on wage rates and the return on capital in the two types of country?
 - What factors determine a country's terms of trade?
 - Go through each of the arguments for restricting trade (both those of general validity and those having some validity for specific countries) and provide a counter-argument for not restricting trade.
 - If countries are so keen to reduce the barriers to trade, why do many countries frequently attempt to erect barriers?
 - What factors will determine whether a country's joining a customs union will lead to trade creation or trade diversion?
 - Why is it difficult to estimate the magnitude of the benefits of completing the internal market of the EU?
 - Look through the costs and benefits that we identified from the completion of the internal market. Do the same costs and benefits arise from the enlarged EU of 27 members?
 - Consider the process of Brexit negotiations since the triggering of Article 50 (to leave the EU) at the end of March 2017. What model of trade relations with the EU27 is likely to be the end result of the negotiations?
 - Is a 'hard Brexit' (reverting to WTO rules and negotiating bilateral trade deals) necessarily an inferior alternative for the UK to remaining in the European single market or, at least, in the customs union?

We live in a world in which events in one country or group of countries can have profound effects on other countries. Look at what happened in 2007/8. Excessive sub-prime mortgage lending in the USA led to huge losses for many financial institutions. With such debt securitised into bonds held by financial institutions across the world, the credit crunch rapidly became global.

As globalisation has increased, with trade and international financial movements having grown much more rapidly than countries' GDP, and, in general, having become much freer, so countries' vulnerability to balance of payments problems and exchange rate fluctuations has increased.

This chapter explores the relationships between a country's balance of payments and its exchange rate. In particular, we ask whether a country should allow its exchange rate to be determined entirely by market forces, with the possible instability that this brings, or whether it should attempt to fix its exchange rate to another currency (such as the US dollar), or at the very least attempt to reduce exchange rate fluctuations through central bank intervention in the foreign exchange market. We also look at the experience of countries in operating different types of exchange rate system.

25.1 ALTERNATIVE EXCHANGE RATE REGIMES

Policy objectives: internal and external

A country is likely to have various *internal* and *external policy objectives*. *Internal* objectives include such things as economic growth, low unemployment and low inflation. *External* objectives include such things as avoiding current account balance of payments deficits, encouraging international trade and preventing excessive exchange rate fluctuations. Internal and external objectives may come into conflict, however.

A simple illustration of potential conflict is with the objectives of *internal balance* and *external balance*.

Internal balance. This is where the economy is at the potential level of national income: i.e. where the output gap is zero (see Box 15.3 on page 460). This can be expressed in various ways, depending on the model of the economy and the policy objectives being pursued.

Thus, in the simple Keynesian model, internal balance is where the economy is at the *full-employment* level of national income: i.e. where Y_e (equilibrium national income) = Y_f (full-employment national income) (see Chapter 17). In the monetarist and new classical models, it would be where the economy is on the vertical Phillips curve with stable inflation. In the context of inflation targeting, it would be where meeting the inflation target is consistent with achieving potential national income: i.e. where the *DAD* crosses the *DAS* curve at the targeted inflation rate (see Figure 20.7 on page 630).

If there is initially internal balance and then aggregate demand falls, in the short run output will fall below the potential level and disequilibrium unemployment will occur. Internal balance will be destroyed. The stickier wages and prices are, the longer it will take for internal balance to be restored.

External balance. This is the term for a *balance of payments* equilibrium. In the context of floating exchange rates, it is normally used in the narrow sense of a current account balance, and therefore also a capital plus financial account balance.

In the context of a fixed exchange rate, or an exchange rate target, it is often used more loosely to refer merely to a *total currency flow balance*. This is where the total demand and supply of the currency are equal at the targeted exchange rate with *no need for intervention from the reserves*: in other words, where any current account deficit is matched by a surplus on the other two accounts, and vice versa.

Conflicts between internal and external balance

It may, however, be difficult to achieve internal and external balance simultaneously. This is illustrated in Figure 25.1. Assume in Figure 25.1(b) that the exchange rate is e_1 . Currency demand and supply curves are given by D and S_1 and

there is no central bank intervention. Thus e_1 is the *equilibrium* exchange rate and there is external balance in the loose sense. Assume also that there is external balance in the narrow sense: i.e. a current account balance.

Let us also assume, however, that there is a recession. This is illustrated in Figure 25.1(a). Equilibrium national income is Y_e , where W_1 equals J_1 . There is a deflationary gap: Y_e is below the full-employment level, Y_f . There is no *internal* balance.

Now assume that the government expands aggregate demand through fiscal policy in order to close the deflationary gap and restore internal balance. It raises injections to J_2 and reduces withdrawals to W_2 . National income rises to Y_e . But this higher national income leads to an increased demand for imports. The supply of sterling will shift to S_2 in Figure 25.1(b). There is now a current account deficit, which destroys external balance in the narrow sense. If the government maintains the exchange rate at e_1 (by buying sterling from the reserves), external balance will be destroyed in the loose sense too.

External balance in the loose sense could be restored by allowing the exchange rate to depreciate to e_2 , so that the demand and supply of sterling are equated at the new lower exchange rate.

But will this also correct the current account deficit and restore external balance in the narrow sense? It will go *some* way to correcting the deficit, as the lower exchange rate will make imports relatively more expensive and exports relatively cheaper. The amount that imports fall and exports rise will depend on their price elasticity of demand.

But there may also be an effect on the financial account. The higher aggregate demand will lead to a higher demand for money. This will drive up interest rates unless money supply is allowed to expand to offset the higher demand for money. If interest rates rise, this will lead to an inflow of finance (a financial account surplus). In Figure 25.1(b), the supply curve of sterling would shift to the left and the demand curve to the right. The exchange rate would not

Definitions

Internal policy objectives Objectives relating solely to the domestic economy.

External policy objectives Objectives relating to the economy's international economic relationships.

Internal balance Where the equilibrium level of national income is at the desired level.

External balance Narrow definition: where the current account of the balance of payments is in balance (and thus also the capital plus financial accounts). Loose definition: where there is a total currency flow balance at a given exchange rate.

Figure 25.1 Internal and external balance

therefore fall as far as er_2 . If the positive effect of higher interest rates on the financial account was bigger than the negative effect of higher imports on the current account, the exchange rate would actually *appreciate*.

Either way, there will be a current account deficit and an equal and opposite financial plus capital account surplus. Narrow external balance has not been restored in the short term. (We explore the long-term current account balance under floating exchange rates in section 25.3.)

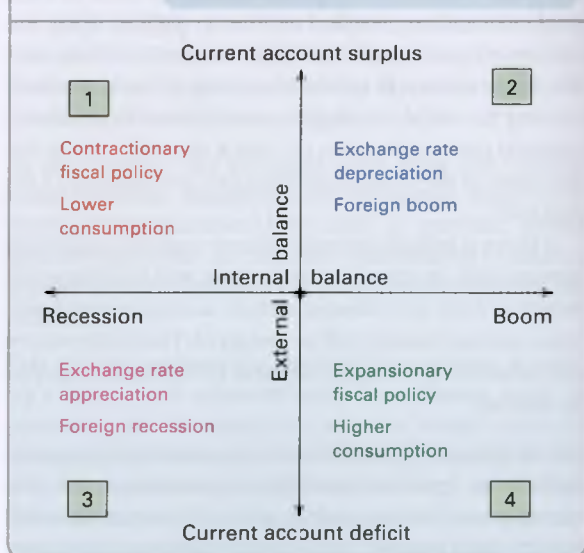

Figure 25.2 shows the effect of various 'shocks' that can affect both internal and narrow external balance.

- ?**
1. Assume that there is both internal and narrow external balance. Now assume that as a result of inflation being below target, the central bank cuts interest rates. Into which of the four quadrants in Figure 25.2 will the economy move?
 2. Imagine that there is an inflationary gap, but a current account equilibrium. Describe what will happen if the government raises interest rates in order to close the inflationary gap. Assume first that there is a fixed exchange rate; then assume that there is a floating exchange rate.

The ability of the economy to correct these imbalances depends on the *exchange rate regime*. We examine alternative exchange rate regimes in the final part of this section, but first we must distinguish between nominal and real exchange rates.

Nominal and real exchange rates

A nominal exchange rate is simply the rate at which one currency exchanges for another. All exchange rates that you see quoted in the newspapers, on television or the

Figure 25.2 Effects on internal and (narrow) external balance

Internet, or at travel agents, banks or airports, are nominal rates. Up to this point we have solely considered nominal rates.

The *real exchange rate* is the exchange rate index adjusted for changes in the prices of imports (measured in foreign currencies) and exports (measured in domestic prices): in other words, adjusted for the terms of trade. Thus if a country has a higher rate of inflation for its exports than the weighted average inflation of the imports it buys from other countries, its real exchange rate index (RERI) will rise relative to its nominal exchange rate index (NERI).

BOX 25.1

THE BALANCE OF TRADE AND THE PUBLIC-SECTOR BUDGET BALANCE

EXPLORING
ECONOMICS

A case of twin deficits?

We have seen that the external situation can affect the ability of an economy to achieve internal balance (where actual income is at the potential level). But it also impacts on the *composition* of aggregate demand. This is most readily demonstrated by observing the relationship between the *public sector's budget balance* and the *balance of trade*.

Consider the circular flow of income model that we introduced in Chapter 15. There we saw that actual (as opposed to planned) withdrawals from the circular flow (net saving (S) plus net taxes (T) plus imports (M)) must equal injections (investment (I) plus government expenditure (G) plus exports (X)):

$$S + T + M = I + G + X \quad (1)$$

The public sector's budget balance is simply the difference between its receipts (taxation and operating receipts, net of transfer expenditures) and its spending on goods and services, or $T - G$. The balance of trade is the difference between expenditure on exports and imports, or $X - M$. If we rearrange equation (1) slightly we find:

$$(T - G) = (X - M) + (I - S) \quad (2)$$

This tells us that if the public sector runs a budget surplus ($T - G$ is positive), there is a likelihood that the trade balance will be in surplus too. We can see from equation (2) that this will depend on the extent to which investment (I) and saving (S) differ from each other. In the case where

investment and saving are equal, then a budget surplus would be exactly matched by a trade surplus, or a budget deficit by an identical trade deficit. The latter gives rise to the term 'the *twin deficits*'.

The chart plots the UK's public-sector budget balance as measured by public-sector net borrowing (see section 22.1) and its balance of trade. Each is presented as a percentage of GDP.

First, we see that from 1955 to 2016 the public sector typically ran a deficit with public-sector net borrowing averaging 2.8 per cent of GDP. Consequently, the public sector has been acting as a net injector of income. Second, we see that the balance of trade has more often than not been negative, with an average deficit of 0.9 per cent of GDP.

The size of the net withdrawal from the trade deficit does not quite match the net injection from the public sector. This means that private-sector investment expenditure has been *less* than private saving ($I < S$). It also reinforces the arguments that we examined in Chapters 16 and 22 that public-sector deficits can reduce private investment. This is known as *crowding out*. In the UK, public-sector borrowing has been financed partly through foreign borrowing from running a trade deficit and partly from the private saving that is not used for private investment.

If the exchange rate depreciated, how would this affect the trade and budget balances?

Source: Based on data from ONS, series J5II, KTM and YBHA.

Definitions

Exchange rate regime The system under which the government allows the exchange rate to be determined.

Real exchange rate A country's exchange rate adjusted for changes in the domestic currency prices of its exports

relative to the foreign currency prices of its imports. If a country's prices rise (fall) relative to those of its trading partners, its real exchange rate will rise (fall) relative to the nominal exchange rate.

The real exchange rate index can be defined as:

$$\text{RERI} = \text{NERI} \times P_X/P_M$$

where P_X is the domestic currency price index of exports and P_M is the foreign currencies weighted price index of imports. Thus if (a) a country's inflation is 5 per cent higher than the trade-weighted average of its trading partners (P_X/P_M rises by 5 per cent per year) and (b) its nominal exchange rate depreciates by 5 per cent per year (NERI falls by 5 per cent per year), its real exchange rate index will stay the same.

Take another example: if a country's export prices rise faster than the foreign currency prices of its imports (P_X/P_M rises), its real exchange rate will appreciate relative to its nominal exchange rate.

The real exchange rate thus gives us a better idea of the *quantity* of imports a country can obtain from selling a given quantity of exports. If the real exchange rate rises, the country can get more imports for a given volume of exports.

Figure 25.3 shows the nominal and real exchange rate indices of sterling. As you can see, the real exchange rate has tended to rise over time *relative* to the nominal exchange

rate. This is because the UK has often experienced higher rates of inflation than the weighted average of its trading partners.

Table 25.1 shows that the size of the UK's *inflation rate differential* with the eurozone since the 1970s. During this period the UK rate of inflation has typically been 1 percentage point higher than the weighted average of the eurozone economies.

Table 25.1 also shows the average percentage change in the nominal and real sterling exchange rate indices since the 1970s. Over this period the nominal sterling exchange rate index has on average fallen by 1.3 per cent per year. However, after adjusting for the domestic price of exports and the foreign currency price of imports, the real sterling exchange rate index has fallen by 0.4 per cent per year. Hence, since 1970 the UK has experienced a small *real* depreciation of sterling.

By looking at the nominal and real exchange rate changes in Table 25.1 can we identify periods during which the UK's terms of trade rose?

BOX 25.2 THE UK'S BALANCE OF PAYMENTS DEFICIT

A cyclical problem or a long-term trend?

In the late 1980s, the UK current account balance of payments moved sharply into deficit, as the chart shows. In 1989, the current account deficit was 4.1 per cent of GDP – then a historic high. Opinions differed dramatically, however, as to how seriously we should have taken these figures. Not surprisingly, the government claimed that the problem was merely temporary and was not something to cause serious concern. The opposition parties (also not surprisingly) saw the figures as disastrous and a sign that the economy was badly off-course.

So who was correct? In fact there was an element of truth in both these claims.

The government was correct to the extent that the severity of the deficit partly reflected the unprecedented boom of the late 1980s. An average growth rate of real GDP of 4.2 per cent between 1984 and 1988 had led to a huge increase in imports. Since the boom could not be sustained, the growth in imports was bound to slow down. Another factor contributing to the deficit was the fall in oil revenues caused by a fall in oil prices. Oil exports fell from £16.1 billion in 1985 to £5.9 billion in 1989. Again, this fall in oil revenues was unlikely to continue once oil prices began to rise again.

The current account deficit was also a mirror image of the financial account surplus. This had been caused by a rise in interest rates, used to slow the economy down. As short-term finance flowed into the country to take advantage of the higher interest rate, so this drove the exchange rate up: the real exchange rate index rose by 4.25 per cent in 1988 (see Figure 25.3). The higher exchange rate contributed to the fall in exports and the rise in imports.

But the opposition parties were also correct. The severity of the deficit reflected an underlying weakness of the UK's trading position. If the deficit had been merely a cyclical

problem associated with the boom phase of the business cycle, the current account should have gone into *surplus* in the early 1990s as the economy moved into recession. But even in the depths of the recession in 1991 (the economy shrank by 1.1 per cent), the current account deficit was still 1.3 per cent of GDP.

The government, however, sought to place a large portion of the blame on a falling demand for exports as the rest of the world began to move into recession.

Subsequent events appeared to support the Conservative government's interpretation. The world economy was recovering in 1994 and the current account deficit virtually disappeared. But then, with a large appreciation of sterling from 1996, and an even larger appreciation of the real exchange rate (see Figure 25.3), the current account started to deteriorate again, as the diagram shows. Optimists claimed that this was, once more, simply a temporary situation, caused by a high exchange rate and low growth in demand in the eurozone.

By 2007, the current account deficit had reached 3.5 per cent of GDP. Optimists claimed that this was, once more, simply a temporary situation, caused by a high exchange rate and a relatively slower rate of growth in demand in the eurozone. Pessimists once more pointed to underlying supply-side weaknesses, with a deterioration in exports of goods not being matched by a rise in services exports.

With the financial crisis of 2007/8 and the subsequent recession hitting the UK economy particularly badly, the fall in confidence led to a depreciation in the exchange rate. Between October 2007 and October 2013 the sterling effective exchange rate fell in nominal terms by 20 per cent and in real terms by 13.5 per cent.

Table 25.1 Inflation rate differential and annual rate of change in sterling exchange rate indices

	Inflation rate differential	Nominal exchange rate index	Real exchange rate index
1970–74	0.8	-3.2	-1.6
1975–79	5.8	-4.0	0.3
1980–84	0.1	-0.8	-0.8
1985–89	1.8	-1.3	-0.8
1990–94	0.8	-2.5	-1.5
1995–99	0.5	3.2	3.5
2000–04	-1.1	0.1	-0.6
2005–09	0.2	-4.5	-4.0
2010–14	0.4	1.5	2.7
2015–16	0.3	-2.3	-2.2
1970–2016	1.0	-1.3	-0.4

Note: Inflation rate differential is the difference between the annual % change in GDP deflator in the UK and the weighted average across the Eurozone.

The real exchange rate also gives a better idea than the nominal exchange rate of how competitive a country is. The lower the real exchange rate, the more competitive will the country's exports be. For example, Figure 25.3 shows that the UK became less competitive between 1996 and 2001, and remained at similarly uncompetitive levels until 2008, thanks not only to a rise in the nominal exchange rate index, but also to higher inflation than its trading partners.

Alternative exchange rate regimes

There are a number of possible exchange rate regimes. They all lie somewhere between two extremes. These two extreme regimes are a *totally fixed rate* and a *freely floating rate*.

In the case of a *fixed rate*, the government or central bank will almost certainly have to intervene in the foreign exchange market in order to maintain that rate, and will probably have to take internal policy measures too.

In the case of a *freely floating rate*, there is no government intervention in the foreign exchange market. Exchange rates fluctuate according to market forces – according to changes

CASE STUDIES AND APPLICATIONS

UK balance of payments as a % of GDP, 1960–2016

Source: Based on data from ONS series D28J, D28K, D28M, D28N and AA6H.

But this was not enough to prevent a further deterioration in the current account from 2011. By 2014, the current account deficit had risen to a new historic high: 4.7 per cent of GDP in 2014. By this point the deficit on the balance of trade in *goods* had risen to close to 7 per cent of GDP.

Pessimists again pointed to a much deeper malaise in the UK exporting sector and claimed that successive supply-side reforms had made too little difference. Indeed, recent governments have stressed the need for a 'rebalancing' of the economy towards greater exports and investment.

With the Brexit vote of 2016, the issue gained greater urgency as the government sought to secure trade deals to compensate for a lack of automatic access to the EU single market. With the fall in sterling since the vote, it was hoped that this would, at least, give exporters a price advantage.

So should we worry about balance of payments deficits? What effect do they have on exchange rates, inflation, growth, unemployment, etc.? What should the government do? These are questions we shall look at in this chapter.

Figure 25.3 Sterling nominal and real exchange rate indices (Jan 1970 = 100)

Note: Exchange rate indices are BIS narrow indices comprising 27 countries, re-based by the authors, Jan 1970 = 100.

in the demand for and supply of currencies on the foreign exchange market. Changes in the exchange rate may well affect internal policy objectives, however, and thus cause the government to take various internal policy measures.

? What adverse internal effects may follow from (a) a depreciation of the exchange rate; (b) an appreciation of the exchange rate?

Between these extremes there are a number of *intermediate regimes*, where exchange rates are partly left to the market, but where the government intervenes to influence the rate. These intermediate regimes differ according to how much the government intervenes, and thus according to how much flexibility of the exchange rate it is prepared to allow.

Correction under fixed exchange rates

Foreign exchange intervention

Unless the demand for and supply of the domestic currency on the foreign exchange markets are equal at the fixed rate – unless, in other words, there is a total currency flow balance

– the central bank will have to intervene in the market and buy or sell the domestic currency to make up the difference. This is illustrated in Figure 25.4, which looks at the case of the UK.

Figure 25.4(a) shows the case of a currency flow deficit (an excess of pounds) of an amount $a - b$. The Bank of England thus has to purchase these excess pounds by drawing on its foreign exchange reserves, or by borrowing foreign currency from foreign banks.

In Figure 25.4(b), there is a currency flow surplus of $c - d$. In this case, the Bank of England has to supply $c - d$ additional pounds to the market, and will acquire foreign currencies in exchange. It can use these to build up reserves or to pay back foreign loans.

Foreign exchange market intervention and the money supply. Maintaining a fixed exchange rate causes changes in the money supply. If the rate is maintained above the equilibrium (Figure 25.4(a)), there is a total currency flow deficit. The Bank of England buys pounds. It thereby withdraws them from circulation and reduces the money supply.

The effect of this reduction in money supply is to raise the equilibrium rate of interest. This attracts financial inflows and improves the financial account. It also dampens aggregate demand, and thus reduces imports and improves the current account. The net effect is to reduce the overall currency flow deficit and thus reduce the gap $a - b$ in Figure 25.4(a). The problem here, of course, is that the lower aggregate demand may well result in a recession.

If the rate is maintained *below* equilibrium (Figure 25.4(b)), there is a total currency flow surplus. The Bank of England supplies additional pounds (which are spent by people abroad on UK exports, etc., and are thus injected into the UK economy). It thereby increases the money supply.

The effect of the increased money supply is to reduce interest rates. This worsens the financial account and, by

Definitions

Totally fixed exchange rate Where the government takes whatever measures are necessary to maintain the exchange rate at some stated level.

Freely floating exchange rate Where the exchange rate is determined entirely by the forces of demand and supply in the foreign exchange market with no government intervention whatsoever.

Intermediate exchange rate regimes Where the government intervenes to influence movements in the exchange rate.

Figure 25.4 Central bank intervention to maintain a fixed exchange rate

boosting aggregate demand, increases imports. The currency flow surplus is reduced. The gap $d - c$ narrows.

Sterilisation. If the Bank of England did not want the money supply to alter, it would have to counter these effects with other monetary measures: e.g. open-market operations. Thus when there is a deficit and money supply falls, the Bank of England could buy back government bonds from the general public, thereby restoring the money supply to its previous level. This will prevent the economy moving into recession.

This process of countering the effects on money supply of a balance of payments deficit or surplus is known as **sterilisation**.

? Describe the open-market operations necessary to sterilise the monetary effects of a balance of payments surplus. Would this in turn have any effect on the current or financial accounts of the balance of payments?

There is a problem with sterilisation, however. If the money supply is not allowed to change, the currency flow deficit or surplus will persist. In the case of a deficit, a recession may be avoided, but the central bank will have to continue using reserves to support the exchange rate. But reserves are not infinite. Sooner or later they will run out! A recession may be inevitable.

Correcting the disequilibrium

If a balance of payments deficit persists, and reserves continue to dwindle or foreign debts mount, the government will have to tackle the underlying disequilibrium. If the exchange rate is to remain fixed, it must shift the demand and supply curves so that they intersect at the fixed exchange rate.

It can use contractionary fiscal and monetary policies for this purpose. Such policies have two main effects on the current account: an income effect (*expenditure reducing*) and a substitution effect between home and foreign goods (*expenditure switching*).

Expenditure reducing. Contractionary policy reduces national income. This in turn reduces expenditure, including expenditure on imports, shifting the supply of sterling

curve to the left in Figure 25.4(a). The bigger the marginal propensity to import, the larger the shift.

There is a possible conflict here, however, between external and internal objectives. The balance of payments may improve, but unemployment is likely to rise and the rate of growth to fall.

? Under what circumstances would (a) contractionary and (b) expansionary policies cause no conflict between internal and external objectives?

Expenditure switching. If contractionary policies reduce the rate of inflation below that of foreign competitors, exports will become relatively cheaper compared with foreign competing goods and imports will become relatively more expensive compared with home-produced alternatives. Some foreign consumers will switch to UK exports. The more elastic the demand, the bigger the switch. Some UK consumers will switch from imports to home-produced goods. Again, the more elastic the demand, the bigger the switch. Demand in both cases will be more elastic the closer UK goods are as substitutes for foreign goods.

To the extent that contractionary policies result in expenditure switching rather than expenditure reducing, so this reduces the conflict between balance of payments and employment objectives.

Definitions

Sterilisation Where the government uses open-market operations or other monetary measures to neutralise the effects of balance of payments deficits or surpluses on the money supply.

Expenditure changing (reducing) from a contraction: the income effect Where contractionary policies lead to a reduction in national income and hence a reduction in the demand for imports.

Expenditure switching from a contraction: the substitution effect Where contractionary policies lead to a reduction in inflation and thus cause a switch in expenditure away from imports and towards exports.

Expenditure switching can also be achieved by placing restrictions on imports (tariffs and/or quotas) or the subsidising of exports. But this would conflict with the objective of free trade.

To the extent that fiscal and monetary policies affect interest rates, so this will affect the financial account of the balance of payments. Higher interest rates will increase the demand for sterling and will thus lead to an improvement on the financial account. (The implications of this are explored in section 25.2.)

Correction under free-floating exchange rates

Freely floating exchange rates should automatically and immediately correct any balance of payments deficit or surplus: by depreciation and appreciation respectively. Foreign exchange dealers simply adjust the exchange rate so as to balance their books – in line with demand and supply.

As with fixed rates, an income effect and a substitution effect of the correction process can be distinguished. But the nature of the income and substitution effects of depreciation/appreciation is quite different from that of deflation. It is only the substitution effect that corrects the disequilibrium. The income effect makes the problem *worse*! First the substitution effect: *expenditure switching*.

Expenditure switching (the substitution effect)

The process of adjustment. Assume a higher rate of inflation in the UK than abroad. As domestic prices rise relative to the price of imports, more imports will be purchased. The supply of pounds curve will shift to the right (to S_2 in Figure 25.5). UK exports will now be relatively more expensive for foreigners. Less will be sold. The demand for pounds curve will shift to the left (to D_2).

Foreign exchange dealers will now find themselves with a glut of unsold pounds. They will therefore lower the

exchange rate (to er_2 in Figure 25.5). The amount that the exchange rate has to change depends on:

- The amount that the curves shift. Thus large differences in international inflation rates or large differences in international interest rates will cause large shifts in the demand for and supply of currencies, and hence large movements in exchange rates.
- The elasticity of the curves. The less elastic the demand and supply curves of sterling, the greater the change in the exchange rate for any given shift in demand and supply.

But what determines the elasticity of the demand and supply curves? This is examined in Case Study 25.1 on the student website.

Expenditure changing (the income effect)

Depreciation, as well as affecting relative prices, will affect national income. This will cause *expenditure changing*.

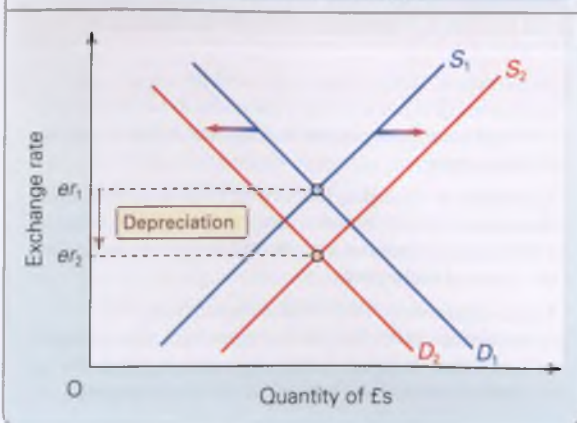

We have already established that, as the exchange rate falls, so more exports will be sold and less imports purchased: this was the substitution effect. But this is only an initial effect.

Exports are an injection into, and imports a withdrawal from, the circular flow of income. There will thus be a multiplied rise in national income. This income effect (*expenditure increasing*) reduces the effectiveness of the depreciation. Two situations can be examined.

A rise in national income and employment, but no change in prices. Assume that there are substantial unemployed resources, so that an increase in aggregate demand will raise output and employment but not prices. As national income rises, so imports rise (thereby tending to offset the initial fall), but exports are unaffected.

This is illustrated by the line $(X - M)_1$ in Figure 25.6. At low levels of national income, spending on imports is low; thus exports (X) exceed imports (M). $X - M$ is positive. As national income and hence imports rise, $X - M$ falls, and after a point becomes negative. Thus the $X - M$ line is downward sloping.

Figure 25.5 Adjustment of the exchange rate to a shift in demand and supply

Definitions

Expenditure switching from depreciation: the substitution effect Where a lower exchange rate reduces the price of exports and increases the price of imports. This will increase the sale of exports and reduce the sale of imports.

Expenditure changing (increasing) from depreciation: the income effect Where depreciation, via the substitution effect, will alter the demand for imports and exports, and this, via the multiplier, will affect the level of national income and hence the demand for imports.

Figure 25.6 The income effect (stable prices)

Assume an initial equilibrium national income at Y_1 , where national income (Y) equals national expenditure (E_1), but with imports exceeding exports by an amount $a - b$. The exchange rate thus depreciates.

This will cause a substitution effect: exports rise and imports fall. The $X - M$ line therefore shifts upwards. But this in turn causes an income effect. Aggregate demand rises, and the E line shifts upwards.

An eventual internal and external equilibrium is reached at Y_2 , where $Y = E_2$ and $(X - M)_2 = 0$.

The positive substitution effect of this depreciation is $c - b$. The negative income effect is $c - a$. The net effect is thus only $a - b$, which is the size of the initial deficit. Had it not been for this negative income effect, a smaller depreciation would have been needed.

At least in this case, the income effect is having a desirable *internal* consequence: reducing unemployment.

A rise in prices. If the economy is near full employment, the rise in aggregate demand from depreciation will make that depreciation even less effective. Not only will the higher demand lead directly to more imports, it will also lead to higher inflation. There will thus be an adverse substitution effect too. This will partially offset the beneficial substitution effect of the depreciation. The higher inflation will have the effect of shifting the $X - M$ line back down again somewhat.

In the extreme case, where money supply expands to accommodate the rise in aggregate demand, $X - M$ may simply return to its original position. The depreciation will fail to correct the balance of payments disequilibrium. In Figure 25.5, the fall in the exchange rate to er_2 will simply lead to a further rightward shift in supply and a leftward shift in demand, until the gap between them is the same as it was at er_1 .

To offset the income effect, a government may feel it necessary to back up a currency depreciation with deflationary demand management policies.

Intermediate exchange rate regimes

There are a number of possible intermediate systems between the two extremes of totally fixed and completely free-floating exchange rates.

Adjustable peg. The *adjustable peg* system is towards the fixed end of the spectrum. Exchange rates are fixed (or 'pegged') for a period of time – perhaps several years.

In the short and medium term, therefore, correction is the same as with a totally fixed system. Central banks have to intervene in the foreign exchange market to maintain the rate. If a deficit persists, then deflationary or other policies must be adopted to *shift* the currency demand and supply curves. This will be a problem, however, if there already exist substantial unemployed resources.

In the long term, if a fundamental disequilibrium occurs, the currency can be repegged at a lower or higher rate. Adjusting the peg downwards is known as *devaluation*. Adjusting it upwards is known as *revaluation*.

Alternatively, more frequent smaller adjustments could be made, thus moving the system away from the fixed end of the spectrum.

Managed floating. The *managed floating* system is towards the free-floating end of the spectrum. Exchange rates are not pegged: they are allowed to float. But the central bank intervenes from time to time to prevent excessive exchange rate fluctuations. It is thus a form of 'managed flexibility'.

Under such a system, the central bank does not seek to maintain a long-term or even medium-term disequilibrium rate. Rather it tries to allow an 'orderly' exchange rate adjustment to major changes in demand and supply, while preventing the violent short-term swings that can occur with a totally free float (swings arising from currency speculation).

To back up the central bank's use of reserves, it may also alter interest rates to prevent exchange rate fluctuations. If,

Definitions

Adjustable peg A system whereby exchange rates are fixed for a period of time, but may be devalued (or revalued) if a deficit (or surplus) becomes substantial.

Devaluation Where the government repeg the exchange rate at a lower level.

Revaluation Where the government repeg the exchange rate at a higher level.

Managed floating A system of flexible exchange rates, but where the government intervenes to prevent excessive fluctuations or even to achieve an unofficial target exchange rate.

for example, there were a large-scale selling of the domestic currency, the central bank could raise interest rates to counter this effect and prevent the exchange rate from falling.

? How would raising interest rates in this way affect the balance between the current and financial accounts of the balance of payments?

The degree of currency stability sought, and hence the degree of intervention required, will vary from country to country and from government to government. At one extreme, the government may intervene only if exchange rate fluctuations become very severe; at the other extreme, the government may try to maintain the exchange rate at some unofficial target level.

Crawling peg. The *crawling peg* system is midway between managed floating and the adjustable peg system. Instead of making large and infrequent devaluations (or revaluations), the government adjusts the peg by small amounts, but frequently – say, once a month, as the equilibrium exchange rate changes.

Joint float. Under a *joint float* a group of countries have a fixed or adjustable peg system between their own currencies, but jointly float against all other currencies.

Exchange rate band. With an *exchange rate band* the government sets a lower and an upper limit to the exchange rate: say, £ = \$1.60 and £1 = \$1.80. It then allows the exchange rate to fluctuate freely within these limits. It will intervene, however, if the rate hits the floor or the ceiling.

Exchange rate bands could be narrow (say ± 1 per cent) or wide (say ± 15 per cent).

Exchange rate bands can be incorporated in other systems – the band could be adjustable, crawling or fixed. For example, Figure 25.7 illustrates a crawling peg system with an exchange rate band.

The exchange rate mechanism (ERM) of the European Monetary System (EMS), which pre-dated the euro, was an example of a joint float against non-member currencies and an adjustably pegged exchange rate band with member currencies (see section 26.2). The ERM2 system for Denmark (and potentially for other members of the EU in preparation to join the euro) is similar.

All these intermediate systems are attempts to achieve as many as possible of the advantages of both fixed and flexible exchange rates, with as few as possible of the attendant disadvantages. To assess any of these compromise systems, therefore, we must examine the advantages and disadvantages of fixed and flexible exchange rates. We do this in the next two sections.

Definitions

Crawling peg A system whereby the government allows a gradual adjustment of the exchange rate.

Joint float Where a group of currencies pegged to each other jointly float against other currencies.

Exchange rate band Where a currency is allowed to float between an upper and lower exchange rate, but is not allowed to move outside this band.

Figure 25.7 The crawling peg within exchange rate bands

Section summary

1. There may be a conflict in achieving both internal and external balance simultaneously. The nature of the conflict depends on the exchange rate regime that the country adopts.
2. Nominal exchange rates are simply the rates at which one currency exchanges for another. Real exchange rates take account of differences in inflation rates between import and export prices and are a measure of the competitiveness of a country's exports.
3. Under a fixed exchange rate system, the government will have to intervene whenever the equilibrium exchange rate ceases to coincide with the fixed rate. If the equilibrium rate falls below the fixed rate, the government will have to buy in the domestic currency on the foreign exchange market. This will have the effect of reducing the money supply. Likewise, selling the domestic currency in order to prevent an appreciation will increase money supply. The government can prevent these changes in money supply by the use of appropriate open-market operations or other monetary measures. This is known as 'sterilisation'. Sterilisation, however, means that the disequilibrium is likely to go uncorrected.
4. If a deficit (or surplus) persists under a fixed rate, the government can attempt to shift the currency demand and supply curves. To cure a deficit, it can use contractionary fiscal or monetary policies. These have two effects. Deflation leads to a fall in national income (the income effect) and hence a fall in the demand for imports. It also leads to a fall in inflation and hence a switch in demand from foreign goods to home-produced goods (the substitution effect).
5. Correction under free-floating exchange rates also involves an income and a substitution effect. If there is a deficit, the exchange rate will depreciate. This will make imports more expensive and exports cheaper, and hence there will be a substitution effect as imports fall and exports rise.
6. The income effect of a depreciation, however, reduces its effectiveness. The rise in exports and fall in imports (i.e. the substitution effect of a depreciation) will lead to a multiplied rise in national income, which will cause imports to rise back again somewhat. The bigger this income effect, the bigger will be the depreciation necessary to achieve equilibrium in the foreign exchange market. Correction is made more difficult if any depreciation leads to increases in domestic prices and hence to a second substitution effect – only this time an adverse one.
7. There are intermediate exchange rate regimes between the extremes of fixed rates and free-floating rates. The exchange rate may be fixed for a period of time (the adjustable peg); or it may be allowed to change gradually (the crawling peg); or the government may merely intervene to dampen exchange rate fluctuations (managed floating); or the exchange rate may be allowed to fluctuate within a band, where the band in turn may be fixed, adjustable or crawling.

25.2 FIXED EXCHANGE RATES

In this section we examine the causes of balance of payments problems under fixed nominal exchange rates, in both the short run and the long run. First, in an optional section, we look at short-run causes and whether balance will be restored. We then look at longer-run, more fundamental causes of balance of payments problems. Finally, we assess the desirability of fixed exchange rates.

*Effects of shocks under fixed exchange rates

Under fixed exchange rates, it is unlikely that internal and external balance can persist for long without government intervention. Various macroeconomic 'shocks', such as changes in injections or withdrawals, or changes in international interest rates, are constantly occurring. These are likely to destroy either internal or external balance or both. Even with government intervention, it may still be very difficult, if not impossible, to restore both balances. Correction of balance of payments disequilibria will come into conflict with the other macroeconomic goals of growth, full employment and stable prices.

How the economy responds to shocks under fixed exchange rates, and which policy measures are most effective in dealing with the resultant disequilibria, depend on two things: (a) whether the shocks are internal or external; (b) the flexibility of wages and prices, which, in turn, depends on the time period under consideration.

Response to an internal shock

Let us assume that there is a fall in aggregate demand, caused by a fall in consumer demand or investment, or by a rise in saving.

Short-run effect. In the short run, prices and especially wages tend to be relatively inflexible (this is a central assumption of Keynesian analysis). The fall in aggregate demand will lead to a recession. Internal balance will be destroyed. In a closed economy, the central bank would probably reduce interest rates to boost the economy, either to tackle the recession directly or because forecast inflation had fallen below its target level.

In an open economy under fixed exchange rates, however, this is not possible. But why?

The lower aggregate demand will lead to a fall in imports, resulting in a *current account* surplus. There is an opposite effect on the *financial account*, however. The reduced aggregate demand will lead to a fall in the demand for money and hence downward pressure on interest rates. If interest rates were allowed to fall, there would be a resulting financial outflow and hence a financial account deficit.

But which would be the larger effect: the current account surplus or the financial account deficit? This depends on the marginal propensity to import (*mpm*) and the mobility of international finance. The higher the *mpm*, the bigger the current account surplus. The higher the international mobility of finance, the bigger the financial outflow and hence the bigger the financial account deficit. In today's world of massive financial flows across the foreign exchanges, international finance is highly, if not perfectly, mobile. If the central bank allows interest rates to fall, the financial account deficit will therefore exceed the current account surplus.

To prevent this happening, interest rates must not be allowed to fall or, at least, must fall only very slightly – just enough for the resulting financial account deficit to match the current account surplus. With hardly any fall in interest rates, money supply must thus be allowed to contract to match the fall in the demand for money.

Thus to maintain the fixed exchange rate (without massively draining reserves) interest rates will be determined by the balance of payments. They cannot be used for domestic purposes, such as targeting inflation, targeting real national income or some combination (e.g. a Taylor rule: see pages 705–6). Internal imbalance will persist in the short run.

Long-run effect. In the long run, there will be much greater, if not perfect, price and wage flexibility. Under new classical assumptions, such flexibility will exist in the short run too. This flexibility will ensure that internal balance is restored. The Phillips curve is vertical at the natural rate of unemployment.

But, with a fixed exchange rate, will it also ensure external balance? Again, let us assume that people decide to spend less and save more. As in the short run, this will lead to a *current account* surplus. This time, however, the effect is much bigger. In the short run, there was little or no price effect (i.e. no substitution effect) since there was little change in inflation. There was only an income effect from reduced imports caused by the recession. In the long run, however, the lower real aggregate demand reduces inflation. Assuming that inflation falls below that of trading partners, the *real* exchange rate falls. This makes exports relatively cheaper and imports relatively more expensive. This causes exports to rise and imports to fall.

The resulting rise in aggregate demand not only helps to eliminate the recession, but also helps to reduce the current account surplus.

Thus, despite a fixed *nominal* exchange rate, wage and price flexibility cause the *real* exchange rate to be flexible. This helps restore overall external balance. Nevertheless, a

current account surplus may persist. Indeed, as the surplus is used to buy foreign assets, so, over time, these will yield an income, further crediting the current account.

But what is clear is that, although interest rates are determined by the need to maintain a fixed nominal exchange rate, wage and price flexibility in the long run will eventually restore internal balance. The question is, how long will the long run be? How long will the recession persist? If it is too long, and if interest rates cannot be cut, then can expansionary fiscal policy be used? We examine this in Box 25.3.

Response to an external shock

Assume now that there is a fall in demand for exports.

Short-run effect. The fall in exports causes the current account to go into deficit. It also reduces aggregate demand, causing a multiplied fall in national income. This reduces the demand for imports: the larger the *mpm*, the bigger the reduction in imports. Aggregate demand will go on falling until the lower injections are matched by lower withdrawals. But the current account deficit will not be eliminated, since the fall in withdrawals to match the fall in exports consists only partly of lower imports; part will consist of lower saving and lower tax receipts.

The reduction in aggregate demand reduces the transactions demand for money, putting downward pressure on interest rates. This would result in a financial outflow and hence a *financial account* deficit, making the overall currency flow deficit worse. To prevent this happening, the central bank must prevent interest rates from falling by reducing the money supply (through open-market operations). Indeed, given the current account deficit, interest rates may have to be slightly higher than they were originally in order to create a financial account surplus sufficient to offset the current account deficit. This will make the recession worse.

Long-run effect. The reduction in aggregate demand will put downward pressure on domestic inflation. This will help to reduce the real exchange rate and hence correct the current account deficit. It will also restore internal balance. Again, however, without fiscal policy, the long run may be some time in coming. The recession may persist.

 Trace through the short-run and long-run internal and external effects (under a fixed exchange rate) of (a) a fall in domestic saving; (b) a rise in the demand for exports.

Causes of longer-term balance of payments problems under fixed exchange rates

With moderately flexible prices, current account balance may eventually be restored after 'one-off' shocks. However, long-term continuing shifts in the demand and supply of imports and exports can make balance of payments problems persist. We will examine four causes of these long-term shifts.

BOX 25.3

THE EFFECTIVENESS OF FISCAL AND MONETARY POLICIES UNDER FIXED EXCHANGE RATES

EXPLORING
ECONOMICS**Monetary policy**

Monetary policy is not very effective under fixed exchange rates.

Assume that the central bank, worried by rising inflation, wishes to reduce the growth in nominal aggregate demand. It thus reduces the rate of growth in money supply. This drives up interest rates and causes a fall in real national income.

What effect will this have on the balance of payments? The lower national income reduces expenditure on imports and hence leads to a surplus on the current account. Also, the higher interest rates encourage an inflow of finance and hence a surplus on the financial account too. This balance of payments surplus will *increase* money supply again and reduce interest rates back towards the original level. Aggregate demand will rise back towards its original level. Monetary policy has been ineffective.

But rather than changing the *supply* of money, can the government not directly alter interest rates? The problem here is that, in order to maintain the rate of exchange at the fixed level, the government's room for manoeuvre is very limited. For example, if it raises interest rates, the resulting inflow of finance will cause a balance of payments surplus. The government could, for a period of time, simply build up reserves, but it may not want to do this indefinitely.

The problem is more serious if the economy is in recession and the central bank wants to increase aggregate demand by *reducing* interest rates. The financial outflow will force the central bank to buy in the domestic currency by using its reserves. But it can do this for only so long. Eventually, it will be forced to raise interest rates again in order to stem the drain on the reserves. In today's world, with little in the way of exchange controls and with massive amounts of short-term international liquidity, such flows can be enormous. This gives the central bank virtually no discretion over changing

interest rates. Interest rates will have to be kept at a level so as to maintain the exchange rate. In the case of *perfect* mobility of international finance, interest rates must be kept at world rates. Monetary policy will be totally ineffective.

Fiscal policy

Fiscal policy is much more effective.

Assume that there is a recession and the government wishes to increase aggregate demand. It thus cuts taxes and/or raises government expenditure. This raises national income and increases expenditure on imports. Also, higher inflation raises the real exchange rate. This makes exports less competitive and imports relatively cheaper. The current account moves into deficit.

The increase in aggregate demand will raise the demand for money and hence put upward pressure on interest rates. This will lead to an inflow of finance and a financial account surplus. To prevent this swamping the current account deficit, the central bank must prevent interest rates from rising very much. In the case of an infinitely elastic supply of finance, interest rates must not be allowed to rise at all.

Thus money supply must be allowed to expand to keep interest rates down. This expansion of the money supply thus reinforces the expansionary fiscal policy and prevents crowding out.

Thus a high level of international financial mobility enhances the effectiveness of fiscal policy.

Suppose that under a managed floating system the central bank is worried about high inflation and wants to keep the exchange rate up in order to prevent import prices rising. To tackle the problem of inflation, it raises interest rates. What will happen to the current and financial accounts of the balance of payments?

Different rates of inflation between countries. If a country has persistently higher rates of inflation than the countries with which it trades, it will have a growing current account deficit. Exports and import substitutes will become less and less competitive as its real exchange rate appreciates.

Different rates of growth between countries. If a country grows faster than the countries with which it trades, its imports will tend to grow faster than its exports.

Income elasticity of demand for imports higher than for exports. If the income elasticity of demand for imports is relatively high, and the income elasticity of demand for exports is relatively low, then as world incomes grow, the country's imports will grow faster than its exports. This has been a particular problem for many developing countries: they import manufactured goods and capital equipment, whose

demand grows rapidly, and export primary products – food and raw materials – whose demand, until recent years, has grown relatively slowly (see section 26.4).

Long-term structural changes

- Trading blocs may emerge, putting up tariff barriers to other countries. Australian and New Zealand exports were adversely affected when the UK joined the EEC.
- Countries may exercise monopoly power to a greater extent than previously. The OPEC oil price increases of 1973/4 and 1978/9 are examples.
- Countries may develop import substitutes. Thus plastics and other synthetics have in many cases substituted for rubber and metals, worsening the balance of payments of traditional primary exporters.

- The nature and quality of a country's products may change. Thus Japan has shifted from producing low-quality simple manufactured goods in the 1950s to producing high-quality sophisticated manufactured goods today. This helped increase its exports.

To maintain a fixed exchange rate under such circumstances, governments have to take measures to correct the disequilibria. They can use demand-side policies (fiscal and monetary: see Box 25.3), supply-side policies or protectionist policies.

Advantages of fixed exchange rates

Many economists are opposed to fixed exchange rates, for reasons to be examined shortly. Nevertheless, many businesspeople are in favour of relatively rigid exchange rates. The following arguments are used.

Certainty. With fixed exchange rates, international trade and investment become much less risky, since profits are not affected by movements in the exchange rate.

Little or no speculation. Provided the rate is absolutely fixed – and people believe that it will remain so – there is no point in speculating. For example, between 1999 and 2001, when the old currencies of the eurozone countries were still used, but were totally fixed to the euro, there was no speculation that the German mark, say, would change in value against the French franc or the Dutch guilder.

? *When the UK joined the ERM in 1990, it was hoped that this would make speculation pointless. As it turned out, speculation forced the UK to leave the ERM in 1992. Can you reconcile this with the argument that fixed rates discourage speculation?*

Automatic correction of monetary errors. If the central bank allows the money supply to expand too fast, the resulting extra demand and lower interest rates will lead to a balance of payments deficit. This will force the central bank to intervene to support the exchange rate. Either it must buy the domestic currency on the foreign exchange market, thereby causing money supply to fall again (unless it sterilises the effect), or it must raise interest rates. Either way this will have the effect of correcting the error.

Preventing governments pursuing 'irresponsible' macroeconomic policies. If a government deliberately and excessively expands aggregate demand – perhaps in an attempt to gain short-term popularity with the electorate – the resulting balance of payments deficit will force it to constrain demand again (unless it resorts to import controls).

Disadvantages of fixed exchange rates

The new classical view

New classicists make two crucial criticisms of fixed rates.

Fixed exchange rates make monetary policy ineffective. Interest rates must be used to ensure that the overall balance of

payments balances. As a result, money supply must be allowed to vary with the demand for money in order to keep interest rates at the necessary level. Thus monetary policy cannot be used for domestic purposes (see Box 25.3). Inflation depends on world rates, which may be high and domestically unacceptable. If the central bank tries to reduce inflation by attempting to reduce money supply and raise interest rates, the current and financial accounts will go into surplus. Money supply will thus increase until domestic inflation rises back to world levels.

Fixed rates contradict the objective of having free markets. Why fix the exchange rate, when a simple depreciation or appreciation can correct a disequilibrium? In the new classical world where markets clear, and supply and demand are relatively elastic, why not treat the foreign exchange market like any other, and simply leave it to supply and demand?

The Keynesian view

In the Keynesian world, wages and prices are relatively 'sticky', and demand-deficient unemployment and cost-push inflation may persist. As such, there is no guarantee of achieving both internal and external balance simultaneously when exchange rates are fixed. This leads to the following problems.

Balance of payments deficits can lead to a recession. A balance of payments deficit can occur even if there is no excess demand. As we saw above, this could be caused by different rates of growth or different rates of inflation from trading partners, a higher income elasticity of demand for imports than for exports, and so on. If protectionism is to be avoided, and if supply-side policies work only over the long run, the government will be forced to reduce the rate of growth of aggregate demand. This will lead to higher unemployment and possibly a recession.

If wages and prices are sticky downwards, the contraction may have to be severe if a significant improvement in the *current* account is to be made. Here, reliance would have to be placed largely on lower *incomes* reducing the demand for imports. If the deflation is achieved through higher interest rates, however, an improvement on the *financial* account may remove the need for a severe deflation, especially given the high degree of financial mobility that exists nowadays. Nevertheless, the rate of interest may still be higher than that desired for purely internal purposes.

If a country has a *persistent* current account deficit, it may need to have persistently higher interest rates than its competitors and suffer persistently lower growth rates as a result. It will also tend to build up short-term debts, as money is put on deposit in the country to take advantage of the higher interest rates. This can make the problem of speculation much more acute if people come to believe that the fixed rate cannot be maintained (see below).

Competitive deflations leading to world depression. If deficit countries deflated, but surplus countries reflat, there would be no overall world deflation or reflation. Countries

may be quite happy, however, to run a balance of payments surplus and build up reserves. Countries may thus competitively deflate – all trying to achieve a balance of payments surplus. But this is beggar-my-neighbour policy. Not all countries can have a surplus! Overall, the world must be in balance. Such policies lead to general world deflation and a restriction in growth.

Problems of international liquidity. If trade is to expand, there must be an expansion in the supply of currencies acceptable for world trade (dollars, euros, gold, etc.): there must be adequate **international liquidity**. Countries' reserves of these currencies must grow if they are to be sufficient to maintain a fixed rate at times of balance of payments disequilibrium. Conversely, there must not be excessive international liquidity. Otherwise the extra demand that would result would lead to world inflation. It is important under fixed exchange rates, therefore, to avoid too much or too little international liquidity. The problem is how to maintain adequate control of international liquidity. The supply of dollars, for example, depends largely on US policy, which may be dominated by the US internal economic situation rather than by any concern for the well-being of the international community. Similarly, the supply of euros depends on the policy of the European Central Bank, which is governed by the internal situation in the eurozone countries.

Why will excessive international liquidity lead to international inflation?

Speculation. If speculators believe that a fixed rate simply cannot be maintained, speculation is likely to be massive.

If there is a huge deficit, there is no chance whatsoever of a revaluation. Either the rate will be devalued or it will remain the same. Speculators will thus sell the domestic currency. After all, it is a pretty good gamble: heads they win (devaluation); tails they don't lose (no devaluation). This speculative selling will worsen the deficit, and may itself force the devaluation. Speculation of this sort had disastrous effects on some South East Asian currencies in 1997 (see Case Study 25.3 on the student website) and on the Argentinean peso in 2002 (see Case Study 26.10).

To what extent do Keynesians and new classicists agree about the role of fixed exchange rates?

Postscript

An argument used in favour of fixed rates is that they prevent governments from pursuing inflationary policies. But if getting inflation down is desirable, why do governments not pursue an anti-inflationary policy directly? Today, many governments make inflation targeting the goal of monetary policy and many do so by delegating monetary policy to the central bank to enhance the credibility of inflation targeting. Most, however, have floating exchange rates.

Definition

International liquidity The supply of currencies in the world acceptable for financing international trade and investment.

Section summary

- *1. Macroeconomic shocks are constantly occurring. Whether internal and external balance will be restored under a fixed exchange rate, following a shock, depends on price and wage flexibility and on the time period.
- *2. In the short run there is a degree of wage and price inflexibility. If there is a fall in aggregate demand, the resulting fall in national income will reduce the demand for imports. This will cause a current account surplus. The fall in aggregate demand will also reduce the demand for money and put downward pressure on interest rates. This will cause a financial account deficit. This effect can be large, given the high mobility of international finance. Interest rates are thus constrained by the need for the financial account to balance the current account.
- *3. In the long run, with wage and price flexibility, the real exchange rate can change. This will help to restore both internal and external balance.
4. Over the longer term, balance of payments disequilibria under fixed exchange rates can arise from different rates of inflation and growth between countries, different income elasticities of demand for imports and exports, and long-term structural changes.
5. Under fixed exchange rates, monetary policy will not be very effective, but fiscal policy will be much more effective.
6. Fixed exchange rates bring the advantage of certainty for the business community, which encourages trade and foreign investment. They also help to prevent governments from pursuing irresponsible macroeconomic policies.
7. Both new classical and Keynesian economists, however, see important disadvantages in fixed exchange rates. New classical economists argue that they make monetary policy totally ineffective, and that they run counter to the efficiency objective of having free markets. Keynesians argue that fixed rates can lead to serious internal imbalance with perhaps a persistent recession; that with competitive deflations a recession can be worldwide; that there may be problems of excessive or insufficient international liquidity; and that speculation could be very severe if people came to believe that a fixed rate was about to break down.

25.3 FREE-FLOATING EXCHANGE RATES

Floating exchange rates and the freeing of domestic policy

With a freely floating exchange rate there can be no overall balance of payments disequilibrium. Foreign exchange dealers will constantly adjust the exchange rate to balance their books, so that the demand for and supply of any currency are equal.

This, therefore, removes the balance of payments constraint on domestic policy that exists under a fixed exchange rate. No reserves are required, since there is no central bank intervention to support the exchange rate. The government would seem free to pursue whatever domestic policy it likes. Any resulting effects on the balance of payments are simply and automatically corrected by a depreciation or appreciation of the exchange rate.

In reality, however, things are not quite so simple. Even under a totally free-floating exchange rate, some constraints on domestic policy may be imposed by the effects of these exchange rate movements. For example, a depreciation of the exchange rate increases the price of imports. If the demand for imports is relatively inelastic, this may lead to a higher rate of inflation.

Response to shocks under a floating exchange rate

Internal shocks

Let us assume that there is a rise in aggregate demand that causes inflation. For the moment, however, let us also assume that monetary policy maintains real interest rates at international levels. For simplicity, let us assume that there is no inflation abroad. How will a floating exchange rate system cope with this internal shock of a rise in aggregate demand? The exchange rate will simply depreciate to maintain the competitiveness of exports and import substitutes.

For example, assume an initial exchange rate of $\text{£}1 = \$2$. A UK product costing $\$2$ in the USA will earn $\text{£}1$ for the UK exporter. If UK inflation now causes prices to double, the exchange rate will roughly halve. If it falls to $\text{£}1 = \$1$, then the same product costing $\$2$ in the USA will now earn $\text{£}2$ for the UK exporter, which in *real* terms is the same amount as before. This is the *purchasing-power parity theory*. This states

Definition

Purchasing-power parity theory The theory that the exchange rate will adjust so as to offset differences in countries' inflation rates, with the result that the same quantity of internationally traded goods can be bought at home as abroad with a given amount of the domestic currency.

that domestic price changes will be offset by (nominal) exchange rate changes, thereby maintaining the same relative prices between countries as before.

If this is the case, need firms worry about losing competitiveness in world markets if domestic inflation is higher than world inflation?

If we now drop the assumption that real interest rates are maintained at the same level as abroad, the purchasing-power parity theory will break down. Let us assume that the rise in aggregate demand causes a rise in UK real interest rates. This could be either the effect of the higher demand for money pushing up interest rates, or a deliberate act of the central bank to bring the inflation rate back down to the target level.

There are now two effects on the exchange rate. The higher aggregate demand and higher inflation rate will cause the current account to move into deficit, thereby putting downward pressure on the exchange rate. The higher real interest rates, however, will cause the financial account to move into surplus as depositors choose to hold their money in pounds. This will put upward pressure on the exchange rate. Whether the exchange rate actually falls or rises depends on which of the two effects is the bigger. In today's world of huge international financial flows, the effect on the financial account is likely to be the larger one: the exchange rate will thus *appreciate*. The greater the interest elasticity of supply of such flows, the greater the appreciation.

But either way, because of the financial account effect, the new equilibrium exchange rate will be above the purchasing-power parity rate. This will adversely affect export industries, since the exchange rate has not fallen sufficiently (if at all) to compensate for their higher sterling price. It will also adversely affect domestic industries that compete with imports, since again the exchange rate has not fallen sufficiently to retain their competitiveness with imports. The current account thus remains in deficit, matched by an equal and opposite financial plus capital account surplus.

This is a position that has characterised the UK for several years. As we saw in Table 25.1, the rate of inflation has frequently been above that of major trading partners, while the current account has been persistently in deficit (see Box 25.2) and the capital plus financial account persistently in surplus (see Figure 15.15 on page 481).

The positive inflation rate differential between the UK and its major trading partners (see Table 25.1) has often meant higher UK interest rates. This was the case following the delegation of monetary policy to the Bank of England in 1997 with its remit to meet an inflation rate target. The resulting interest rate differential contributed to an appreciating real exchange rate in the late 1990s, which remained persistently high up to the onset of the financial crisis (see Figure 25.3).

The carry trade. The problem for current account deficit countries has often been made worse by the *carry trade*, especially in the period running up to the financial crisis. This involves international investors taking advantage of nominal interest rate differences between countries.

Prior to the financial crisis of 2008, current account deficit countries, such as the UK, Australia and New Zealand, typically had relatively high interest rates, while current account surplus countries such as Japan and Switzerland had relatively low ones. It was thus profitable to borrow, say, yen at the low interest rate that obtains in Japan, exchange it into sterling and deposit the money at the higher interest rate available in the UK. If there was no change in the exchange rate between the pound and the yen, the investor made a profit equal to the difference in the interest rates.

If, however, the higher interest rates in the UK and other deficit countries were simply to compensate investors for the risk of currency depreciation, then there would be no excessive inflow of finance. The benefit of the higher interest rate would be offset by a depreciating currency. But the carry trade had the effect of making deficit currencies *appreciate*, thereby further boosting the carry trade by speculation of further exchange rate rises.

Thus the currencies of deficit countries appreciated, making their goods less competitive and worsening their current account deficit. Between 1996 and 2006, the average current account deficits as a percentage of GDP for Australia, the USA and the UK were 4.3, 3.8 and 1.5 respectively. Between January 1996 and December 2006, the broad-based *real* exchange rate index of the Australian dollar appreciated by 17.1 per cent, of the US dollar by 3.8 per cent and of sterling by some 23.5 per cent.

Currencies of surplus countries depreciated, making their goods more competitive and further boosting their current account surpluses. For example, between 2004 and 2006 the average current account surpluses as a percentage of GDP for Japan and Switzerland were 3.7 and 14.2 respectively. Their short-term interest rates averaged a mere 0.1 and 1.0 per cent respectively (compared with 3.4, 4.7 and 5.7 per cent for the USA, the UK and Australia). Yet between January 2004 and December 2006, the *real* exchange rate index of the yen depreciated by 20.6 per cent while that of the Swiss franc depreciated by 6.0 per cent.

With the credit crunch of 2007/8, however, short-term flows of finance declined significantly. This had the effect of reducing the carry trade and its effect on exchange rates.

Hence, the current account became relatively more significant in determining exchange rates. The currencies of deficit countries, such as the UK and USA, began to depreciate and those of surplus countries, such as Japan and Switzerland, began to appreciate. Between September 2007 and September 2008, the *real* exchange rate indices of the US dollar and sterling depreciated by 2.3 and 13.3 per cent respectively; the yen and the Swiss franc appreciated by 2.6 and 2.7 per cent.

External shocks

Now let us assume that the rest of the world goes into recession (but with no change in international interest rates). The demand for UK exports will fall. This will lead to a depreciation of the exchange rate. This in turn will boost the demand for UK exports and domestic substitutes for imports. This boost to demand again will help to offset the dampening effect of the world recession.

Floating exchange rates thus help to insulate the domestic economy from world economic fluctuations.

? Will there be any cost to the UK economy from a decline in the demand for exports resulting from a world recession?

The path to long-run equilibrium

If there is a single shock, and if there is initially both internal balance and also external balance in the narrow sense (i.e. a current account balance), eventually both internal balance and current account balance will be restored. Current account balance will be restored by a change in the exchange rate that restores purchasing-power parity. This is illustrated in Figure 25.8.

Assume that the country experiences the same long-term rate of inflation as its trading partners and that, therefore, the nominal exchange rate follows the same path as the real exchange rate. Assume also that there are no *long-term* changes to cause an appreciation or depreciation and that, therefore, the long-term equilibrium exchange rate is constant over time. This is shown by the horizontal line at e_{L1} .

Figure 25.8 Exchange rate path to long-run equilibrium after a shock at time t_1

Definition

Carry trade Borrowing at low interest rates and then using it to buy assets that earn higher rates. In foreign exchange markets, the carry trade involves borrowing money in a currency of a country where interest rates are low and exchanging it for another currency where the country pays higher interest rates.

BOX 25.4 THE PRICE OF A BIG MAC

The Economist's guide to purchasing-power parity rates

At least once a year *The Economist* publishes its 'Big Mac index'. It is a light-hearted attempt to see if currencies are exchanging at their purchasing-power parity rates. The test is the price at which a 'Big Mac' McDonald's hamburger sells in different countries! According to this simplified version of the purchasing-power parity theory, exchange rates should adjust so that a Big Mac costs the same in dollars everywhere.

If a Big Mac is taken as representative of all goods and services, then in January 2017, with a Big Mac selling for \$5.06 in the USA, but only the equivalent of \$2.83 in China, this implies that the Chinese yuan was undervalued by 44 per cent.

As we can see from the table, it was not the only Asian currency to be undervalued in Big Mac PPP terms. The Malaysian ringgit and the Thai baht, for instance, were also substantially undervalued. In Malaysia a Big Mac cost 8.00 ringgits, while in Thailand it cost 119 bahts. With, at the time, exchange rates of 4.47 ringgits and 35.57 bahts to the dollar, this meant that in Malaysia a Big Mac cost \$1.79, while in Thailand it cost \$3.35. This implied that the Malaysian ringgit was undervalued in Big Mac PPP terms by 65 per cent while the Thai baht was undervalued by 34 per cent.

In India, the nearest product is a 'Maharajah Mac', which uses chicken rather than beef. Given that the meat accounts for less than 10 per cent of a burger's cost, it is a fair approximation to use this rather than a Big Mac. In January 2017, with a price of \$2.49 at the dollar-rupee exchange rate, this implied that the rupee was undervalued by 51 per cent.

While Asia was often found to be the cheapest place to eat a burger, Europe tended to be more expensive. For instance, the Swiss franc was estimated to be 25 per cent overvalued. At the prevailing exchange rate of 1.02 francs to the dollar, a Big Mac in Switzerland cost the equivalent of \$6.35. For a Big Mac to cost the same in Switzerland as in America, the exchange rate would have had to be 1.28 francs to the dollar.

The hamburger standard

Country	Big Mac price in dollars at current exchange rate	Under (-) or over (+) valuation against the dollar (%)
Egypt	1.46	-71
Malaysia	1.79	-65

Now assume, as before, that there is a rise in aggregate demand and a resulting rise in interest rates. This occurs at time t_1 . As the demand for imports rises, the current account goes into deficit. Higher interest rates, however, lead to a financial inflow and an immediate appreciation of the exchange rate to e_1 . But then the exchange rate will gradually fall back to its long-run rate as the higher interest rates curb demand and interest rates can thus come back down.

What determines the level of e_1 ? This exchange rate must be high enough to balance the gain from the higher interest rate against the fact that the exchange rate will be expected to depreciate again back to its long-run equilibrium level e_L . For example, if the interest rate rises by 1 per cent, the exchange rate must rise to the level where people anticipate that it will fall by 1 per cent per year. Only that way will finance stop flowing into the country.

Describe the exchange rate path if there were a single shock that caused interest rates to fall. What determines the magnitude and speed of changes in the exchange rate in such a scenario?

Speculation

In the real world, shocks are occurring all the time. Also, there is considerable uncertainty over the future course of the exchange rate path. What is more, things are made more complicated by the activities of speculators. As soon as any exchange rate change is anticipated, speculators will buy or sell the currency.

Assume, for example, that there is a rise in UK inflation above international rates, but no change in interest rates. This causes a fall in the demand for exports and hence a fall in the demand for sterling (assuming a price elasticity of

Across the eurozone a Big Mac in January 2017 cost on average €3.88. With an exchange rate of $\text{€}1 = \$1.05$, the eurozone Big Mac cost \$4.06, implying an undervaluation of the euro of 20 per cent.

So what of the UK? A Big Mac in January 2017 cost an average of £3.09. At the exchange rate at the time of $\text{£}1 = \$1.21$, this meant a Big Mac cost \$4.63 in the UK. This implies an *undervaluation* of 26 per cent. Yet as recently as July 2014 the Big Mac index was indicating an overvaluation of sterling, albeit a small overvaluation of 3 per cent. The significant change reflects a Brexit effect. In particular, the uncertainty generated, the short-term relaxation of the Bank of England's monetary stance (see Box 22.10) and the expectation that long-term growth would be adversely affected.

International patterns

Generally, richer, developed countries' currencies seem to be overvalued and poorer ones' undervalued (exceptions in the table being Brazil and Venezuela). The explanation lies in differences in local costs, such as rents and wages. These are higher in rich countries. According to David Parsley, of Vanderbilt University, and Shang-Jin Wei, of the International Monetary Fund, non-traded inputs, such as labour, rent and electricity, account for between 55 and 64 per cent of the price of a Big Mac.¹

With lower rents and wages,

you would expect average prices to be cheaper in poor countries than in rich ones because labour costs are lower. This is the basis of the so-called 'Balassa-Samuelson effect'. Rich countries have much higher productivity and hence higher wages in the traded-goods sector than poor countries do. Because firms compete for workers, this also pushes up wages in non-tradable goods and services, where rich countries' productivity advantage is smaller.²

A Big Mac index is now produced adjusting for GDP per capita. In January 2017, it still suggested that the Indian rupee and Chinese yuan were undervalued, but now by only 10 and 6 per cent respectively. On the other hand, the Thai baht was now overvalued by as much as 14 per cent. While this adjustment may capture some of the differences between countries, such as in labour costs, it cannot capture differences attributable to transportation costs, or to consumer tastes which affect the amount consumers are willing to pay.

Also, exchange rates can diverge from their PPP values because of factors influencing the *financial account* of the balance of payments: factors such as actual and expected interest rate differentials, investment prospects and speculation about exchange rate movements.

Nevertheless, despite the limitation of the original Big Mac index, it does give some indication of whether a currency is above or below its long-term equilibrium rate.

- ?
1. If the Chinese yuan is undervalued by 44 per cent in PPP terms against the US dollar and the Swiss franc overvalued by 25 per cent, what implications does this have for the interpretation of Chinese, Swiss and US GDP statistics?
 2. Why do developing countries' currencies tend to be undervalued relative to those of developed countries (see table)?
 3. At the time the table was compiled, the Big Mac PPP rate for the Norwegian krone was $\$1 = \text{kr}9.68$. What was the market exchange rate?

1 David C. Parsley and Shang-Jin Wei, 'A prism into the PPP puzzles: the microfoundations of Big Mac real exchange rates', *NBER Working Paper No. 10074* (National Bureau of Economic Research, November 2003), www.nber.org/papers/w10074

2 *The Economist*, 30 July 2011.

demand greater than 1), and a rise in imports and hence a rise in the supply of sterling. This is illustrated in Figures 25.9 and 25.10. The exchange rate depreciates from e_{r1} to e_{r2} . Speculators seeing the exchange rate falling can react in one of two ways. The first is called *stabilising speculation*; the second is called *destabilising speculation* (see section 3.2).

Stabilising speculation

This occurs when speculators believe that any exchange rate change will soon be reversed.

In our example, speculators may anticipate that the central bank will raise interest rates or take some other measure to reduce inflation. They thus believe that the exchange rate will appreciate again. As a result, they buy more pounds and sell fewer. But this very act of speculation causes the appreciation they had anticipated.

This is illustrated in Figure 25.9. Inflation has caused the demand for and supply of pounds to shift from D_1 and S_1 to

Figure 25.9 Stabilising speculation

BOX 25.5 THE EURO/DOLLAR SEESAW

Ups and downs in the currency market

For periods of time, world currency markets can be quite peaceful, with only modest changes in exchange rates. But with the ability to move vast sums of money very rapidly from one part of the world to another and from one currency to another, speculators can suddenly turn this relatively peaceful world into one of extreme turmoil – a turmoil that can be very damaging for business.

In this box we examine the huge swings of the euro against the dollar since the euro's launch in 1999.

First the down . . .

On 1 January 1999, the euro was launched and exchanged for \$1.16. By October 2000 the euro had fallen to \$0.85. The main cause of this 27 per cent depreciation was the growing fear that inflationary pressures were increasing in the USA and that, therefore, the Federal Reserve Bank would have to raise interest rates. At the same time, the eurozone economy was growing only slowly and inflation was well below the 2 per cent ceiling set by the ECB. There was thus pressure on the ECB to cut interest rates.

The speculators were not wrong. As the diagram shows, US interest rates rose, and ECB interest rates initially fell, and when eventually they did rise (in October 1999), the gap between US and ECB interest rates soon widened again.

In addition to the differences in interest rates, a lack of confidence in the recovery of the eurozone economy and a

continuing confidence in the US economy encouraged investment to flow to the USA. This inflow of finance (and lack of inflow to the eurozone) further pushed up the dollar relative to the euro.

The low value of the euro meant a high value of the pound and other currencies relative to the euro. This made it very difficult for companies outside of the eurozone to export to eurozone countries and also for those competing with imports from the eurozone (which had been made cheaper by the fall in the euro).

In October 2000, with the euro trading at around 85¢, the ECB plus the US Federal Reserve Bank (America's central bank), the Bank of England and the Japanese central bank all intervened on the foreign exchange market to buy euros. This arrested the fall, and helped to restore confidence in the euro.

. . . Then the up

The position completely changed in 2001. With the US economy slowing rapidly and fears of an impending recession, the Federal Reserve Bank reduced interest rates 11 times during the year: from 6.5 per cent at the beginning of the year to 1.75 per cent at the end (see the chart). Although the ECB also cut interest rates, the cuts were relatively modest: from 4.75 at the beginning of the year to 3.25 at the end. With eurozone interest rates now considerably above US rates, the euro began to rise.

Fluctuations between the euro and the dollar

Notes: Federal reserve rate is the federal funds effective rate; ECB interest rate is the main refinancing operations rate.

D_2 and S_2 , and the exchange rate to fall from e_1 to e_2 . Stabilising speculation then shifts the curves back again, to D_3 and S_3 , and the exchange rate rises again to e_3 .

The action of speculators in this case, therefore, prevents excessively large exchange rate changes. In general, stabilising speculation occurs whenever speculators believe that the

exchange rate has 'overreacted' to the current economic situation.

Draw a similar diagram to Figure 25.9, showing how an initial appreciation of the exchange rate would similarly be reduced by stabilising speculation.

In addition, a massive deficit on the US balance of payments current account, and a budget deficit nearing 4 per cent of GDP, made foreign investors reluctant to invest in the American economy. In fact, investors were pulling out of the USA. One estimate suggests that European investors alone sold \$70 billion of US assets during 2002. The result of all this was a massive depreciation of the dollar and appreciation of the euro, so that by December 2004 the exchange rate had risen to \$1.36: a 60 per cent appreciation since June 2001!

In 2004–5, with the US economy growing strongly again, the Fed raised interest rates several times, from 1 per cent in early 2004 to 5.25 by June 2006. The ECB kept interest rates constant at 2 per cent until early 2006. The result was that the euro depreciated against the dollar in 2005. But then the rise of the euro began again as the US growth slowed and eurozone growth rose and people anticipated a narrowing of the gap between US and eurozone interest rates.

In 2007 and 2008, worries about the credit crunch in the USA led the Fed to cut interest rates to stave off recession. In August 2007, the US federal funds rate was 5.25 per cent. It was then reduced on several occasions to stand at between 0 and 0.25 per cent by December 2008. The ECB, in contrast, kept the eurozone rate at 4 per cent for the first part of this period and even raised it to 4.25 per cent temporarily in the face of rapidly rising commodity prices. As a result, short-term finance flooded into the eurozone and the euro appreciated again, from \$1.37 in mid-2007 to \$1.58 in mid-2008.

... Then the steps down

Eventually, in September 2008, with the eurozone on the edge of recession and predictions that the ECB would cut interest rates, the euro at last began to fall. It continued to do so as the ECB cut rates. However, with monetary policy in the eurozone remaining tighter than in the USA, the euro began to rise again, only falling once more at the end of 2009 and into 2010 as US growth accelerated and speculators anticipated a tightening of US monetary policy.

Growing worries in 2010 about the level of government deficits and debt in various eurozone countries, such as Greece, Portugal, Spain, Italy and Ireland, contributed to speculation and thus growing volatility of the euro. Throughout the first part of 2010 investors became increasingly reluctant to hold the euro, as fears of debt default mounted. As such, the euro fell substantially from

\$1.44 in January 2010 to \$1.19 in June – a 17 per cent depreciation.

Then, as support was promised by the ECB and IMF to Greece in return for deficit reduction policies, and similar support could be made available to other eurozone countries with severe deficits, fears subsided and the euro rose again. By the end of October 2010, the euro was trading at \$1.39. In April 2011, the euro increased to a high of \$1.44.

Then began a dramatic fall in the euro as concerns grew over the eurozone's sluggish recovery and continuing high debt levels. Speculators thus believed that eurozone interest rates would have to continue falling. The ECB cut the main interest rate from 1.5 per cent in October 2011 in a series of steps to 0.05 per cent by September 2014.

With the ECB reducing interest rates and people increasingly predicting the introduction of quantitative easing (QE), the euro depreciated during 2014. Between March and December 2014 it depreciated by 11 per cent against the dollar, while the euro exchange rate index depreciated by 4 per cent. With the announced programme of QE being somewhat larger than markets expected, in the week following the announcement in January 2015, the euro fell a further 2.3 per cent against the dollar, and the euro exchange rate index also fell by 2.3 per cent. The result was that the euro was trading at its lowest level against the US dollar since April 2003.

With the long-awaited rise in US interest rates starting in December 2015, a fall in the main EU rate to 0 per cent in March 2016 and the announcement that the ECB's quantitative easing programme would continue to at least the end of 2017, the euro remained weak against the dollar.

The path of the euro shows that interest rate volatility and divergence in interest rates between the USA and the eurozone have been a major factor in the exchange rate volatility between the euro and the dollar – itself a cause of uncertainty in international trade and finance. However, more recently concerns over the fiscal health of national eurozone governments have played a particularly important role in explaining fluctuations in the euro.

Find out what has happened to the euro/dollar exchange rate over the past 12 months. (You can find the data from the Bank of England's Statistical Interactive Database at www.bankofengland.co.uk/boeapps/iadb/newintermed.asp.) Explain why the exchange rate has moved the way it has.

Destabilising speculation

This occurs when speculators believe that exchange rate movements will continue in the same direction.

In our example, speculators may believe that inflation will not be brought under control. They anticipate a continuing fall in the exchange rate and thus sell *now* before the

exchange rate falls any further. In Figure 25.10, this speculation causes the demand and supply curves to shift further, to D_3 and S_3 , and causes the exchange rate to fall further, to e_3 .

Eventually, however, this destabilising speculation could cause *overshooting*, with the exchange rate falling well below the purchasing-power parity rate. At this point speculators,

Figure 25.10 Destabilising speculation

believing that the rate will rise again, will start buying pounds again. This causes the exchange rate to rise.

Obviously, governments prefer stabilising to destabilising speculation. Destabilising speculation can cause severe exchange rate fluctuations. The resulting uncertainty is very damaging to trade. It is very important, therefore, that governments create a climate of confidence. People must believe that the government can prevent economic crises from occurring.

Conclusion

Whatever speculators anticipate will happen to the exchange rate, their actions will help to bring it about. If they think the sterling exchange rate will fall, they will sell pounds, hence causing it to fall. Thus speculators as a whole will gain. This applies to both stabilising and destabilising speculation.

If speculators on average gain from their speculation, who loses?

Advantages of a free-floating exchange rate

The advantages and disadvantages of free-floating rates are to a large extent the opposite of those of fixed rates.

Automatic correction. The government simply lets the exchange rate move freely to the equilibrium. In this way,

Definition

Exchange rate overshooting Where a fall (or rise) in the long-run equilibrium exchange rate causes the actual exchange rate to fall (or rise) by a greater amount before eventually moving back to the new long-run equilibrium level.

balance of payments disequilibria are automatically and instantaneously corrected without the need for specific government policies – policies that under other systems can be mishandled.

No problem of international liquidity and reserves. Since there is no central bank intervention in the foreign exchange market, there is no need to hold reserves. A currency is automatically convertible at the current market exchange rate. International trade is thereby financed.

Insulation from external economic events. A country is not tied to a possibly unacceptably high world inflation rate, as it is under a fixed exchange rate. It can choose its own inflation target. It is also to some extent protected against world economic fluctuations and shocks (see pages 802–4).

Governments are free to choose their domestic policy. Under a fixed rate, a government may have to deflate the economy even when there is high unemployment. Under a floating rate, the government can choose whatever level of domestic demand it considers appropriate, and simply leave exchange rate movements to take care of any balance of payments effect. This is a major advantage, especially when the effectiveness of deflation is reduced by downward wage and price rigidity, and when competitive deflation between countries may end up causing a world recession.

Disadvantages of a free-floating exchange rate

Despite these advantages, there are still some serious problems with free-floating exchange rates.

Speculation. Short-run instability can be lessened by stabilising speculation, thus making speculation advantageous. If, due to short-run inelasticity of demand, a deficit causes a very large depreciation, speculators will buy pounds, knowing that in the long run the exchange rate will appreciate again. Their action therefore helps to lessen the short-run fall in the exchange rate.

Nevertheless, in an uncertain world where there are few restrictions on currency speculation, where the fortunes and policies of governments can change rapidly, and where large amounts of short-term deposits are internationally ‘foot-loose’, speculation can be highly destabilising in the short run. Considerable exchange rate overshooting can occur.

An example of such overshooting occurred between June 2008 and March 2009 when the pound depreciated 14 per cent against the euro, 28 per cent against the US dollar and 34 per cent against the yen (see Figure 15.16 on page 482). The nominal sterling exchange rate index fell 16 per cent and the real index by 15 per cent. Speculators were predicting that interest rates in the UK would fall further than in other countries and stay lower for longer. This was because the recessionary implications of a highly financialised economy such as the UK following the financial crisis were expected to be deeper. Consequently, inflation was expected to

undershoot the Bank of England's 2 per cent target and perhaps even become negative. But the fall in the exchange rate represented considerable overshooting and both the nominal and real exchange rate indices rose by 9 per cent between March and June 2009.

This is just one example of the violent swings in exchange rates that have occurred in recent years. They even occur under managed floating exchange rate systems where governments have attempted to dampen such fluctuations!

The continuance of exchange rate fluctuations over a number of years is likely to encourage the growth of speculative holdings of currency. This can then cause even larger and more rapid swings in exchange rates.

Uncertainty for traders and investors. The uncertainty caused by currency fluctuations can discourage international trade and investment. To some extent, the problem can be overcome by using the *forward exchange market*. Here traders agree with a bank today the rate of exchange for some point in the future (say, in six months' time). This allows traders

to plan future purchases of imports or sales of exports at a known rate of exchange. Of course, banks charge for this service, since they are taking upon themselves the risks of adverse exchange rate fluctuations.

This will not help long-term investment, however, where decisions are made based on anticipated costs and revenue flows for many years to come. The possibility of exchange rate appreciation may well discourage firms from investing abroad.

Why would banks not be prepared to offer a forward exchange rate to a firm for, say, five years from now?

Definition

Forward exchange market Where contracts are made today for the price at which a currency will be exchanged at some specified future date.

BOX 25.6

THE EFFECTIVENESS OF MONETARY AND FISCAL POLICIES UNDER FLOATING EXCHANGE RATES

EXPLORING ECONOMICS

With a floating exchange rate, monetary policy is strong and fiscal policy is weak (the reverse of the case with fixed exchange rates).

Monetary policy

Assume that the economy is in recession and the central bank wishes to increase aggregate demand. It thus reduces interest rates. Three effects follow, each contributing to the effectiveness of the monetary policy.

1. **The expansionary monetary policy directly increases aggregate demand.** The size of the effect here depends on the amount that interest rates change and the elasticity of aggregate demand in response to the changes in interest rates.
2. **The exchange rate depreciates.** Higher aggregate demand increases imports and (via higher prices) reduces exports. This and the lower interest rates reduce the demand for and increase the supply of domestic currency on the foreign exchange market. The exchange rate thus depreciates.

This reinforces the increase in domestic demand. A lower exchange rate makes exports less expensive again and therefore increases their demand (an injection). Imports become more expensive again and therefore their demand falls (a withdrawal). There is thus a *further* multiplied rise in income.

3. **Speculation may cause initial exchange rate overshooting.** Lower interest rates cause speculative financial outflows in anticipation of the depreciation. This causes the exchange rate to fall below its eventual rate – to overshoot, thus causing a further rise in aggregate demand.

This is only a short-term effect, however, since speculators will stop selling the domestic currency when the rate has gone so low that they feel it must rise again (back towards the purchasing-power parity level) sufficiently fast to offset the lower interest rates they are now getting. The greater the mobility of international finance and the better the information of the speculators, the shorter will the short run be.

Fiscal policy

Fiscal policy is relatively weak under a floating rate. Again, let us assume that the objective is to raise aggregate demand to combat a recession. The government thus reduces taxes and/or increases its expenditure. The rise in aggregate demand raises imports and (via higher prices) reduces exports. This effect on the current account of the balance of payments puts downward pressure on the exchange rate.

The higher aggregate demand, however, increases the transactions demand for money and hence *raises* interest rates. These higher interest rates will lead to financial inflows. This will put upward pressure on the exchange rate, which is likely to swamp the downward pressure from the current account deficit. There will therefore be an *appreciation* of the exchange rate. This will increase imports and reduce exports, thus reducing aggregate demand again, and reducing the effectiveness of the fiscal expansion.

Compare the relative effectiveness of fiscal and monetary policies as means of reducing aggregate demand under a system of floating exchange rates.

Lack of discipline on the domestic economy. Governments may pursue irresponsibly inflationary policies. Also, unions and firms may well drive up wages and prices, without the same fear of losing overseas markets or of the government imposing deflationary policies. The depreciation resulting from this inflation will itself fuel the inflation by raising the price of imports.

Conclusion

Neither fixed nor free-floating exchange rates are free from problems. For this reason, governments have sought a

compromise between the two, the hope being that some intermediate system will gain the benefits of both, while avoiding most of their disadvantages.

One compromise was tried after the Second World War. This was the *adjustable peg*. Another is the system that replaced the adjustable peg in the early 1970s and continues for much of the world today. This is the system of *managed floating*. We examine these systems in the next section.

Section summary

1. Under a free-floating exchange rate, the balance of payments will automatically be kept in balance by movements in the exchange rate. This removes the *balance of payments* constraint on domestic policy. It does not, however, remove external constraints entirely.
2. According to the purchasing-power parity theory, any changes in domestic prices will simply lead to equivalent changes in the exchange rate, leaving the international competitiveness of home-produced goods unaffected. If, however, internal shocks cause changes in interest rates, there will be a change in the *financial* account balance. This will influence exchange rates and destroy the purchasing-power parity theory. The current account will go out of balance (in an equal and opposite way to the financial account).
3. This problem is made more acute by the carry trade, whereby people borrow money in low interest rate (current account surplus) countries and deposit them in high interest rate (current account deficit) countries. This causes deficit countries' exchange rates to appreciate, thereby worsening their current account deficit.
4. External shocks will be reflected in changes in exchange rates and will help to insulate the domestic economy from international economic fluctuations.
5. Exchange rate movements are highly influenced by speculation. If speculators believe that an appreciation or depreciation is merely temporary, their activities will help to stabilise the exchange rate. If, however, they believe that an exchange rate movement in either direction will continue, their activities will be destabilising and cause a bigger movement in the exchange rate.
6. The advantages of free-floating exchange rates are that they automatically correct balance of payments disequilibria; they eliminate the need for reserves; and they give governments a greater independence to pursue their chosen domestic policy.
7. On the other hand, a completely free exchange rate can be highly unstable, made worse by destabilising speculation. This may discourage firms from trading and investing abroad. What is more, a flexible exchange rate, by removing the balance of payments constraint on domestic policy, may encourage governments to pursue irresponsible domestic policies for short-term political gain.

25.4 EXCHANGE RATE SYSTEMS IN PRACTICE

The adjustable peg system: 1945–73

After the collapse in 1931 of the fixed exchange rate system of the gold standard (see section 16.2), the huge scale of the initial disequilibria caused wild swings in exchange rates. Many countries resorted to protectionism, given the great uncertainties associated with free trade under fluctuating exchange rates.

The Bretton Woods system

In 1944, the allied countries met at Bretton Woods in the USA to hammer out a new exchange rate system: one that would avoid the chaos of the 1930s and encourage free

trade, but that would avoid the rigidity of the gold standard. The compromise they worked out was an adjustable peg system that lasted until 1971.

Under the *Bretton Woods system* there was a totally fixed dollar/gold exchange rate (\$35 per ounce of gold). The USA guaranteed that it would freely convert dollars into gold. It was hoped that this would encourage countries to hold dollars as their major reserve currency. After all, if dollars were freely convertible into gold, they were as good as gold. All other countries pegged their exchange rate to the dollar.

To prevent temporary, short-term fluctuations in the exchange rate, central banks *intervened* on the foreign

exchange markets using their foreign reserves. This enabled them to maintain the pegged rate within a 1 per cent band.

If the disequilibrium became more serious, governments were supposed to pursue policies of *deflation* or *reflation*. In the meantime, in the case of a deficit, the central bank might have insufficient reserves to maintain the exchange rate. The International Monetary Fund was set up to provide such liquidity. All countries were required to deposit a quota of funds with the IMF, depending on the size of their trade. The IMF would then lend to countries in balance of payments deficit to enable them to maintain their exchange rate. The more a country had to borrow from the IMF, the more the IMF would insist that it pursued appropriate deflationary policies to correct the disequilibrium.

If the deficit became severe, countries could *devalue*: the pegged rate could be adjusted (in consultation with the IMF).

? Under this system, how would you expect countries to respond to a balance of payments surplus? Would a revaluation benefit such countries?

Advocates of an adjustable peg system argue that the Bretton Woods arrangement made a significant contribution to the long boom of the 1950s and 1960s.

- Since rates were fixed for a long period of time – perhaps many years – uncertainty was reduced and trade was encouraged.
- Pegged rates, plus the overseeing role of the IMF, prevented governments from pursuing irresponsible policies, and helped to bring about an international harmonisation of policies. They kept world inflation in check.
- If a deficit became severe, countries could devalue. This prevented them being forced into a depression or into adopting protectionist policies. The IMF ensured an orderly process of devaluation.

However, there were two serious weaknesses with the system. These became more and more apparent during the 1960s, and eventually led to the system's downfall.

Problems of adjustment to balance of payments disequilibria

To avoid internal policy being governed by the balance of payments, and to avoid being forced into a depression, countries with a fundamental deficit were supposed to devalue. There were several difficulties here, however.

- Identifying whether a deficit was fundamental. Governments were frequently overoptimistic about the future balance of payments position.
- If devaluation did take place, it could be very disruptive to firms. A devaluation suddenly alters the costs and revenues of importers and exporters by a substantial amount.

If a devaluation is felt to be imminent, it can cause great uncertainty and may make them reluctant to take on new trade commitments.

? Would this uncertainty have a similar or a different effect on exporting companies and companies using imported inputs?

- At first a devaluation might make a current account deficit *worse*: the *J-curve effect*. The price elasticities of demand for imports and exports may be low in the short run (see Case Study 25.1 on the student website). Directly after devaluation, few extra exports may be sold, and more will have to be paid for imports that do not have immediate substitutes. There is thus an initial deterioration in the balance of trade before it eventually improves. In Figure 25.11, devaluation takes place at time t_1 . As you can see, the diagram has a J shape.

For these reasons, countries in deficit tended to put off devaluing until they were forced to by a crisis. The reluctance of countries to devalue caused other problems.

Stop-go policies. Countries had to rely much more on deflation as a means of curing deficits. The UK in particular found that, whenever the economy started to grow, the balance of payments went into deficit. This forced the government to curb demand again through fiscal and/or monetary policies.

Figure 25.11 The J-curve effect

Definition

Bretton Woods system An adjustable peg system whereby currencies were pegged to the US dollar. The USA maintained convertibility of the dollar into gold at the rate of \$35 to an ounce.

J-curve effect Where a devaluation causes the balance of payments first to deteriorate and then to improve. The graph of the balance of payments over time thus looks like a letter J.

Speculation. If countries delayed devaluing until a deficit became really severe, an eventual large devaluation became inevitable. This provided a field day for speculators: they could not lose, and there was a high probability of a substantial gain.

Large-scale disruption. The delay in devaluing plus the build-up of speculative pressure could cause the devaluation to be very large when it eventually came. This could be highly disruptive.

Countries' balance of payments deficits could be reduced and adjustment made easier if surplus countries were willing to revalue. There was a reluctance to do this, however, by countries such as Japan. Revaluation was strongly opposed by exporters (and producers of import substitutes), who would find it suddenly more difficult to compete. What is more, there were not the same pressures for surplus countries to revalue as there were for deficit countries to devalue. A lack of reserves can force deficit countries to devalue. Surplus countries, however, may be quite happy to carry on building up reserves.

The USA was not allowed to devalue when in deficit. The onus was on other countries to revalue, which they were reluctant to do. Hence large US deficits persisted. The problem of these deficits was linked to the second major problem area: that of international liquidity.

Problems of international liquidity and the collapse of the system

With an adjustable peg system, there have to be sufficient stocks of internationally acceptable currencies or other liquid assets. This 'international liquidity' is necessary both to finance trade and to provide enough reserves for central banks to support their currencies whenever there is a currency flow deficit. Under the Bretton Woods system, there were three main sources of liquidity: gold, dollars and IMF quotas. But since IMF quotas were only in existing currencies, they were not a source of *additional* liquidity.

As world trade expanded (see section 24.1), so deficits (and surpluses) were likely to be larger, and therefore more reserves were required. But the supply of gold was not expanding fast enough, so countries increasingly held dollars. After all, dollars earned interest. The willingness to hold dollars enabled the USA to run large balance of payments deficits. All the USA needed to do to pay for the deficits was to 'print' more dollars, which other countries were prepared to accept as reserves.

US balance of payments deficits in the 1960s got steadily worse. The financing of the Vietnam War, in particular, deepened the deficit. Dollars flooded out of the USA. World liquidity thus expanded rapidly, fuelling world inflation. Furthermore, the rapid growth in overseas dollar holdings meant that US gold reserves were increasingly inadequate to guarantee convertibility. Some countries, fearful that the USA might eventually be forced to suspend convertibility,

chose to exchange dollars for gold. US gold reserves fell, creating a further imbalance and a deepening of the crises.

Despite various attempts to rescue the system, with its overreliance on the dollar, it eventually collapsed. The dollar was devalued against gold by 8 per cent in December 1971. In June 1972 the pound was floated. Over the following year, other countries followed suit, and despite a further dollar devaluation the system was finally abandoned in 1973. By mid-1973 gold was trading at \$120 per ounce.

Why would the adjustable peg system have been less suitable in the world of the mid-1970s than it was back in the 1950s?

Managed floating

The world has been on a floating exchange rate system since the breakdown of the Bretton Woods system in the early 1970s. This allows adjustment to be made to the inevitable shifts in demand and supply, shifts that got more extreme in the early 1970s with a quadrupling of oil prices in 1973–4 and rapid changes in world trading patterns. Domestic policy has been largely freed from balance of payments constraints. At the same time, *managed* floating was claimed to allow adjustment to be more gentle, ideally avoiding wild swings in the exchange rate aggravated by speculation.

Some minor currencies remain pegged (but adjustable) to a major currency such as the dollar, but float along with it against other currencies. Other currencies are pegged to each other, but jointly float against the rest of the world. The most notable examples of this have been the currencies of the exchange rate mechanism (ERM) of the European Monetary System (see section 26.2) and now the members of ERM2 (see page 796).

Some countries allow their currencies to float freely. Most countries, however, from time to time have attempted to stabilise their exchange rate, and have thus been operating a system of 'managed flexibility'.

If the country decides to adopt a managed floating system, how could the central bank prevent the exchange rate from falling? There are two main methods:

- Using reserves or foreign loans to purchase domestic currency on the foreign exchange market.
- Raising interest rates to attract short-term financial inflows.

Problems with managed floating since 1972

Managing the exchange rate involved problems, however. Governments needed to know when to intervene, what exchange rate level they should aim to maintain, and how persistently they should try to maintain that rate in the face of speculative pressure.

Predicting the long-term equilibrium exchange rate

Differing inflation rates between countries will require exchange rate adjustments to maintain purchasing-power

parity. It is not correct, however, for governments to assume that this will be the *only* cause of shifts in the long-term equilibrium exchange rate. For example, the 1973–4 and 1979–80 oil crises caused fundamental and unpredictable changes in currency demand and supply. So too did other factors, such as the dismantling of trade barriers within the EU, protectionist measures adopted in different parts of the world, changes in technology and changes in tastes.

It is therefore very difficult for the government to predict what the long-term equilibrium will be, and what proportion of any exchange rate movement is therefore due to *long-term* and what proportion merely to *short-term* phenomena.

The growth in speculative financial flows

The OPEC oil price increase in 1973–4 caused huge balance of payments deficits for oil importers. The OPEC countries could not spend all of these surpluses on additional imports since (a) they did not have the capacity to consume such a huge increase in imports and (b) the oil-importing countries did not have the capacity to supply such a huge increase in exports. The surpluses were thus largely invested in short-term dollar (and, to a lesser extent, other major currency) assets. This created a large capacity for short-term loans by Western banks. These moneys could be rapidly shifted from one world financial centre to another, depending on which country had the most favourable interest rates and exchange rates. This created a massive capacity for speculation, and thus made it difficult for countries to control exchange rates by currency sales alone.

Over the years, the scale of speculative flows has continued to increase. Foreign exchange market data from the Bank for International Settlements show that in 2016 some \$5 trillion was passing across the international exchanges every day. Reserves and access to foreign loans are simply inadequate to prevent concerted speculative selling.

To manage the exchange rate, therefore, central banks would have to rely much more on using interest rates.

Conflicts with internal policy

Using interest rates to support the exchange rate has become more and more unpopular as countries have preferred to use interest rates to keep inflation at or below a target level.

As a result of these problems, countries have increasingly opted for a system of freely floating exchange rates. The UK experience is considered in Box 25.7.

Would any of these problems be lessened by the world returning to an adjustable peg system? If so, what sort of adjustable peg system would you recommend?

The volatility of exchange rates

Exchange rates have become extremely volatile. We continue to observe this volatility when we adjust for changes in the prices of exports (measured in domestic prices) relative to the prices of imports (measured in foreign currencies). In other words, the *real* exchange rate is volatile too (see Figure 25.12). This means that nominal exchange rates have typically moved more than the relative prices of exported and imported goods and services.

As a result of exchange rate volatility, currencies can gain or lose several percentage points in the space of a few days. These changes can then make all the difference between profit and loss for trading companies. There are a number of reasons for this volatility:

- Inflation or money supply targets. Central banks may have to make considerable changes to interest rates in order to keep to their targets. These in turn cause exchange rate fluctuations.

Figure 25.12 Real exchange rate indices (2010 = 100)

Note: Exchange rate indices are BIS narrow indices comprising 27 countries; prior to the introduction of the euro in 1999, eurozone figures are weighted average exchange rates of currencies that made up to the euro.

Source: Based on data from *Effective Exchange Rate Indices* (Bank for International Settlements).

BOX 25.7 STERLING SINCE THE 1990S

The sterling seesaw

Between October 1990 and September 1992, sterling was in the ERM, at a central rate of £1 = 2.95 German marks, with permitted fluctuations of ± 6 per cent against any other ERM currency. However, this exchange rate proved unsustainably high and the UK was forced out of the ERM by a massive wave of speculation. Within two months of this, sterling had depreciated by some 15 per cent.

Since 1992, the UK has adopted a virtually free-floating exchange rate. Between 1992 and 1996, fluctuations in the exchange rate were relatively minor. The government was now targeting inflation, and with inflation coming down, it was at first able to reduce interest rates. But this mirrored reductions in inflation and interest rates in other countries, and thus there was little need for exchange rate changes.

A rise in sterling

By the beginning of 1996, however, speculators began buying pounds, believing that the exchange rate would appreciate.

They saw that the economy was now beginning to grow quite rapidly, and was likely to continue doing so, given that an election was coming up. Inflation was thus likely to rise and this would force the government to raise interest rates. Indeed, by mid-1996 interest rates bottomed out *and began to rise*.

When the new Labour government was elected in 1997, the Bank of England was made independent. Over the following months, the Bank raised interest rates several times in order to bring the inflation down to the target level. The effect was to further fuel a large-scale appreciation of sterling. Between January 1996 and April 1998, the *real* exchange rate index rose by 28 per cent (see chart). This made it *more* difficult for UK exporters and industries competing with imports.

From 1998 to 2007 the pound was well above its purchasing-power parity rate. This was largely the result of UK interest rates being higher than eurozone and Japanese rates, and frequently above US rates too.

Real exchange rate indices (2010 = 100)

Note: Exchange rate indices are BIS narrow indices comprising 27 countries.

Source: Based on data from *Effective Exchange Rate Indices* (Bank for International Settlements).

- A huge growth in international financial markets. This has encouraged the international transfer of money and capital.
- The abolition of exchange controls in most industrialised countries.
- The growth in information technology. The simple use of a computer can transfer capital and finance internationally in a matter of seconds.
- The preference for liquidity. With the danger of currency fluctuations, companies prefer to keep their financial capital as liquid as possible. They do not want to be locked into assets denominated in a declining currency.
- The growing speculative activities of trading companies. Many large companies have a team of dealers to help manage their liquid assets: to switch them from currency to currency in order to take advantage of market movements.
- The growing speculative activities of banks and other financial institutions.
- The growing belief that rumour and 'jumping on the bandwagon' are more important determinants of currency buying or selling than cool long-term appraisal. If people *believe* that speculation is likely to be destabilising, their actions will ensure that it is. Many companies

With the growth of the carry trade (see page 803), this had helped keep the exchange rate above the PPP rate. The overvaluation of the pound continued to put both the export and import competing sectors in the UK under great competitive pressure. The current account remained in deficit and in most years deteriorated (see the chart in Box 25.2 on page 790).

A fall in sterling

In late 2007, at last the pound began depreciating. With the effects of speculation, this became rapid. Worries about recession suggested that the Bank of England would reduce interest rates – as indeed it did: Bank Rate fell from 5 per cent in October 2008 to 0.5 per cent in March 2009.

But other central banks were reducing their rates too, so why did the pound depreciate while other currencies, including the Japanese yen and Australian dollar, appreciated. There were various reasons for this:

- The cut in the Bank Rate was greater than in the eurozone.
- There were worries that the recession would be deeper and more prolonged in the UK than elsewhere and that low interest rates would therefore persist for longer than in other countries.
- Investment in the UK was seen as more risky than in other countries, given the importance of the financial services sector in the UK (a sector badly hit by the credit crunch) and the more rapid rise in government borrowing than in many other countries.
- Commodity prices were rising, which pushed up the exchange rates for commodity exporting countries, such as Australia.

Significantly, the carry trade began to unwind. With the onset of recession, the UK's high current account deficit was no longer seen as a reason to expect relatively high interest rates. Many who had borrowed in yen or other low interest rate currencies to purchase sterling, now began selling sterling and returning to the original currencies, causing such currencies to appreciate substantially.

Between September 2008 and September 2010 the real sterling exchange rate depreciated by 8 per cent while the real exchange rate of the Japanese yen appreciated by 20 per cent. This appreciation of the yen prompted the Japanese central bank in September 2010 to begin intervening in the foreign exchange markets by selling yen and buying dollars.

Rising again

Eventually, in mid-2013, sterling began to rise. With recovery gaining momentum more rapidly in the UK than in the eurozone, speculators were predicting that the Bank of England would raise rates before the ECB and that this would cause the pound to appreciate. The actions of speculators ensured that this occurred.

The Brexit fall

On 23 June 2016, the UK held a referendum on whether to remain a member of the EU. As soon as it became clear that the UK had voted to leave the EU the pound began to fall sharply. Investor concern about the UK's future trading relationships and its likely negative impact on long-term growth, coupled with the Bank of England's reduction in Bank Rate from 0.5 to 0.25 per cent, a further round of quantitative easing (see Box 22.10) and the potential for further monetary loosening helped to fuel a marked fall in sterling.

Six weeks after the vote, sterling had depreciated by 10.8 per cent against the dollar and 9.3 per cent against the euro compared with directly before the referendum. By the end of 2016, the real sterling exchange rate index was some 15 per cent lower than at the end of 2015, while the euro index was up by 1 per cent and the US dollar up by 5 per cent.

1. Identify two factors in the UK economy which help to explain the appreciation of the real exchange rate after 1996.
2. What longer-term determinants are there of the sterling exchange rate index?

involved in international trade and finance have developed a 'speculative mentality'.

- The growing belief that governments are powerless to prevent currency movements. As short-term capital (or 'hot money') grows relative to official reserves, it is increasingly difficult for central banks to stabilise currencies through exchange market intervention.

Although most governments and firms dislike highly volatile exchange rates, few today advocate a return to fixed

exchange rates, or a system like the Bretton Woods one. In fact, apart from the Gulf states, very few countries still peg their currencies to the dollar. Even China, which from 1997 to 2005 was pegged to the dollar at \$1 = 8.27 yuan, has moved to a managed float based round the weighted average of a basket of currencies. In May 2017, the yuan was trading at 6.90 to the dollar – an appreciation of 20 per cent since 2005.

Despite the preference of most countries for floating exchange rates, suggestions have been made for reducing volatility. We examine some of these in Chapter 26.

BOX 25.8

DO INFLATION RATES EXPLAIN LONGER-TERM EXCHANGE RATE MOVEMENTS?

EXPLORING ECONOMICS

Does PPP hold in the long run?

As we have seen in section 25.4, exchange rates have become extremely volatile. We can see from Figure 25.1 (page 788) that the trade-weighted *real* exchange rate of sterling exhibits considerable volatility. The real exchange rate adjusts for the terms of trade. The significance of movements in the real exchange rate is that it demonstrates that purchasing-power parity (PPP) fails to hold in the short run.

But does PPP hold in the long run? If so, differences in countries' inflation rates need to be reflected in changes in exchange rates. In this box, we consider whether long-term inflation rate differentials between the UK and nine other countries have been reflected in long-term movements in the foreign currency price of sterling, i.e. in the number of foreign currency units per £.

Consider the chart. On the horizontal axis is plotted the average annual percentage change in the number of foreign currency units per £1 from 1976 to 2016. Positive values indicate that sterling appreciated against that currency; negative values that it depreciated. For instance, sterling appreciated by 0.95 per cent per annum against the Swedish krona, but depreciated by 2.56 per cent per annum against the Japanese yen.

On the vertical axis is plotted the inflation differential; this measures the difference between the average annual rate of inflation in the UK and that in each of the other nine countries. For instance, the average annual British inflation rate was 3.96 percentage points higher than in Japan, but 0.79 percentage points lower than in New Zealand.

If inflation differentials are to be reflected in exchange rate changes we would expect to see the observations for the nine countries lying along the downward-sloping blue line. This links positive values of the inflation differential with the equivalent percentage depreciation; this would be consistent with PPP holding in the long run.

Eight of our nine observations lie to various degrees *above* the blue line. This tells us that that for the inflation rate differential with each country, sterling has appreciated more or depreciated less than might be expected. This means that the *real* exchange rate of sterling has *appreciated* against each country's currency over the period of analysis.

Take Japan as an example. As we noted above, the inflation rate differential with the UK is 3.96 percentage points per annum. The higher rate of inflation in the UK means that the exchange rate would need to depreciate by 3.96 per cent per annum to compensate. Although sterling has indeed depreciated against the yen, it has done so by only 2.56 per cent per annum.

New Zealand is slightly *below* the blue line, consistent with sterling having appreciated less or depreciated more than we would have expected (a depreciation of the real sterling exchange rate). In fact, the real depreciation of sterling against the New Zealand dollar is relatively small. While the average UK annual rate of inflation was 0.79 percentage points lower, the nominal appreciation of sterling was 0.65 percentage points.

From observing the data, it would appear that long-term inflation differentials do affect movements in bilateral exchange rates. However, it also appears that we need to take into account more than just inflation differentials in understanding exchange rate movements. Other causes of exchange rate movements include changes in relative interest rates, various international shocks, longer-term shifts in demand and supply for imports and exports, and speculation.

Identify two factors in the UK economy which help to explain the appreciation of the real exchange rate.

Inflation differentials and appreciation of sterling, 1976–2016

Section summary

1. Under the Bretton Woods system (1945–71), currencies were pegged to the US dollar. The rate was supported from countries' reserves and if necessary with loans from the IMF. If there was a moderate disequilibrium, countries were supposed to use deflationary/reflationary policies. If the disequilibrium became severe, they were supposed to devalue/revalue.
2. The system was claimed to bring certainty for business and a constraint on governments pursuing irresponsible fiscal and monetary policies, while avoiding the problem of a recession if a balance of payments deficit became severe.
3. However, it was sometimes difficult to identify whether a deficit was severe enough to warrant a devaluation; a devaluation itself could be very disruptive for firms; and devaluation at first could make the deficit worse (the J-curve effect). If a country was reluctant to devalue, it would have to rely on deflation and a possible recession to tackle a balance of payments deficit.
4. Problems for deficit countries were made worse by an unwillingness of surplus countries to revalue or reflate.
5. Dollars were the main source of international liquidity under the Bretton Woods system. The USA, by creating dollars to pay for balance of payments deficits, caused excessive liquidity. This caused worldwide inflation, a lack of confidence in the USA and an eventual collapse of the system.
6. Since the early 1970s the world has largely been on a managed floating exchange rate system. The degree of intervention varies from country to country and from time to time.
7. In theory, managed floating can give the necessary degree of exchange rate flexibility in a world where shifts in currency demand and supply have become much larger. It can also release domestic policy from being dominated by balance of payments considerations. At the same time, the intervention could (in theory) prevent violent exchange rate fluctuations and allow a more orderly adjustment to new equilibrium exchange rates.
8. Nevertheless, there are problems under managed floating of predicting long-term equilibrium exchange rates. What is more, with the massive growth in 'hot money' since the early 1970s, it has become increasingly difficult for countries on their own to counteract speculation. The main instrument of intervention has become the rate of interest. There may be a conflict, however, in using interest rates both to control exchange rates *and* to control the domestic economy.
9. Sterling exchange rates have shown considerable volatility over the years, with large divergences from the purchasing-power parity rate. For example, the rise in UK interest rates in 1997–8 caused a large appreciation of sterling, much to the consternation of exporters. The cut in interest rates in 2008 was accompanied by an equally large depreciation.
10. The volatility of exchange rates around the world has grown. Reasons include: a growth in international financial markets and a liberalisation of international financial movements combined with easier computer transfer of funds, a growth in speculative activities and a growing belief in the impotence of governments acting on their own to stabilise rates.

*APPENDIX: THE OPEN ECONOMY AND ISLM ANALYSIS

In this appendix, we show how the *ISLM* analysis that we examined in the appendix to Chapter 19 can be extended to incorporate the open economy. We will first assume a fixed rate of exchange and then later a free-floating rate.

Analysis under a fixed exchange rate

The BP curve

We start by introducing a third curve, the *BP* (balance of payments) curve. This curve, like the *IS* and *LM* curves, plots a relationship between the rate of interest (r) and the level of national income (Y). All points along the *BP* curve represent a position of *balance of payments equilibrium*.

We assume that prices are fixed in the short run; hence a change in the real interest rate (r) corresponds to an equivalent change in the nominal rate of interest (i). The *BP* curve slopes upwards from left to right (see Figure 25.13). Increases

Figure 25.13 The *BP* curve

in the rate of interest (r) will cause the financial account to move into surplus as finance is attracted into the country. Increases in real national income (Y), in contrast, will cause the current account to move into deficit as more imports are purchased. If the overall balance of payments is to stay in equilibrium, current account deficits must be matched by financial (plus capital) account surpluses and vice versa. Thus a rise in Y must be accompanied by a rise in r , and reductions in Y must be accompanied by reductions in r . The BP curve therefore slopes upwards. Any point below the BP line represents a position of overall deficit; any point above the line, a position of surplus.

The slope of the BP curve depends on two factors.

The marginal propensity to import ($mpm = \Delta M/\Delta Y$). The higher the mpm , the steeper will be the BP curve. The reason is that with a high mpm there will be a correspondingly large rise in imports for any given rise in national income. This will cause a large current account deficit. To maintain an overall balance of payments equilibrium, this will require a correspondingly large financial account surplus. This in turn will require a large rise in interest rates. Thus the bigger the mpm , the larger the rise in interest rates that will be necessary to restore balance of payments equilibrium, and hence the steeper will be the BP curve.

The elasticity of supply of international finance. The greater the elasticity of supply of international finance, the less will be the rise in interest rates necessary to attract an inflow of finance and thereby restore balance of payments equilibrium after a rise in national income, and hence the flatter will be the BP curve. In the case of a perfectly elastic supply of international finance, the BP curve will be horizontal at the world rate of interest.

Equilibrium in the model

If we now put the BP curve on an $ISLM$ diagram, we have the position shown in Figure 25.14. Point a represents full equilibrium. At r_1 and Y_1 , investment equals saving (point a is on the IS curve), the demand for money equals the supply

Figure 25.14 Full equilibrium in the goods, money and foreign exchange markets

(point a is also on the LM curve), and finally the balance of payments is in balance (point a is also on the BP curve).

But what is the mechanism that ensures that all three curves intersect at the same point? To answer this question, let us assume that the three curves just happen to intersect at the same point, and then let us examine the effects of changes in fiscal and monetary policies, which shift the IS and LM curves respectively. Will equilibrium be restored? The answer is yes, via a change in the money supply. Let us examine fiscal and monetary policy changes in turn.

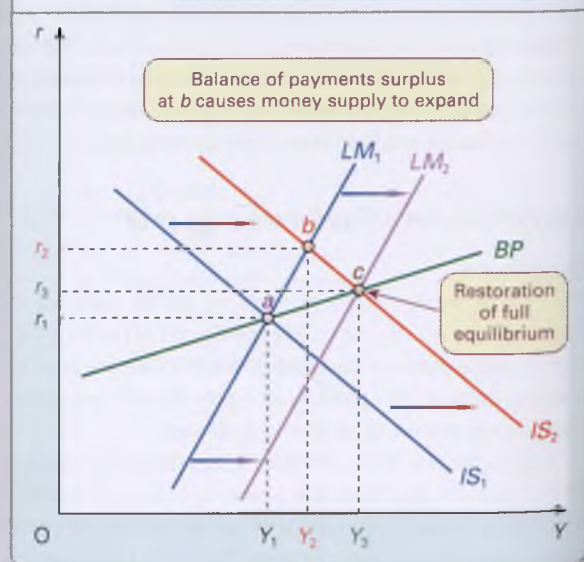

Fiscal policy under fixed exchange rates

An expansionary fiscal policy, i.e. a rise in government spending and/or a reduction in tax, will have the effect of shifting the IS curve to the right (e.g. to IS_2 in Figure 25.15). The reason is that for any given rate of interest there will be a higher equilibrium level of national income than before.

This will increase national income, but the extra demand for money that results will drive up interest rates. In a *closed* economy, equilibrium would now be at point b (r_2, Y_2), where $IS_2 = LM_1$. But in our open economy model, this equilibrium is *above the BP curve*. There is a balance of payments surplus. The reason for this is that the higher interest rates have caused a financial account surplus that is bigger than the current account deficit that results from the higher national income.

Such a surplus will cause the money supply to rise as funds flow into the country. This will in turn cause the LM curve to shift to the right. Equilibrium will finally be achieved at point c (r_3, Y_3), where $IS_2 = LM_2 = BP$. Thus under these conditions, the monetary effect of the change in the balance of payments will *reinforce* the fiscal policy and lead to a bigger rise in national income.

Figure 25.15 An expansionary fiscal policy under fixed exchange rates

What will be the effect of an expansionary fiscal policy on interest rates and national income if there is a perfectly elastic supply of international finance?

If the BP curve were steeper than the LM curve, the effect would be somewhat different. (Remember the BP curve will be steep if there is a high mpm and an inelastic supply of international finance.) This is illustrated in Figure 25.16.

Under these circumstances, an initial rise in national income to Y_2 (where $IS_2 = LM_1$) will cause a balance of payments deficit (point b is below the BP curve). The reason is that this time the current account deficit is bigger than the financial account surplus (due to a large mpm and a small inflow of finance). This will reduce the money supply and cause the LM curve to shift to the left. Equilibrium will be achieved at point c , where $LM_2 = IS_2 = BP$.

When the BP curve is steeper than the LM curve, therefore, the monetary effect of the change in the balance of payments will dampen the effect of the fiscal policy and lead to a smaller rise in national income.

Monetary policy under fixed exchange rates

An expansionary monetary policy will cause the LM curve to shift to the right (e.g. to LM_2 in Figure 25.17). The increased supply of money will drive down the rate of interest and increase national income. In a closed economy, equilibrium would now be at point b (r_2, Y_2), where $LM_2 = IS$. But in an open economy, this extra demand will have sucked in extra imports, and the lower interest rate will have led to net financial outflows. There will be a balance of payments deficit: point b is below the BP curve.

The balance of payments deficit will cause the money stock to fall as money flows abroad. This will cause the LM

curve to shift back again to its original position. The economy will return to its initial equilibrium at point a .

Thus under a fixed exchange rate regime, monetary policy alone will have *no long-term effect* on national income and employment. Only when accompanied by an expansion in aggregate demand (either through fiscal policy or through an autonomous rise in investment or a fall in savings) will an expansion of money supply lead to higher national income.

1. Why does this conclusion remain the same if the BP curve is steeper than the LM curve?
2. Trace through the effects of a fall in exports (thereby shifting the BP curve).
3. Show what will happen if there is (a) a rise in business confidence and a resulting increase in investment; (b) a rise in the demand for money balance (say, for precautionary purposes).

Analysis under free-floating exchange rates

As the exchange rate changes, the BP curve will shift (see Figure 25.18). If the IS and LM curves intersect *above* the BP curve, there will be a balance of payments surplus. This will cause the exchange rate to appreciate. The appreciation will cause the surplus to disappear. This in turn will cause the BP curve to shift upwards.

Similarly, if the IS and LM curves intersect *below* the BP curve, the resulting balance of payments deficit will cause a depreciation and a downward shift of the BP curve. Thus the BP curve will always shift so that it intersects where the IS and LM curves intersect.

Figure 25.16 An expansionary fiscal policy under fixed exchange rates: a steep BP curve

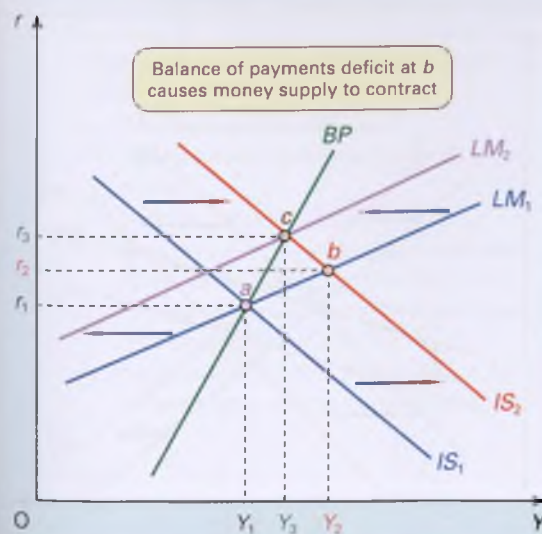

Figure 25.17 An expansionary monetary policy under fixed exchange rates

Fiscal policy under floating exchange rates

Assume that the government pursues a reflationary fiscal policy. The IS curve shifts to IS_2 in Figure 25.19.

At point b , where the LM curve and the new IS curve intersect, there is a balance of payments surplus (due to higher financial inflows attracted by the higher rate of interest). This causes the exchange rate to appreciate and the BP curve to shift upwards.

But the higher exchange rate will cause a fall in exports and a rise in imports. This fall in aggregate demand will cause the IS curve to shift back towards the left. The new equilibrium will be at a point such as c . This represents only a modest change from point a . Thus under a floating exchange rate the effects of fiscal policy may be rather limited.

The effect will be stronger, however, the steeper the BP curve. In Figure 25.20, the BP curve is steeper than the LM

curve. This time a rise in the IS curve from IS_1 to IS_2 will lead to a balance of payments deficit and hence a depreciation of the exchange rate. The BP curve will shift downwards. The depreciation will cause a rise in exports and a fall in imports. This rise in aggregate demand will cause the IS curve to shift to the right. The new equilibrium will be at point c , which is at a higher level of national income, Y_3 . Under these circumstances, the balance of payments effect makes fiscal policy stronger.

Under what circumstances would an expansionary fiscal policy have no effect at all on national income?

Figure 25.18 Movements of the BP curve under floating exchange rates

Figure 25.19 An expansionary fiscal policy under floating exchange rates

Figure 25.20 An expansionary fiscal policy under floating exchange rates: steep BP curve

Figure 25.21 An expansionary monetary policy under floating exchange rates

Monetary policy under floating exchange rates

An expansionary monetary policy will shift the LM curve to the right, to LM_2 in Figure 25.21. In a closed economy, equilibrium would now be at point b .

In an open economy under a floating exchange rate, the fall in the rate of interest will cause the exchange rate to depreciate and the BP curve to shift downwards. The depreciation will cause exports to rise and imports to fall. This

increase in aggregate demand will shift the IS curve to the right. The new equilibrium will thus be at point c , where $LM_2 = IS_2 = BP_2$. This represents a large change from the initial point a .

Thus monetary policy can have a substantial effect on the level of national income under a system of floating exchange rates.

What will determine the size of the shift in the BP curve in each case?

Appendix summary

1. A BP curve can be added to an $ISLM$ diagram. It shows all the combinations of national income and interest rates at which the balance of payments is in equilibrium. The curve is upward sloping, showing that a rise in national income (causing a current account deficit) will require a rise in interest rates to give a counterbalancing financial account surplus.
2. The lower the mpm and the more elastic the supply of international finance, the flatter will be the BP curve.
3. Under a fixed exchange rate, the flatter the BP curve, the larger will be the effect on national income of an expansionary fiscal policy. Provided the BP curve is flatter than the LM curve, an expansionary fiscal policy will cause a balance of payments surplus (via its effect of increasing interest rates). The resulting increase in money supply will strengthen the initial effect of the fiscal policy.
4. Monetary policy under fixed exchange rates will have no effect on national income. Any expansion of money supply will, by depressing interest rates, simply lead to a balance of payments deficit and thus a reduction in the money supply again.
5. Under a floating exchange rate an appreciation will shift the BP curve upwards and a depreciation will shift it downwards.
6. If the BP curve is flatter than the LM curve, fiscal policy under a floating exchange rate will be dampened by the resulting changes in the exchange rate. An expansionary fiscal policy will lead to an appreciation (due to the effects of higher interest rates), which in turn will dampen the rise in aggregate demand.
7. Monetary policy will have a relatively large effect on aggregate demand under floating rates. A rise in money supply will reduce interest rates and raise aggregate demand. This will cause a balance of payments deficit and thus a depreciation. This in turn will lead to a further expansion of aggregate demand.

END OF CHAPTER QUESTIONS

1. Assume a free-floating exchange rate. Draw a diagram like Figure 25.6 (on page 759), only this time show an initial equilibrium national income with a balance of payments surplus.
 - (a) Mark the size of the surplus.
 - (b) Show the resulting shifts in the $(X-M)$ and the E curves.
 - (c) Mark the eventual equilibrium.
 - (d) Show the size of the income and substitution effects (of the change in the exchange rate).
 - (e) Under what circumstances will the income effect be (i) 'desirable'; (ii) 'undesirable'?
 - (f) Could the income effect of the change in the exchange rate ever be larger than the substitution effect?
2. Compare the relative effectiveness of fiscal and monetary policy under (a) fixed; (b) free-floating exchange rates. How is the effectiveness influenced by the elasticity of supply of international finance?
3. What will be the effects on the domestic economy under free-floating exchange rates if there is a rapid expansion in world economic activity? What will determine the size of these effects?
4. The following table shows a selection of nominal exchange rate indices (effective exchange rates) for the years 2010 to 2016, based on 2010 = 100.
 - (a) Explain what is meant by an exchange rate index/ an effective exchange rate.
 - (b) Calculate the annual rate of appreciation or depreciation for each currency for each year from 2010.

(continued)

	2010	2011	2012	2013	2014	2015	2016
Australian \$	100.0	107.10	109.32	103.23	97.87	88.75	89.35
US \$	100.0	95.48	98.24	99.36	102.33	115.24	120.33
Japanese yen	100.0	105.72	107.21	87.09	81.50	76.57	88.30
Sterling	100.0	99.37	103.17	101.06	108.09	114.10	102.73
Euro	100.0	100.49	95.83	100.10	102.47	95.10	98.48
Chinese yuan	100.0	100.19	105.92	111.87	114.71	125.65	119.91

Source: Based on data from Bank for International Settlements.

- (c) Calculate the percentage appreciation or depreciation of each currency when comparing 2016 with 2010.
- For what reasons might the exchange rate diverge from the purchasing-power parity rate over the longer term?
 - Why does exchange rate overshooting occur? What determines its magnitude?
 - Consider the argument that in the modern world of large-scale, short-term international capital movements, the ability of individual countries to affect their exchange rate is very limited.
 - If speculators had better information about future exchange rates, would their actions be more or less stabilising than at present?
 - Using *ISLMBP* analysis, trace through the effect of (a) a deflationary fiscal policy and (b) a deflationary monetary policy under (i) a fixed exchange rate; (ii) a free-floating exchange rate.

The oil shocks of the 1970s	854
Coping with debt: rescheduling	854
Dealing with debt: structural reform within the developing countries	856
Dealing with debt: debt forgiveness	857

With the growth in globalisation, countries have become increasingly dependent on each other. In the first section, we explore the nature of the interdependence of economies and why countries are so vulnerable to international fluctuations. We then look at what can be done to create a greater co-ordination of international economic policies and consider the role of the G7 and G20 countries in this process.

The extreme solution to currency instability is for countries to adopt a common currency. In section 26.2, we look at the euro and how economic and monetary union (EMU) operates. Has the adoption of a single currency by 19 EU countries been of benefit to them? How have the members sought to tackle the problems of some of the member states?

Then we turn to the economic problems of the poorer countries of the world. These include all the countries of Africa and Latin America and most of the countries of Asia. More than three-quarters of the world's population lives in these countries. As Theodore Schultz said when accepting the Nobel Prize in Economics in 1979:

Most of the people of the world are poor, so if we knew the economics of being poor we would know much of the economics that really matters.

In section 26.3 we look at the nature and extent of their poverty and the means by which it can be measured. Then, in section 26.4, we look at the trade relations between the poorer countries and the advanced industrialised world. As we shall see, most developing countries are highly dependent for their development, or lack of it, on their relationships with the rich world.

The final section looks at one of the most serious problems facing poorer countries: the problem of huge international debts. We look at various measures to reschedule debts so as to reduce repayments. We also look at various moves to cancel some of the debts, especially of the poorest countries.

26.1 GLOBALISATION AND THE PROBLEM OF INSTABILITY

We live in an interdependent world. Countries are affected by the economic health of other countries and by their governments' policies. Problems in one part of the world can spread like a contagion to other parts, with perhaps no country immune.

There are two major ways in which this process of 'globalisation' affects individual economies. The first is through trade. The second is through financial markets.

Interdependence through trade

So long as nations trade with one another, the domestic economic actions of one nation will have implications for those which trade with it. For example, if the US administration feels that the US economy is growing too fast, it might adopt various contractionary fiscal and monetary measures, such as higher tax rates or interest rates. US consumers will not only consume fewer domestically produced goods, but also reduce their consumption of imported products. But US imports are other countries' exports. A fall in these other countries' exports will lead to a multiplier effect in these countries. Output and employment will fall.

Changes in aggregate demand in one country thus send ripples throughout the global economy. The process whereby changes in imports into (or exports from) one country affect national income in other countries is known as the *international trade multiplier*.

? Assume that the US economy expands. What will determine the size of the multiplier effect on other countries?

The more open an economy, the more vulnerable it will be to changes in the level of economic activity in the rest of the world. This problem will be particularly acute if a nation is heavily dependent on trade with one other nation (e.g. Canada on the USA) or one other region (e.g. Switzerland on the EU).

Until very recently, international trade had been growing as a proportion of countries' national income for many years. This is illustrated in Figure 26.1, which shows the ratio of the sum of global exports and imports of goods and services to global GDP since 1960. This is the measure of openness we introduced in Chapter 24 (see page 747). Over the period, the ratio has risen from 24 per cent to around 60 per cent.

With most nations still committed to freer trade, and with the WTO overseeing the dismantling of trade barriers, so international trade may continue growing as a proportion of world GDP. This will increase countries' interdependence and their vulnerability to world trade fluctuations, such as the global recession of the late 2000s. World output fell by 2.1 per cent in 2009 (at market exchange rates), while the volume of goods and services (imports and exports) fell by 10.5 per cent. This was the biggest contraction in global trade since the Second World War.

Definition

International trade multiplier The effect on national income in country B of a change in exports (or imports) of country A.

Figure 26.1 World trade in goods and services (imports plus exports) as a percentage of GDP

There is some doubt, however, over world attitudes towards free trade. With the growth in protectionist rhetoric under the Trump administration and in other countries, it is possible that world trade may have peaked as a proportion of GDP – at least for the time being.

Are exports likely to continue growing faster than GDP indefinitely? What will determine the outcome?

Financial interdependence

International trade has grown rapidly over the past 30 years, but international financial flows have grown much more rapidly. Trillions of dollars are traded across the foreign exchanges each day. Many of the transactions are short-term financial flows, moving to where interest rates are most favourable or to currencies where the exchange rate is likely to appreciate. This has meant that non-deposit financial institutions like pension funds, insurance companies and investment trusts have become important players on foreign exchange markets.

In Chapter 18 we identified a variety of financial instruments. The global nature of financial systems means that these financial instruments readily cross national borders. It also means that financial institutions operating in one country will have liabilities to foreign residents (individuals and institutions).

Figure 26.2 shows the growth in the claims of foreign residents on banks operating in the UK which take the form of sterling-denominated sight deposits, time deposits and repos. Holdings by foreign residents of these three financial instruments rose from £135 billion at the beginning of 1998 (11 per cent of sterling liabilities) to nearly £630 billion in April 2008

(21 per cent of sterling liabilities). By March 2017, following the global banking crisis and subsequent consolidation by banks of their balance sheets, the value of these liabilities was £446 billion (12 per cent of sterling liabilities), but this was still well above the 1998 values, even after taking inflation into account.

Another demonstration of global financial interdependence is the foreign holdings of government securities. Figure 26.3 shows the importance of foreign demand for British gilts, i.e. for long-term British government securities. At the start of 1987, about £15 billion worth of gilts were held overseas, the equivalent to 11 per cent of holdings of gilts. By 2008, the total had risen to £191 billion or 36 per cent of all holdings. Then, with government borrowing rising rapidly in the aftermath of the financial crisis, foreign holdings rose rapidly, but not as rapidly as domestic holdings, so that by the start of 2017, although foreign holding had risen to close to £525 billion, the percentage had fallen to 28 per cent of holdings.¹ In Box 26.1 we consider the significance of foreign purchases of American government debt.

A stark example of global financial interdependence was the collapse of the sub-prime credit markets in the USA in the late 2000s, which spread like a contagion to cause a global recession. Household debt in many advanced economies, including the UK and USA, had grown markedly as a proportion of household disposable income. Between 1995 and 2007, the stock of debt held by UK households increased from around 100 per cent to 175 per cent of annual disposable income (see Box 17.2). In the USA over the same period, the stock of household debt increased from 95 to 145 per cent of annual disposable income.

¹ Note that this still means that the bulk of national debt is held by residents in the UK. In other words, most of what the government owes is in the form of the savings by UK individuals and companies.

BOX 26.1 ECONOMIC AND FINANCIAL INTERDEPENDENCIES: TRADE IMBALANCE IN THE US AND CHINA

Is the world paying for excessive American expenditure?

America's current account deficit

In 2016, the USA had a current account deficit of \$481 billion – the equivalent of 2.6 per cent of GDP (see chart). American current account deficits are not new. Over the 20-year period up to 2016, the US current account deficit has averaged 3.6 per cent of GDP, reaching as high as 5.9 per cent in 2006.

The current account deficit is offset by an equal and opposite capital-plus-financial account surplus, much of which consists of the purchase of US government bonds and Treasury bills. These massive inflows to the USA are thought to represent some three-quarters of all the savings which the rest of the world invests abroad. These financial inflows have

permitted the persistence of sizeable US current account deficits.

To attract such large inflows, it might be expected that US interest rates would have to be high. Yet for much of the 2000s they were at historically low levels. Nominal interest rates from mid-2003 to mid-2004 were a mere 1 per cent (see chart in Box 25.5 on pages 806–7) and real rates were close to minus 1.5 per cent. Similarly, since the financial crisis of the late 2000s, interest rates have been very low by comparison with other countries. How is it, then, that with such low interest rates, the USA has managed to attract such vast inflows of finance and thereby maintain such a large financial account surplus?

Note: 2017 figures are forecasts.

Source: Based on data from World Economic Outlook Database (IMF).

As we discussed in section 18.2, the growth of domestic credit has been facilitated both by financial deregulation, including the removal of capital controls, and the greater use by financial institutions of wholesale funding. The process of securitisation (see page 561–3), for instance, enabled financial institutions to raise capital from financial investors across the globe in order to provide domestic households with both mortgages and short-term credit. In other words, the aggressive expansion of domestic banks' balance sheets was funded by international financial flows.

Financial deregulation and innovation has therefore created a complex chain of interdependencies between financial institutions, financial systems and economies. But this chain is only as strong as its weakest link. In the financial crisis of the late 2000s overly aggressive lending practices by banks in one part of the world impacted on financial investors worldwide. As US interest rates rose from 2004 to 2007 (see figure in Box 25.5), the income flows from American households to banks began to dry up; US households began

to fall in arrears and, worse still, default on their loans. But these income flows were the source of the return for global financial investors who had purchased collateralised debt obligations (see page 561). Hence, the new financial order meant the contagion went international.

Global financial interdependence also means that changes in interest rates in one country can affect the economies of other countries. Assume that the Federal Reserve Bank in the USA, worried about rising inflation, decides to raise interest rates. What will be the effect on business in America's trading partners? There are three major effects.

- If aggregate demand in America falls, so will its expenditure on imports from firms abroad, thus directly affecting businesses exporting to the USA. With a decline in their exports, aggregate demand in these other countries falls.
- The higher interest rate in the USA will tend to drive up interest rates in other countries. This will depress investment. Again, aggregate demand will tend to fall in these countries.

CASE STUDIES AND APPLICATIONS

China's appetite for dollars

Several Asian currencies, including the Chinese yuan (or 'renminbi'), were pegged to the dollar and had been running large current account surpluses. For instance, the Chinese current account surplus was running as high as 8 to 9 per cent of GDP during the 2000s (see chart). Instead of letting the yuan appreciate against the dollar, the Chinese central bank used the surpluses to buy dollars.

There were three perceived advantages in doing this. First, it allowed China to *build up reserves* and thereby bolster its ability to resist any future speculative attacks on its currency. Chinese foreign exchange reserves rose from around \$170 billion in 2000 to \$4 trillion in 2014 – a staggering 24-fold increase. The effect was a huge increase in global liquidity and hence money supply.

Second, and more important, it *kept their exchange rates low* and thereby helped to keep their exports competitive. This helped to sustain their rapid rates of economic growth. Third, it helped to *keep US interest rates down* and therefore boost US spending on Asian exports.

In 2005, the Chinese, after much international pressure, agreed to revalue the yuan and would then peg it against a basket of currencies with subsequent further revaluations. Between July 2005 and July 2008 the yuan was allowed to appreciate by around 18 per cent against the US dollar while the exchange rate index rose by 7 per cent (the exchange rate index of the US dollar fell by 15 per cent).

But, with the global economic downturn biting in 2008 and concerns about slowing Chinese export growth, the Chinese authorities effectively fixed the yuan once again.

This remained the case until June 2010 when again the yuan was revalued. Between June 2010 and January 2014 the yuan appreciated a further 12 per cent against the US dollar. Therefore, over the period from July 2005 to January 2014 the yuan had appreciated by around 33 per cent against the US dollar.

China's economic slowdown

The managed appreciation of the yuan, coupled with the slowdown of the global economy, saw China's current account surplus begin to wane, falling from 9 per cent of GDP in 2008 to 1½ per cent by 2013. Meanwhile, though still sizeable, the USA's current account deficit had shrunk. By 2013 the deficit had fallen to 2.2 per cent of GDP – less than half the level of the mid-2000s.

China's economic growth rate, which had been as high as 14 per cent in 2007, had fallen back to around 8 per cent in 2012 and 2013 and to around 7 per cent in 2014 to 2016 (see figure in Box 1.4 on page 22). This weakening of growth reflected a sharp decline in the growth of China's exports of goods and services. While export volumes grew by 24 per cent per annum from 2002 to 2007, from 2012 to 2016 export growth was just 4 per cent per annum and the indication pointed to the slowdown gathering pace (the IMF has forecast an annual export growth of under 3 per cent from 2017 to 2022).

In late 2014, China's central bank began cutting interest rates in response to weaker growth. Then, in August 2015, it took the step to devalue the yuan by 2 per cent against the US dollar. However, this raised concerns of further devaluations and loosening of monetary policy. Hence, the yuan began falling more sharply.

The central bank responded by *selling* dollars to curb the depreciation. Despite this, the yuan depreciated by over 6 per cent against the now rising dollar in 2016 on the back of rising US interest rates (see Box 25.5). Hence, private capital was now being attracted to the USA, while China was experiencing 'capital flight'. In its efforts to support the yuan, China's stock of foreign exchange reserves are estimated to have fallen by \$830 billion during 2015 and 2016 to a little over \$3 trillion (a fall of nearly 22 per cent).

Examine the merits for the Chinese of (a) floating the yuan freely; (b) pegging it to a trade-weighted basket of currencies.

- The higher interest rate will attract an inflow of funds to the USA from other countries. This will cause the dollar to appreciate relative to other currencies, which will make these other countries' exports to the USA more competitive and imports from the USA relatively more expensive. This will result in an improvement in the current account of the USA's trading partners: their exports rise and imports fall. This represents a *rise* in aggregate demand in these countries – the opposite from the first two effects.

What will be the effect on the UK economy if the European Central Bank cuts interest rates?

International business cycles

There is an old saying: 'If America sneezes, the rest of the world catches a cold.' Viruses of a similar nature regularly infect the world economy. The credit crunch of 2007/8 resulting from defaults on US sub-prime debt was a dramatic example of this. As a consequence of both trade and financial interdependence, the world economy, like the economy of any individual country, tends to experience periodic fluctuations in economic activity – an *international* business cycle. The implication of this is that countries will tend to share common problems and concerns at the same time. At one time, the most pressing problem may be world inflationary pressures; at another time, it may be a world recession.

In order to avoid 'beggar-my-neighbour' policies, it is better to seek *common* solutions to these common problems: i.e. solutions that are international in scope and design rather than narrowly based on national self-interest. For example, during a world recession, countries are likely to suffer from rising unemployment. Policies that lead to a depreciation of the exchange rate (such as cutting interest rates) will help to stimulate demand by making exports cheaper and imports more expensive. But this will then only worsen the trade balance of other countries, whose aggregate demand will thus fall. The first country is thus tackling its own unemployment at the expense of rising unemployment in other countries.

However, if other nations (which will also be experiencing higher unemployment) can be convinced to co-ordinate their policy actions, an expansionary *international* economic policy will benefit all. In addition to the resulting rise in their imports, all nations will also experience rising export sales.

Even if national policies are not in the strictest sense co-ordinated, discussions between nations regarding the nature and magnitude of the problems they face may help to improve the policy-making process.

Give some examples of beggar-my-neighbour policies.

The need for international policy co-ordination

Global economic interdependence and an international business cycle can aid the process of international co-operation between countries. For instance, in response to the financial crisis of the late 2000s world leaders were seriously worried that the whole world would plunge into recession. What was needed was a co-ordinated policy response from governments and central banks. This came in October 2008 when governments in Britain, Europe, North America and other parts of the world injected some \$2 trillion of extra capital into banks.

Countries frequently meet in various groupings – from the narrow group of the world's seven richest countries (the G7) to broader groups such as the G20, which, in addition to the G7 and other rich countries, also includes larger developing countries, such as China, India, Brazil and Indonesia.

Today the G20 is considered to be the principal economic forum for discussing global economic and other concerns and for considering policy responses. In effect, the emergence of the G20 as the premier global forum recognises two important developments:

- First, there has been a remarkable growth seen in emerging economies such as India and China (see sections 24.1 and 26.4).
- Second, the increasing scale of interdependency through trade and finance typically requires a co-ordinated response from a larger representation of the international community.

Global interdependence also raises questions about the role that international organisations like the World Trade Organization (WTO) and the International Monetary Fund (IMF) should play. The WTO's role is to encourage freer trade. We considered its role in section 24.2. The IMF's remit is to promote global growth and stability, to help countries through economic difficulty and to help developing economies achieve macroeconomic stability and reduce poverty. In response to the global economic and financial crisis of the late 2000s, the IMF's budget was substantially increased and it became more actively involved with what were previously defined as 'strong performing economies'.

International harmonisation of economic policies

The five main underlying causes of exchange rate movements are divergences in *interest rates*, *growth rates*, *inflation rates*, *current account balance of payments* and *government deficits*. Table 26.1 shows the variation in the levels of these indicators across a sample of nine countries. These divergences still remain considerable.

An important issue for G8 and G20 meetings is how to generate world economic growth without major currency fluctuations. To achieve this it is important that there is a

Table 26.1 International macroeconomic indicators

		Australia	Canada	China	France	Ireland	Germany	Japan	UK	USA
Nominal exchange rate index (annual % change)	1997–2001	-3.4	-1.6	2.7	-2.3	-1.2	-2.8	0.3	3.5	4.2

harmonisation of economic policies between nations. In other words, it is important that all the major countries are pursuing consistent policies aiming at common international goals.

But how can policy harmonisation be achieved? As long as there are significant domestic differences between the major economies, there is likely to be conflict, not harmony. For example, if one country, say the USA, is worried about the size of its budget deficit, it may be unwilling to respond to world demands for a stimulus to aggregate demand to pull the world economy out of recession. What is more, speculators, seeing differences between countries, are likely to exaggerate them by their actions, causing large changes in exchange rates. The G8 countries have therefore sought to achieve greater **convergence** of their economies. But whilst convergence may be a goal of policy, in practice it has proved more elusive.

Referring to Table 26.1, in what respects was there greater convergence between these countries in the period 2012–16 than in the period 2002–6?

Because of a lack of convergence, there are serious difficulties in achieving international policy harmonisation:

- Countries' budget deficits and national debt may differ substantially as a proportion of their national income. This puts very different pressures on the interest rates necessary to service these debts. In 2016, the UK had a general government gross debt to GDP ratio of 89 per cent. This compared with 41 per cent for Australia,

Definition

International harmonisation of economic policies Where countries attempt to co-ordinate their macroeconomic policies so as to achieve common goals.

Convergence of economies When countries achieve similar levels of growth, inflation, budget deficits as a percentage of GDP, balance of payments, etc.

- 68 per cent for Germany, 92 per cent for Canada, 97 per cent for France and 239 per cent for Japan.
- Harmonising rates of monetary growth or inflation targets would involve letting interest rates fluctuate with the demand for money. Without convergence in the demand for money, interest rate fluctuations could be severe.
 - Harmonising interest rates would involve abandoning monetary, inflation and exchange rate targets (unless interest rate 'harmonisation' meant adjusting interest rates so as to maintain monetary or inflation targets or a fixed exchange rate).
 - Countries have different internal structural relationships. A lack of convergence here means that countries with higher endemic *cost* inflation would require higher interest rates and higher unemployment if international inflation rates were to be harmonised, or higher inflation if interest rates were to be harmonised.
 - Countries have different rates of productivity increase, product development, investment and market penetration. A lack of convergence here means that the growth in exports (relative to imports) will differ for any given level of inflation or growth.

- Countries may be very unwilling to change their domestic policies to fall in line with other countries. They may prefer the other countries to fall in line with them!

If any one of the five – interest rates, growth rates, inflation rates, current account balance of payments or government deficits – could be harmonised across countries, it is likely that the other four would then not be harmonised.

Total convergence and thus total harmonisation may not be possible. Nevertheless, most governments favour some movement in that direction: some is better than none. To achieve this, co-operation is necessary.

Although co-operation is the ideal, in practice discord often tends to dominate international economic relations. The reason is that governments are normally concerned with the economic interests of other countries only if they coincide with those of their own country. This, however, can create a prisoners' dilemma problem (see pages 235–7 and 403–5). With each country looking solely after its own interests, the world economy suffers and everyone is worse off.

If total convergence were achieved, would harmonisation of policies follow automatically?

Section summary

1. Changes in aggregate demand in one country will affect the amount of imports purchased and thus the amount of exports sold by other countries and hence their national income. There is thus an international trade multiplier effect.
2. Changes in interest rates in one country will affect financial flows to and from other countries, and hence their exchange rates, interest rates and national income.
3. To prevent problems in one country spilling over to other countries and to stabilise the international business cycle will require co-ordinated policies between nations.
4. Currency fluctuations can be lessened if countries harmonise their economic policies. Ideally this will involve achieving compatible growth rates, inflation rates, balance of payments and government deficits (as percentages of GDP) and interest rates. The attempt to harmonise one of these goals, however, may bring conflicts with one of the other goals.
5. Leaders of the G8 and G20 countries meet at least annually to discuss ways of harmonising their policies. Usually, however, domestic issues are more important to the leaders than international ones, and frequently they pursue policies that are not in the interests of the other countries.

26.2 EUROPEAN ECONOMIC AND MONETARY UNION (EMU)

The ultimate way for a group of countries to achieve greater currency stability between themselves is to adopt a single currency and, therefore, to have a common central bank and a common monetary policy – to form an *economic and monetary union (EMU)*. This is what has happened in the EU, with countries coming together to adopt a single currency – the euro. The euro began in 1999, with notes and coins circulating from 2002. Initially 11 countries joined; by 2015 there were 19 members.

Definition

Economic and monetary union (EMU) The adoption by a group of countries of a single currency with a single central bank and a single monetary policy. In the EU the term applies to the countries that have adopted the euro.

The ERM (exchange rate mechanism)

The forerunner to EMU was the *exchange rate mechanism (ERM)*. This was an adjustable peg system, where members pegged their exchange rates to each other while floating against the rest of the world. This encouraged trade between the members and enabled the combined reserves of all member countries to prevent excessive fluctuations of their currencies with the rest of the world.

Under the system, each currency was given a central exchange rate with each of the other ERM currencies in a grid. However, fluctuations were allowed from the central rate within specified bands, typically of up to 0.25 per cent. The central rates were adjusted from time to time by agreement. All the currencies floated jointly with currencies outside the ERM.

If a currency approached the upper or lower limit against any other ERM currency, intervention would take place to maintain the currencies within the band. This would take the form of central banks in the ERM selling the strong currency and buying the weak one. It could also involve the weak currency countries raising interest rates and the strong currency countries lowering them.

The ERM in practice

The ERM came into existence in March 1979 and the majority of the EU countries were members. The UK, however, initially chose not to join. Spain joined in 1989, the UK in 1990 and Portugal in April 1992.

Sterling entered the ERM at a central rate of £1 = 2.95 German marks with permitted fluctuations of ± 6 per cent against any other ERM currency. This rate proved unsustainable. German interest rates were rising to dampen inflationary pressures partly fuelled by substantial public expenditures following the reunification of Germany. US interest rates by contrast were falling to help stimulate economic growth in the face of recession. The result was a large outflow of capital from the USA, much of it going to Germany. The effect was to push up the value of the German mark. Consequently, currencies like sterling and the Italian lira were repeatedly at the bottom of their permitted exchange rate band with the mark. This was despite high and rising interest rates and, in the case of the UK, despite the economy sliding rapidly into recession.

In September 1992, things reached a crisis point. On 16 September – known thereafter as ‘Black Wednesday’ – the UK and Italy were forced to suspend their membership of the ERM. Both currencies were floated and depreciated substantially.

Turmoil returned in the summer of 1993, with pressure this time on the French franc. In response, EU finance ministers agreed to adopt very wide ± 15 per cent bands, though with bands this wide it hardly seemed like a ‘pegged’ system at all. Within months, however, the crisis passed and exchange rate fluctuations began to fall within a very narrow range and for most of the time within ± 2.25 per cent.

Italy rejoined the ERM in November 1996 as part of its bid to join the single European currency. Austria joined in 1995, Finland in 1996 and Greece in 1998. By the time the ERM was replaced by the single currency in 1999, only Sweden and the UK were outside the ERM.

The Maastricht Treaty and the road to the single currency

The ERM was conceived as a stage on the road to complete economic and monetary union (EMU) of member states. Details of the path towards EMU were finalised in the Maastricht Treaty, which was signed in February 1992. The timetable for EMU involved the adoption of a single currency by 1999 at the latest.

Before they could join the single currency, member states were obliged to achieve convergence of their economies. Each country had to meet five convergence criteria:

- Inflation: should be no more than 1.5 per cent above the average inflation rate of the three countries in the EU with the lowest inflation.
- Interest rates: the rate on long-term government bonds should be no more than 2 per cent above the average of the three countries with the lowest inflation rates.
- Budget deficit: should be no more than 3 per cent of GDP at market prices.
- National debt: should be no more than 60 per cent of GDP at market prices.
- Exchange rates: the currency should have been within the normal ERM bands for at least two years with no realignments or excessive intervention.

Before the launch of the single currency, the Council of Ministers had to decide which countries had met the convergence criteria and would thus be eligible to form a *currency union* by fixing their currencies permanently to the euro. Their national currencies would effectively disappear.

At the same time, a European System of Central Banks (ESCB) would be created, consisting of a European Central Bank (ECB) and the central banks of the member states. The ECB would be independent, both from governments and from EU political institutions. It would operate the monetary policy on behalf of the countries that had adopted the single currency.

Definitions

Exchange rate mechanism A semi-fixed system whereby participating EU countries allow fluctuations against each other's currencies only within agreed bands. Collectively they float freely against all other currencies.

Currency union A group of countries (or regions) using a common currency.

The birth of the euro

In March 1998, the European Commission ruled that 11 of the 15 member states were eligible to proceed to EMU in January 1999. The UK and Denmark were to exercise their opt-out, and Sweden and Greece failed to meet one or more of the convergence criteria. (Greece joined the euro in 2001.)

All 11 countries unambiguously met the interest rate and inflation criteria, but doubts were expressed by many 'Eurosceptics' as to whether they all genuinely met the other three criteria.

- **Exchange rates.** Neither Finland nor Italy had been in the ERM for two years and the Irish punt was revalued by 3 per cent on 16 March 1998. However, the Commission regarded these three countries as being sufficiently close to the reference value.
- **Government deficits.** All 11 countries met this criterion, but some countries only managed to achieve a deficit of 3 per cent or below by taking one-off measures, such as a special tax in Italy and counting privatisation receipts in Germany. Yet, under the Stability and Growth Pact, eurozone countries would be required to keep their deficits within the 3 per cent limit (see Box 22.4). The concern was that countries that only just met this criterion at time of entry would find it difficult to keep within the limit in times of recession or slow growth. This proved to be the case with France and Germany from 2002 to 2005.
- **Government debt.** Only four countries had debts that did not exceed 60 per cent (France, Finland, Luxembourg and the UK). However, the Maastricht Treaty allowed countries to exceed this value as long as the debt was 'sufficiently diminishing and approaching the reference value at a satisfactory pace'. Critics argued that this phrase was interpreted too loosely.

The euro came into being on 1 January 1999, but euro banknotes and coins were not introduced until 1 January 2002. In the meantime, national currencies continued to exist alongside the euro, but at irrevocably fixed rates. The old notes and coins were withdrawn a few weeks after the introduction of euro notes and coins.

Ten new members joined the EU in May 2004, and another two in January 2007. Under the Maastricht Treaty, they were all required to make preparations for joining the euro by meeting the convergence criteria and being in a new version of the exchange rate mechanism with a wide exchange rate band. Under ERM II, euro candidate countries must keep their exchange rates within ± 15 per cent of a central rate against the euro. Estonia, Lithuania and Slovenia were the first to join ERM II in June 2004 with Latvia, Cyprus, Malta and Slovakia following in 2005. Slovenia adopted the euro in 2007, Malta and Cyprus in 2008, Slovakia in 2009, Estonia in 2011, Latvia in 2014 and Lithuania in 2015, making a total of 19 countries using the euro.

Advantages of the single currency

EMU has several major advantages for its members.

Elimination of the costs of converting currencies. With separate currencies in each of the EU countries, costs were incurred each time one currency was exchanged into another. The elimination of these costs, however, was probably the least important benefit from the single currency. The European Commission estimated that the effect was to increase the GDP of the countries concerned by an average of only 0.4 per cent and perhaps less so for those countries with well-developed financial markets.

Increased competition and efficiency. Not only does the single currency eliminate the need to convert one currency into another (a barrier to competition), but it has brought more transparency in pricing, and has put greater downward pressure on prices in high-cost firms and countries. This, of course, does not necessarily favour business, which might find its profits squeezed, but it generally benefits consumers. Although there has been some price convergence across the eurozone, it has not been as extensive as many thought it would be.

Elimination of exchange rate uncertainty (between the members). Removal of exchange rate uncertainty has helped to encourage trade between the eurozone countries. Perhaps more importantly, it has encouraged investment by firms that trade between these countries, given the greater certainty in calculating costs and revenues from such trade.

In times of economic uncertainty, such as the credit crunch of 2008, exchange rate volatility between countries can be high, as we saw with the experience of sterling. However, if the UK had adopted the euro, the uncertainty created by this volatility for the UK in its trade with the eurozone countries would have been eliminated.

Increased inward investment. Investment from the rest of the world is attracted to a eurozone of some 340 million inhabitants, where there is no fear of internal currency movements. As well as potentially increasing its global share of FDI, by removing the uncertainty arising from possible exchange rate volatility between its 19 members, the eurozone countries may experience less volatility in FDI flows than would otherwise be the case.

Lower inflation and interest rates. A single monetary policy forces convergence in inflation rates (just as inflation rates are very similar between the different regions within a country). With the ECB being independent from short-term political manipulation, this has resulted in a low average inflation rate in the eurozone countries. This, in turn, has helped to convince markets that the euro will be strong relative to other currencies. The result is lower long-term rates of interest. This, in turn, further encourages investment in the eurozone countries, both by member states and by the rest of the world.

Opposition to EMU

European monetary union has, however, attracted considerable criticism. Many 'Eurosceptics' see within it a surrender of national political and economic sovereignty. Their arguments are essentially ones of principle.

Others, including those more sympathetic to monetary union in principle, raise concerns about the design of the monetary and fiscal systems within which monetary union operates – a design that, in principle, can be amended (see Boxes 22.4 and 22.7).

Arguments against EMU in principle

The lack of national currencies. This is a serious problem if an economy is at all out of harmony with the rest of the Union. For example, if countries such as Greece and Spain have higher rates of inflation (due, say, to greater cost-push pressures), then how are they to make their goods competitive with the rest of the Union? With separate currencies these countries could allow their currencies to depreciate. With a single currency, however, they could become depressed 'regions' of Europe, with rising unemployment and all the other problems of depressed regions within a country. This might then require significant regional policies – policies that might not be in place or, if they were, would be seen as too interventionist by the political right.

 How might multiplier effects (the principle of cumulative causation) lead to prosperous regions becoming more prosperous and less prosperous regions falling even further behind?

Proponents of EMU argue that it is better to tackle the problem of high inflation in such countries by the disciplines of competition from other EU countries, than merely to feed that inflation by keeping separate currencies and allowing repeated depreciation, with all the uncertainty that they bring.

What is more, the high-inflation countries tend to be the poorer ones with lower wage levels (albeit faster wage increases). With the increased mobility of labour and capital as the single market deepens, resources are likely to be attracted to such countries. This could help to narrow the gap between the richer and poorer member states.

The critics of EMU counter this by arguing that labour is relatively immobile, given cultural and language barriers. Thus an unemployed worker in Dublin could not easily move to a job in Turin or Helsinki. What the critics are arguing here is that the EU is not an *optimal currency area* (see Box 26.2).

Loss of separate monetary policies. Perhaps the most serious criticism is that the same rate of interest must apply to all eurozone countries: the 'one-size-fits-all' problem. The trouble is that while one country might require a lower rate of interest in order to ward off recession (such as Portugal, Ireland and Greece in 2010–11), others might require a

higher one to prevent inflation. Furthermore, some countries may be more sensitive to interest changes than others, hence the optimal change in interest rates for one country may represent too much or too little of a change in another.

The greater the convergence between economies within the eurozone, the less serious this problem is. Consequently, it was hoped that, with common fiscal rules and free trade, these divergences would diminish over time. Eurosceptics, however, argue that there has been increasing divergence between members especially in terms of the size of government deficits and debt and the confidence of the financial markets in countries' ability to tackle these deficits.

Asymmetric shocks. A third and related problem for members of a single currency occurs in adjusting to a shock when that shock affects members to different degrees. Such occurrences are known as *asymmetric shocks*. For example, the banking crisis affected the UK more severely than other countries, given that London is a global financial centre. This problem is more serious, the less the factor mobility between member countries and the less the price flexibility within member countries.

This problem, however, should not be overstated. Divergences between economies are often the result of a lack of harmony between countries in their demand-management policies. This is impossible in the eurozone in the case of monetary policy, and more difficult in the case of fiscal policy, due in part, to the constraints of the Growth and Stability Pact and Fiscal Compact (see Box 22.4). Also, many of the shocks that face economies today are global and have similar (albeit not identical) effects on all countries. Adjustment to such shocks would often be better with a single co-ordinated policy, something that is much easier with a single currency and a single central bank.

Even when shocks are uniformly felt in the member states, however, there is still the problem that policies adopted centrally will have different effects on each country. This is because the transmission mechanisms of economic policy (i.e. the way in which policy changes impact on economic variables like growth and inflation) vary across countries.

Criticisms of the current design of EMU

Others, who are currently critical of the design of EMU, argue that with appropriate changes, the problems could be significantly reduced.

Definitions

Optimal currency area The optimal size of a currency area is the one that maximises the benefits from having a single currency relative to the costs. If the area were increased or decreased in size, the costs would rise relative to the benefits.

Asymmetric shocks Shocks (such as an oil price increase or a recession in another part of the world) that have different-sized effects on different industries, regions or countries.

BOX 26.2

OPTIMAL CURRENCY AREAS

EXPLORING
ECONOMICS

When it pays to pay in the same currency

Imagine that each town and village used a different currency. Think how inconvenient it would be having to keep exchanging one currency into another, and how difficult it would be working out the relative value of items in different parts of the country.

Clearly, there are benefits to using a common currency, not only within a country but across different countries. The benefits include greater transparency in pricing, more open competition, greater certainty for investors and the avoidance of having to pay commission when you change one currency into another. There are also the benefits from having a single monetary policy if that is delivered in a more consistent and effective way than by individual countries.

So why not have a single currency for the whole world? The problem is that the bigger a single currency area gets, the more likely the conditions are to diverge in the different parts of the area. Some parts may have high unemployment and require expansionary policies. Others may have low unemployment and suffer from inflationary pressures. They may require *contractionary* policies.

What is more, different members of the currency area may experience quite different shocks to their economies, whether from outside the union (e.g. a fall in the price of one of their major exports) or from inside (e.g. a prolonged strike). These 'asymmetric shocks' would imply that different parts of the currency area should adopt different policies. But with a common monetary policy and hence common interest rates, and with no possibility of devaluation/revaluation of the currency of individual members, the scope for separate economic policies is reduced.

The costs of asymmetric shocks (and hence the costs of a single currency area) will be greater, the less the mobility of labour and capital, the less the flexibility of prices and wage rates, and the fewer the alternative policies there are that can be turned to (such as fiscal and regional policies).

So is the eurozone an optimal currency area? Certainly strong doubts have been raised by many economists.

- Labour is relatively immobile.
- There are structural differences between the member states.
- The transmission effects of interest rate changes are different between the member countries, given that countries have different proportions of borrowing at variable interest rates and different proportions of consumer debt to GDP.
- Exports to countries outside the eurozone account for different proportions of the members' GDP, and thus their economies are affected differently by a change in the rate of exchange of the euro against other currencies.
- Wage rates are relatively inflexible.
- Under the Stability and Growth Pact and the Fiscal Compact (see Box 22.4), the scope for using discretionary fiscal policy is curtailed except in times of severe economic difficulty (as in 2009).

This does not necessarily mean, however, that the costs of having a single European currency outweigh the benefits. Also, the problems outlined above should decline over time as the single market develops. Finally, the problem of asymmetric shocks can be exaggerated. European economies are highly diversified; there are often more differences *within* economies than between them. Thus shocks are more likely to affect different industries or localities, rather than whole countries. Changing the exchange rate, if that were still possible, would hardly be an appropriate policy in these circumstances.

Why is a single currency area likely to move towards becoming an optimal currency area over time?

Monetary policy. In the case of monetary policy, it is argued that the ECB's remit makes it especially inflation-averse. Hence, it will tend to be more 'hawkish' and less proactive in response to economic downturns in the eurozone, particularly if the downturn is accompanied by a persistence in inflation or by rising rates of inflation.

Some argue that the hawkishness of the ECB is most clearly seen when comparing its monetary stance with other central banks in the aftermath of the financial crisis (see Box 22.7). Concerned by the above-target consumer price inflation rates that had resulted from the rising rates of global commodity inflation before the financial crisis, the ECB was cautious in relaxing monetary policy. In comparison, central banks such as the US Federal Reserve, the Bank of England and the Bank of Japan were more 'dovish' and aggressively relaxed monetary policy (see Boxes 22.5 and 22.6). Indeed, it was not until late in 2014 that the ECB announced that it would be starting a programme of

quantitative easing, around the very time that the Federal Reserve's programme was winding down.

Critics also point to the underlying weakness of a single currency operating alongside separate *national* government debt issues. The greater the divergence of the eurozone countries, in terms of growth, inflation, deficits, debt and the proportions of debt securities maturing in the short term, the greater this problem becomes.

Fiscal policy. Under the Stability and Growth Pact (SGP), countries were supposed to keep public-sector deficits below 3 per cent of GDP and their stocks of debt below 60 per cent of GDP (see Box 22.4 on page 684). However, the Pact was not rigidly enforced. Furthermore, because the rules allowed for discretion in times of recession, deficits and debt rose sharply in the late 2000s (see Table 22.1 on page 671).

Subsequently, efforts have been made to change the framework within which national governments make their

fiscal choices. The result is the Fiscal Compact, signed in March 2012 (see Box 22.4). This reaffirmed the Stability and Growth Pact rules, but added other requirements. For example, eurozone countries would now be required to keep *structural deficits* at or below 0.5 per cent of GDP and tougher penalties would be imposed on countries breaking the rules.

There are those who argue that, for eurozone members to benefit fully from monetary union, tighter fiscal rules alone are insufficient. Instead, they advocate greater fiscal harmonisation. In other words, the problem, they say, is one of incomplete integration.

By what means would a depressed country in an economic union with a single currency be able to recover? Would the market provide a satisfactory solution to its problems or would (union) government intervention be necessary, and if so, what form could that intervention take?

Future of the euro

When Lithuania adopted the euro on 1 January 2015 it became the nineteenth country to do so. Yet debates around the advantages and disadvantages of EMU intensified as the ongoing Greek debt crisis raised the prospect of Greece's exit from the euro (Grexit).

The Greek crisis

The perilous state of Greece's public finances had already seen two international bailouts agreed. These involved the IMF, the European Commission and the ECB – the so-called 'Troika' – and were worth €240 billion. However, these loans were contingent on the Greek government undertaking a series of economic measures, including significant fiscal tightening. However, the fiscal austerity measures contributed to a deterioration of the macroeconomic environment.

Matters came to a head at the end of 2014 when the final tranches of the Greek bailout programme were suspended by the Troika. This followed the formation in December 2014 of a Syriza-led Greek government which had fought the election on an anti-austerity platform.

What followed was a drawn-out set of negotiations between Greece and its international creditors. With no agreement on further aid to Greece yet reached, Greece was unable to meet a €1.55 billion repayment to the IMF on 30 June 2015. This made Greece the first developed country to have defaulted on a loan from the IMF. Meanwhile, conditions for Greek citizens continued to deteriorate. In July the ECB announced that it would maintain its emergency liquidity assurance for the Greek financial system at levels agreed at the end of June. Without further credit for an already financially distressed banking system, capital controls were imposed with strict limits on withdrawals from bank accounts.

In August 2015, the Greek government and its international creditors reached an agreement on the terms of a third bailout worth €85 billion over three years. Further austerity measures continued. These were required in order for the

periodic release of funds, but they were to place further strains on an already weak economy.

Concerns continued to grow, however, that the fiscal arithmetic (see section 22.1) to sustain Greece's current public sector debt-to-GDP ratio simply did not add up. Larger and larger primary surpluses were needed merely to sustain the current national debt, thereby requiring further fiscal austerity and structural reform. Some, including the IMF, were arguing that only debt relief would ensure the long-term sustainability of Greece's public finances.

For the time being at least, Grexit had been avoided. Yet the Greek debt crisis brought to the fore fundamental questions about the future of the euro and the conditions under which it would be beneficial for other EU member states to join or for existing members to exit.

The single currency and gains from trade

The benefits from a country being a member of a single currency are greater the more it leads to trade with other members of the single currency. Table 26.2 shows for a sample of member states of the European Union (including the UK), the proportion of their exports and imports to and from other member states. From the table we can see that about two-thirds of trade in the EU is between member states. However, there are considerable differences in the importance of intra-EU trade for member states.

On the basis of intra-industry trade, it might be argued that countries like Greece and Malta (and the UK, had it chosen to join when a member of the EU) have least to gain from being part of a single currency with other EU nations. But we need to consider other factors too. The theory of optimal currency areas (see Box 26.2) suggests, for example, that the degree of convergence between economies and the flexibility

Table 26.2 Intra-European Union exports and imports, % of total exports or imports

	Exports		Imports	
	2002–8	2009–16	2002–8	2009–16
EU-28	68.4	64.0	64.9	62.4

of labour markets are important considerations for countries considering the costs of relinquishing their national currency.

The more similar economies are, the more likely it is that they will face similar or symmetric shocks which can be accommodated by a common monetary policy. Furthermore, greater wage flexibility and mobility of labour provide mechanisms for countries within a single currency to remain internationally competitive.

Table 26.3 shows a series of macroeconomic indicators for a sample of countries within the eurozone. From it we can see that there remain considerable differences in the macroeconomic performance of these countries, reflecting continuing differences in the structures of their economies. These differences were exacerbated by the financial crisis of the late 2000s and the subsequent deterioration of the macroeconomic environment.

Among the differences captured by Table 26.3 is the contrasting trade positions of eurozone economies. In the period 2002–8 Greece and Spain ran large current account deficits, averaging 12 and 7 per cent of GDP respectively. By contrast, Germany ran a current account surplus of around 4.5 per cent of its GDP.

In the absence of nominal exchange rate adjustments, countries like Greece and Spain, looking to a fall in the *real* exchange rate to boost competitiveness, need to have

relatively lower rates of price inflation (see pages 788–91 and Box 25.8 on page 816 on nominal and real exchange rates). Therefore, in a single currency productivity growth and wage inflation take on even greater importance in determining a country's competitiveness.

In Table 26.3, labour productivity is captured by the growth in output per hour worked. Again significant variations exist. Where labour productivity growth is lower, it needs lower nominal wage growth to help prevent countries losing their competitiveness. Even in countries where labour productivity is higher, as is often observed in countries with lower levels of income, their competitive position will deteriorate if wage growth exceeds productivity growth. In this scenario unit labour costs (labour costs per unit of output) will increase. In the period from 2002 to 2008, Table 26.3 shows unit labour costs increasing at between 3 and 4 per cent per annum in Greece, Spain and Italy compared with close to zero in Germany. This, other things being equal, puts these countries at a competitive disadvantage.

The euro and the fiscal framework

The discussion so far highlights the importance of economic convergence in affecting the benefits and costs of being a member of the euro. Fiscal policy can provide some buffer against asymmetric shocks by enabling transfers of income to those areas experiencing lower rates of economic

Table 26.3 Macroeconomic indicators for eurozone, 2002–16

	2002–8							2009–16

Notes: (i) Unit labour costs are the ratio of compensation per employee to real GDP per person employed; (ii) the economy-wide inflation rate is the annual rate of change of the GDP deflator.

Source: Based on data from AMECO database (European Commission, DGEFIN) and OECD.stat (OECD).

growth. Therefore, the fiscal framework within which the euro operates is important when considering the future of the euro.

To date, the eurozone has resisted a centralisation of national budgets. In a more centralised (or federal) system we would see automatic income transfers between different regions and countries. A country, say Greece, affected by a negative economic shock would pay less tax revenues and receive more expenditures from a central eurozone budget, while in a country, say Germany, experiencing a positive shock the opposite would be the case.

Since national budgets in the eurozone remain largely decentralised, fiscal transfers are principally determined by national fiscal frameworks. But the ability of these to offset the effects of negative economic shocks is constrained by the sustainability of national budgets. This is important because it places limits on the ability of national governments to use fiscal policy to offset the effects of negative economic shocks.

When analysing the sustainability of national budgets, economists look at the balance needed between spending and revenues to prevent the ratio of the stock of public-sector debt to annual GDP from rising. The key here is the flow of receipts compared to those expenditures other than the interest payments on servicing the existing public-sector debt. If receipts are greater than expenditures excluding interest payments then a *primary surplus* occurs (see page 673). A primary surplus is needed to maintain the debt-to-GDP ratio if the effective real rate of interest payable on public-sector debt is greater than the economy's economic growth rate. Furthermore, the required size of the primary

surplus-to-GDP ratio rises the lower is the rate of economic growth relative to the real interest rate and the larger is the existing debt-to-GDP ratio.

Table 26.4 shows the public-sector debt-to-GDP ratios in a sample of eurozone economies in 2008 and 2016 alongside the factors that affect the path of the ratio. In other words, the table provides important insights into the sustainability of levels of public-sector debt of eurozone economies (see Box 22.1 for an analysis of the 'fiscal arithmetic' of countries outside of the eurozone).

The final column of the table provides a rule-of-thumb estimate of the average primary surplus-to-GDP ratio needed to maintain the 2008 debt stock-to-GDP ratio. It can then be compared with the average primary surplus-to-GDP ratio the countries ran from 2009 to 2016. Belgium, Germany, Italy and Malta ran primary balances close to or in excess of that needed to maintain existing debt-to-GDP levels. Other countries, including Greece, Spain and Ireland, ran primary balances that fell short of that needed to prevent the debt-to-GDP ratio from rising.

The table also illustrates considerable differences between countries in the state of their public finances. Therefore, in a decentralised fiscal environment countries with an already high debt-to-GDP ratio, such as Greece, Italy and Portugal, will find it considerably more difficult to mitigate through fiscal policy the impact of future adverse economic shocks. Consequently, the sustainability of the current decentralised approach to fiscal policy in the eurozone is likely to be crucial in determining the future for the euro and those countries using the euro.

Table 26.4 Debt sustainability in the eurozone

	General government gross debt-to-GDP, %		2009–16 averages			
	2008	2016	Primary surplus-to-GDP, %	Real short-term interest rates, %	Economic growth, % p.a.	Required primary surplus-to-GDP, %
Eurozone	68.6	91.3	-1.0	-0.4	0.4	-0.5
Belgium	92.5	105.9	-0.2	-0.7	0.8	-1.4
France	68.0	96.0	-2.6	0.1	0.6	-0.4
Germany	65.1	68.3	1.2	-0.5	1.0	-1.0
Greece	109.4	179.0	-3.7	0.4	-3.7	4.5
Ireland	42.4	75.4	-6.6	0.8	4.7	-1.7
Italy	102.4	132.6	1.1	-0.5	-0.7	0.3
Lithuania	14.6	40.2	-2.3	-0.2	1.0	-0.2

Section summary

1. One means of achieving greater currency stability is for a group of countries to peg their exchange rates with each other and yet float jointly with the rest of the world. The exchange rate mechanism of the EU (ERM) was an example. Members' currencies were allowed to fluctuate against other member currencies within a band. The band was ± 2.25 per cent for the majority of the ERM countries until 1993.
2. The need for realignments seemed to have diminished in the late 1980s as greater convergence was achieved between the members' economies. Growing strains in the system, however, in the early 1990s led to a crisis in September 1992. The UK and Italy left the ERM. The bands were widened in 1993 to ± 15 per cent, although in practice fluctuations were kept within ± 2.25 per cent for most of the time from 1993 to the start of the euro in 1999.
3. The ERM was seen as an important first stage on the road to complete economic and monetary union.
4. The euro was born on 1 January 1999. Twelve countries adopted it, having at least nominally met the Maastricht convergence criteria. Euro notes and coins were introduced on 1 January 2002, with the notes and coins of the old currencies withdrawn a few weeks later.
5. The advantages claimed for EMU are that it eliminates the costs of converting currencies and the uncertainties associated with possible changes in inter-EU exchange rates. This encourages more investment, both inward and by domestic firms. What is more, a common central bank, independent from domestic governments, provides the stable monetary environment necessary for a convergence of the EU economies and the encouragement of investment and inter-Union trade.
6. Critics claim, however, that it makes adjustment to domestic economic problems more difficult. The loss of independence in policy making is seen by such people to be a major issue, not only because of the loss of political sovereignty, but also because domestic economic concerns may be at variance with those of the Union as a whole. A single monetary policy is claimed to be inappropriate for dealing with asymmetric shocks. What is more, countries and regions at the periphery of the Union may become depressed unless there is an effective regional policy.
7. The Greek sovereign debt crisis raised concerns about the future of the euro. Considerable differences remain in key macroeconomic indicators. This includes differences in the growth of labour productivity and unit labour costs, which are especially significant in the absence of nominal exchange rate adjustments.
8. There are also considerable differences in the financial health of the public finances of eurozone governments. This is significant because it affects the ability of national governments to use fiscal policy to absorb the adverse economic effects of negative shocks.

26.3 GLOBAL INEQUALITY

The gulf between rich and poor countries

The typical family in North America, western Europe, Japan and Australasia has many material comforts: plentiful food to eat; a house or apartment with electricity and running hot and cold water; an inside toilet connected to an underground sewerage system; access to free or affordable health care and education; numerous consumer durables; holidays away from home; visits to the cinema, concerts, sports events, etc. There are some people, it is true, who are very poor and, indeed, the problem of poverty in many developed countries has worsened in recent years. But it is only a small minority that cannot afford the basics of life, such as adequate food, shelter and clothing.

In most of Africa and large parts of Asia and Latin America, the picture is quite different. The majority of people live in poverty. For them life is a daily struggle for survival. Affluence does exist in these countries, but here it is the fortunate few who can afford good food, good housing and the various luxury items that typify life in the industrialised world.

A large proportion of the inhabitants live in the countryside. For many, this means living in a family with many children and working on a small amount of land with too little income to buy adequate agricultural machinery, fertilisers or pesticides. With a rapid growth in population there is less and less land to go round. As land is passed on from generation to generation, it is divided up between the offspring into smaller and smaller plots. Many who cannot make ends meet are forced to sell their land to the local landlords. Then as landless labourers they have to accept very low-paid jobs on the large farms or plantations. Others try to survive by borrowing, hoping to be able to pay off their debts with future crop sales. But often the only source of finance is again the local landlord who charges exorbitant rates of interest. As a result, they end up in a state of 'debt bondage' where they can never pay off their debts, but year in year out have to give part of their crops to the landlord as interest.

Others come to the rapidly growing cities. In the cities, at least there are some jobs. But typically more people migrate

to the cities than there are jobs available. Thus the number of unemployed in the cities has grown inexorably. People are forced to do anything to earn a living: selling wares on street corners, or working as casual labourers, domestic servants or shoe shiners; some resort to prostitution and crime, others merely beg.

All round the outskirts of cities throughout the developing world, shanty towns mushroom as the poor flock in from the countryside. Families crowd into one- or two-roomed shacks, often with no electricity, no water and no sanitation. There are schools in these towns, but often parents cannot afford to allow their children to attend. Instead they have to send them out to work to supplement the family's meagre income. In some emerging countries, programmes to provide work and education in the shanty towns have helped reduce the problem somewhat; in other countries, the problem continues to worsen.

Statistics cannot give the complete picture, but they can give us some indication of the gulf between rich and poor countries. Table 26.5 gives some details.

In 2015, some 84 per cent of the world's population lives in developing countries (low- and middle-income countries), but these people earn only 54 per cent of global GNY² (in purchasing-power parity terms). In fact, as Figure 26.4 shows, this share has been rising over time. In 1990, developing countries' share of GNY was only 44 per cent. Despite this overall increase across developing countries, the poorest economies have experienced relatively little change in their share of global income.

In high-income countries, the average GNY per head in 2015 was just over \$41 900. In low-income countries it was a mere \$619. Even in purchasing-power parity terms, the figures were \$46 100 and \$1600 respectively. The gulf between rich and poor countries can also be seen in other basic indicators, including health, life expectancy and literacy. This is illustrated in Table 26.5, which shows a series of indicators under one of four categories: size of the economy, poverty and quality of life, promoting sustainability and gender development.

² GNY (gross national income): see appendix to Chapter 15.

Table 26.5 Selected development indicators

		Low-income economies	Lower-middle-income economies	Upper-middle-income economies	High-income economies	World
Economy	Population (2015, billions)	638.3	2927.5	2593.9	1187.1	7346.7
	Population growth (p.a., 2011–15)	2.8	1.5	0.8	0.6	1.2
	GNY (2015, PPP, \$ trillions)	1.0	18.8	40.6	54.8	115.0
	GNY per capita (2015, PPP, \$)	1602	6409	15 670	46 135	15 659
	Growth in real GNY per capita (%. 2011–15)	2.0	3.9	n.a.	1.1	0.9
Poverty and quality of life	Under-5 mortality rate (per 1000 births, 2011–15)	82.5	56.7	10.1	5.8	45.8
	Primary school completion rate (number in last grade as % of those of entrance age, 2014)	65.9	91.0	110.4	98.2	90.1
	Growth in output per person employed (%. 2012–16)	2.2	3.1	3.3	0.8	1.8
Promoting sustainability	Population in 2015 with access to improved sanitation services (%)	28.3	52.0	80.0	99.4	67.5
	Population in 2014 with access to electricity (%)	28.3	79.8	98.7	100.0	85.3
	Population using the internet (%. 2011–15)	6.3	20.8	45.3	76.9	37.7
Gender development	Male life expectancy (years, 2015)	60.2	65.8	72.5	78.2	69.6
	Female life expectancy (years, 2015)	63.4	69.4	77.0	83.5	73.8
	Firms with female top manager (% of firms)	14.0	19.2	19.7	19.2	18.6
	Women in parliament (% of parliamentarians, 2016)	23.9	17.7	24.1	26.5	23.0

Notes: (i) Low-income economies are those with GNY per capita of \$1025 or less in 2015; lower-middle income, \$1026 – \$4035; upper-middle income, \$4036–\$12 475; and high income, \$12 476 or more; (ii) n.a. = not available.

Source: Based on data from Databank (World Bank).

Figure 26.4 World GNY in PPP terms (2011 prices)

Note: Developing countries are classified as low, lower-middle and upper-middle-income economies; developed economies are high-income economies.
Source: Based on data from *Databank* (World Bank), series NY.GNP.MKTP.PP.KD.

Nevertheless, as the table shows, growth in GNY per capita over recent years has been faster in developing countries than in rich countries. The income gap between the developed and developing world has been narrowing.

The meaning of 'development'

Countries want to develop. But just what do we mean by 'development'? Clearly it is a normative concept. Its definition will depend on the goals that the economist assumes societies want to achieve. So how do economists define and measure development?

The basic needs approach

A starting point is to identify the basic needs that people have if they are to be able to realise their potential as human beings. Different economists have identified various lists of requirements, including the following items:

- Adequate food, shelter, warmth and clothing.
- Universal access to education.
- Availability of adequate health care.
- Availability of non-demeaning jobs.
- Sufficient free time to be able to enjoy social interaction.
- Freedom to make one's own economic decisions.
- Freedom to participate in the decisions of government and other bodies that affect one's life.

? What other items might be included as basic needs?

There are four major problems with defining development in terms of a basic list of requirements.

The first is in deciding *what to include*. Any definition of economic development would clearly include people's *material* standard of living. But should development include social and political factors such as 'self-esteem', freedom from servitude and freedom of religion?

The second problem is in *measuring each of the items*. It is possible to measure such things as income per head, literacy rates and mortality rates. It is much more difficult, however, to measure the achievement of social and political objectives such as self-esteem.

The third problem is in arriving at a *single measure* of the level of development. You cannot add the average calorific intake to the number of doctors and nurses to the percentage of homes having various basic amenities such as running water. You can meaningfully add things up only if they are expressed in the same units, or if appropriate *weights* are attached to each of the items. Clearly, the assigning of any such weights would be highly controversial.

The fourth problem is in deciding the importance of the *distribution* of the various items. If, say, the average calorific intake increases, but the poorest sections of the population have less to eat, has the country really experienced an increase in the level of development?

However, many economists argue that the basic needs approach does provide a useful 'checklist' to see whether a country's development is broadly based or confined to just one or two indicators.

? Would it be possible with this basic needs approach to say
(a) that one country was more developed than another;
(b) that one country was developing faster than another?

Using GNY to measure development

The desire to have a single measure for development and thus to be able to make simple comparisons between countries has led to the universal use of real gross national income (GNY) per capita as the main indicator. It has some major advantages:

- It takes into account virtually all the goods and services produced in a country, and converts them into a single measure by the use of market prices.
- Although markets are by no means perfect, they do reflect the strength of demand and the opportunity costs of supply.
- The rules for the measurement of GNY are universally agreed.
- Virtually all countries compile GNY statistics.
- Although not every item that affects human welfare is included in GNY, a sustained rise in GNY is generally agreed to be a *necessary* condition for a sustained rise in welfare.
- There is a fairly close correlation between the level of per capita GNY and other indicators such as mortality rates, literacy rates, and calorific and protein intake.

However, there are four fundamental criticisms of relying on simple GNY per capita as an indicator of development.

Many items are excluded. Much of production that does not get bought and sold will escape being recorded. This is a

particular problem with rural societies that are largely subsistence-based. People grow their own food, build their own houses, make their own clothes and provide their own entertainment. GNY statistics are therefore likely to *understate* the level of production in these societies.

On the other hand, as these societies 'develop', the size of the market sector is likely to grow. A larger proportion of people's consumption will be of items they have purchased and which therefore do enter into GNY statistics. Thus GNY figures will *overstate* the rate of growth of production and consumption.

As an economy becomes more urbanised, there is likely to be a growth in *external* costs of production and consumption, such as pollution and crime. Traditional ways of life will be destroyed; people may find themselves increasingly in a competitive, uncaring environment. Again the growth in GNY is likely to *overstate* the growth in human welfare.

Market prices may be highly distorted. GNY is based on market prices, but these prices may be distorted. Markets are often highly fragmented, and there is little competition to ensure that prices reflect undistorted marginal costs. Companies often have considerable monopoly power to push up prices of manufactured goods; landlords often have power to push up rents; governments may impose price controls on food; employers with monopoly power may be able to pay very low wages.

Figure 26.5 GNY per head as a percentage of world GNY per head, 2016 (using purchasing-power parity exchange rates)

Source: Based on data from *Databank* (World Bank), series NY.GNP.PCAP.PP.CD.

How would a redistribution of income to the powerful be likely to affect GNY?

Exchange rates may not reflect local purchasing power. GNY statistics are initially compiled in terms of the domestic currency. For purposes of international comparison they then have to be converted into a common currency – usually the US dollar – at the current exchange rate. But exchange rates reflect demand and supply of *traded* goods; they do not

reflect the prices of *non-traded* goods. Generally, the price of non-traded goods and services in developing countries will be lower than the price of similar goods and services in advanced countries. The *level* of GNY is therefore likely to *understate* the level of production in poor countries. If, on the other hand, the proportion of traded goods increases over time, the *growth* of GNY will again *overstate* the growth in production.

It is much better, therefore, to estimate GNY using purchasing-power parity (PPP) exchange rates. Even if this is

BOX 26.3 THE HUMAN DEVELOPMENT INDEX (HDI)

A measure of human welfare?

Since 1990, the United Nations Development Programme (UNDP) has published an annual Human Development Index (HDI). This is an attempt to provide a more broadly based measure of development than GDP or GNY. HDI is the average of three indices based on three sets of variables: (i) life expectancy at birth, (ii) education (a weighted average of (a) the mean years that a 25-year-old person or older has spent in school and (b) the number of years of schooling that a 5-year-old child is expected to have over their lifetime) and (iii) real GNY per capita, measured in US dollars at purchasing-power parity exchange rates. The 188 countries are then placed in one of four equal-sized groups according to their HDI: very high human development (top quartile), high human development (next quartile), medium human development (next quartile) and low human development (bottom quartile).

For each of the three indices making up the HDI, a sophisticated formula is used. Thus the index for GNY attempts to measure material well-being by building in the assumption of a rapidly diminishing marginal utility of income above average world levels.

The table, based on the 2016 Human Development Report, gives the 2015 HDIs for selected countries and their rankings. It also shows the development of the HDI since 1990 as well as GNY per capita in purchasing power terms for 2015.

The final column of the table shows the divergence between the HDI and GNY per capita rankings in 2015. A positive number shows that a country has a higher ranking for HDI than GNY per capita. As can be seen, the rankings differ substantially in some cases between the two measures. For some countries, such as Australia, Ireland and Cuba, GNY *understates* their relative level of human development, whereas for others, such as the United Arab Emirate, Kuwait and Nigeria, GNY per capita *overstates* their relative level of human development. Thus South Africa (PPP) GNY per capita is 62 per cent higher than that of Cuba and yet its HDI is lower.

The point is that countries with similar levels of national income may use that income quite differently.

Recently, work has been done to adjust HDI figures for various other factors, such as overall income distribution, gender inequalities and inequalities by region or ethnic group. Thus the overall HDI can be adjusted downwards to reflect greater degrees of inequality. Alternatively, separate HDIs can be produced for separate regions or ethnic groups, or for women and men within a country.

1. For what reasons are HDI and per capita GDP rankings likely to diverge?
2. Why do Kuwait and South Africa have such a large negative figure in the final column of the table?

done, however, massive differences remain in GNY per head between rich and poor countries. This is illustrated in Figure 26.5, which shows GNY per head at PPP exchange rates as a percentage of the estimated world GNY per head.

Simple GNY per head ignores the distribution of income. Since the early 1980s, many developing countries have achieved relatively rapid growth in per capita GNY as they have sought overseas investment, privatised their industries and cut the levels of public provision. But with a deepening of

poverty, a growing inequality in the distribution of income and an increase in unemployment, few would argue that this constitutes genuine 'development'.

Many who have advocated the concentration on GNY and its rate of growth have argued that, while the rich may be the first to benefit from prosperity, gradually the benefits will 'trickle down' to the poor. In practice, the wealth has failed to trickle down in many countries. The rich have got richer while the poor have got poorer.

EXPLORING
ECONOMICS*Human Development Index for selected countries (2015)*

	Human Development Index (HDI)				GNY per head in 2015 (PPP \$, 2011 prices)		GNY (PPPS) rank minus HDI rank

Source: Based on data from 2016 Human Development Report (United Nations Development Programme, 2016).

Given the weaknesses of GNY, but given the desirability of having a single measure of development, various composite indicators have been constructed. The most widely used is the **Human Development Index (HDI)**, which is a combined measure of life expectancy, education and GDP per head at PPP exchange rates. This index is examined in Box 26.3.

Definition

Human Development Index (HDI) A composite index made up of three elements: an index for life expectancy, an index for school enrolment and adult literacy, and an index for GDP per capita (in PPPS).

Section summary

1. There are a number of ways of categorising countries according to their level of development.
2. The level of development of a country can be defined in terms of the extent to which it meets basic needs for human life. There is no universal agreement, however, about which items should be measured or about how to measure and weight them. Nevertheless, the approach provides a useful indicator of whether development is broadly based and how rapidly the most serious problems of poverty are being tackled.
3. The most widely used measure of development is GNY per head at PPP exchange rates. However, there are serious problems with using GNY: many items may be excluded, especially for a more subsistence-based society; prices may be highly distorted; and the statistics ignore the question of the distribution of income. Another widely used measure is the Human Development Index.

26.4 TRADE AND DEVELOPING COUNTRIES

The role of international trade is one of the most contentious issues in development economics. Should countries adopt an open trading policy with few if any barriers to imports? Should governments actively promote trade by subsidising their export sector? Or should they restrict trade and pursue a policy of greater self-sufficiency? These are issues that we will be looking at in this section.

Whether it is desirable that developing countries should adopt policies of more trade or less, trade is still vital. Certain raw materials, capital equipment and intermediate products that are necessary for development can be obtained only from abroad. Others *could* be produced domestically, but only at much higher cost.

The relationship between trade and development

What makes the issue of trade so contentious is the absence of a simple relationship between trade and development. Instead the relationship is complex and determined by a series of interactions between variables affecting both trade and development. Furthermore, while some countries have managed to use trade as an engine for economic growth and wider human development, others, despite trade liberalisation, have seen relatively little improvement in either their export performance or in human development.

In constructing a trade and development index, the UN³ identified three broad groups of influences or dimensions which interact and affect a country's trade and development

performance. Within these broad groups are various indicators which themselves interact. We consider briefly these three dimensions and some of the indicators within each dimension.

Structural and institutional dimension

Human capital. This relates to the skills and expertise of the workforce which affect a country's performance and its productivity. Education and health are key influences here. As well as affecting the economic growth of a country, higher educational attainment and better health conditions positively impact on social and human development.

Physical infrastructure. Infrastructure affects a country's productive capacity and so its potential output. Poor transport infrastructure, for example, is thought to be a major impediment to a country's export performance.

Financial environment. Credit is important to producers and consumers alike in helping to finance both short-term and longer-term commitments. For instance, it enables firms to finance day-to-day operational purchases but also longer-term investments in fixed assets such as buildings and machinery.

Institutional quality. This relates to issues of governance not just of firms themselves, but also to institutions, largely governmental.

³ Developing Countries in International Trade 2005: Trade and Development Index (United Nations, 2005).

Environment sustainability. The argument here is that excessive activity, particularly at the early stages of development, can result in environmental degradation. This can adversely affect human development and, in turn, economic development.

Trade policies and process dimension

Openness to trade. In the absence of market failures and externalities, trade liberalisation is argued to be a driver of development. However, there can be significant human costs in the transition process.

Effective access to foreign markets. The success of a country's export performance is crucially dependent on its effective access to markets. Barriers to access include tariffs and non-tariff barriers, such as regulatory standards in the markets of recipient countries. A wider definition of 'effective' access recognises other factors too. These might include the size of foreign markets, transport links, the characteristics of the goods being exported – for example how differentiated they are – as well as the cost of the exported goods.

Levels of development dimension

The third series of factors affecting both trade and human development relate to existing levels of development. In section 26.3 we discussed some of the issues in defining and measuring development. But, in general terms, we can think of the relevant development issues here as encompassing three components: economic development, social development and gender development.

Trade strategies

Despite the complexity of the relationship between trade and development, countries' policies towards trade typically go through various stages as they develop.

Primary outward-looking stage. Traditionally, developing countries have exported primaries – minerals such as copper, cash crops such as coffee and non-foodstuffs such as cotton – in exchange for manufactured consumer goods. Having little in the way of an industrial base, if they want to consume manufactured goods, they have to import them.

Secondary inward-looking stage. In seeking rapid economic development, most developing countries drew lessons from the experience of the advanced countries. The main conclusion was that industrialisation was the key to economic success.

But industrialisation required foreign exchange to purchase capital equipment. This led to a policy of *import-substituting industrialisation*, which involved cutting back on non-essential imports and thereby releasing foreign exchange. Tariffs and other restrictions were imposed on those imports for which a domestic substitute existed or which were regarded as unimportant.

Secondary outward-looking stage. Once an industry had satisfied domestic demand, it had to seek markets abroad if expansion was to continue. What is more, as we shall see, import substitution brought a number of serious problems for developing countries. The answer seemed to be to look outward again, this time to the export of manufactured goods. Many of the most economically successful developing countries (especially Hong Kong, Singapore, South Korea, Taiwan and, more recently, China, India and Indonesia) have owed their high growth rates to a rapid expansion of manufactured exports.

We will now examine the three stages in more detail.

Approach 1: Exporting primaries – exploiting comparative advantage

The justification for exporting primaries

Despite moves towards import substitution and secondary export promotion, many developing countries still rely heavily on primary exports. Three major arguments have traditionally been used for pursuing a policy of exporting primaries. In each case the arguments have also been used to justify a policy of free or virtually free trade.

Exporting primaries exploits comparative advantage. Traditional trade theory implies that countries should specialise in producing those items in which they have a comparative advantage: i.e. those goods that can be produced at relatively low opportunity costs. For most developing countries, this means that a large proportion of their exports should be primaries.

The reasons for differences in comparative costs were examined by two Swedish economists, Eli Heckscher and Bertil Ohlin. They believed that comparative cost differences arise from differences in factor endowments. The *Heckscher-Ohlin theory* states that *a country should specialise in those goods that are intensive in the country's abundant factor*. The more abundant a factor, the relatively cheaper it is likely to be, and thus the lower will be the opportunity cost of producing goods that are intensive in its use. Thus labour-abundant developing countries should specialise in labour-intensive products. By exporting these products, which will typically be primaries, they can earn the foreign exchange to import goods that use large amounts of capital and other resources that are in short supply.

Definitions

Import-substituting industrialisation A strategy of restricting imports of manufactured goods and using the foreign exchange saved to build up domestic substitute industries.

Heckscher-Ohlin version of comparative advantage A country has a comparative advantage in those goods that are intensive in the country's relatively abundant factor.

According to this theory, international trade would lead not only to higher consumption, but also to **factor price equalisation**: i.e. the erosion of income inequalities between trading nations. For example, if wage rates are low in developing countries, trade will increase the demand for their labour-intensive products and thereby push up wage rates. International trade will also erode income differentials *within* countries. The demand for exports will increase the demand for the relatively cheap factors, and imports will reduce the demand for the relatively expensive ones. Thus the cheap factors will go up in price and the expensive ones will come down.

1. What effect will trade have on the price of capital in developing and developed countries?
2. It is sometimes claimed that trade with developing countries is unjust because it leads to the importation of goods produced at pitifully low wages. How can the Heckscher–Ohlin theory be used to refute this claim? Is there any validity in the claim? (See Box 24.3.)

Exporting primaries provides a 'vent for surplus'. Trade offers a **vent for surplus**: i.e. a means of putting to use resources that would otherwise not be used. These surpluses occur where the domestic market is simply not big enough to consume all the available output of a particular good. There is far too little demand within Zambia to consume its potential output of copper. The same applies to Namibian uranium and Peruvian tin.

Exporting primaries provides an 'engine for economic growth'. According to this argument, developing countries benefit from the growth of the economies of the developed world. As industrial expansion takes place in the rich North, this creates additional demand for primaries from the poor South. In more recent years, the rapid growth in China, India and other industrialising developing countries saw a rapid growth in demand for commodities, many produced in the least developed countries. This drove up commodity prices in the first decade of the 2000s and benefited primary exporters (see Figure 26.6 on page 847). However, as we shall see, commodity prices can be very volatile; indeed, they fell in the first part of the 2010s.

Traditional trade theory in the context of development

There are several reasons for questioning whether the above arguments justify a policy of relying on primary exports as the means to development.

Definitions

Factor price equalisation The tendency for international trade to reduce factor price inequalities both between and within countries.

Vent for surplus Where international trade enables a country to exploit resources that would otherwise be unused.

Comparative costs change over time. Over time, with the acquisition of new skills and an increase in the capital stock, a developing country that once had a comparative advantage in primaries may find that it now has a comparative advantage in certain *manufactured* products, especially those that are more labour-intensive and use raw materials of which the country has a plentiful supply. The market, however, cannot necessarily be relied upon to bring about a smooth transition to producing such products.

Concentrating on primary production may hinder growth. The theory of comparative advantage shows how trade allows a country to consume beyond its production possibility curve (see pages 753–4). As its economy grows, however, this production possibility curve will *shift outwards*. By concentrating on primaries, the curve may shift outwards more slowly than if the country had pursued a policy of industrialisation. In other words, economic growth may be slower from a policy of exporting primaries than from a policy of industrialisation.

The benefits from trade may not accrue to the nationals of the country. If a mine or plantation is owned by a foreign company, it will be the foreign shareholders who get the profits from the sale of exports. In addition, these companies may bring in their own capital and skilled labour from abroad. The benefits gained by the local people will probably be confined to the additional wages they earn. With these companies being in a position of monopsony power, the wages are often very low.

In recent years the Fair Trade movement has focused attention on the low incomes received by many primary producers and their lack of market power. Only a tiny fraction of the price you pay for coffee, tea or bananas goes to local growers.

Why does this argument make GNY a better indicator of development than GDP? (See the appendix to Chapter 15.)

Trade may lead to less equality. Trade shifts income distribution in favour of those factors of production employed intensively in the export sector. If exports are labour intensive, greater equality will tend to result. But if they are land or raw material intensive, trade will redistribute income in favour of large landowners or mine owners.

Exporting primary exports may involve external costs. Mining can lead to huge external costs, such as the despoiling of the countryside and damage to the health of miners. Mines and plantations can lead to the destruction of traditional communities and their values.

These arguments cast doubt on whether a policy of relying on free trade in primary exports is the best way of achieving economic development. Various trends in the international economy have also worked against primary exporters, causing them serious balance of payments problems.

Balance of payments problems: long term

Long-term trends in international trade have caused problems for primary exporting countries in various ways.

Low income elasticity of demand for primary products. As world incomes grow, so a smaller proportion of these incomes is spent on primaries. Since food is a necessity, consumers, especially in rich countries, already consume virtually all they require. A rise in incomes, therefore, tends to be spent more on luxury goods and services, and only slightly more on basic foodstuffs. The exceptions are certain 'luxury' imported foodstuffs such as exotic fruits. In the case of raw materials, as people's incomes grow, they tend to buy more and more expensive products. The extra value of these products, however, arises not from the extra raw materials they might contain, but from their greater sophistication.

This argument, however, has not always applied in recent years. The rapid growth of countries such as China and India, where people spend a relatively large proportion of any increase in their income on food, has led to periods of rapidly rising world food prices (see Figure 26.6). This has been aggravated by poor harvests in many parts of the world and by switching land to growing crops for biofuels instead of food. This has raised concerns among developing countries about 'food security' and hence the ability of people to afford foodstuffs. There has also been a rapid growth in demand by such countries for raw materials as inputs into the construction industry and the expanding industrial sector.

Agricultural protection in advanced countries. Faced with the problem of a slowly growing demand for food produced by their own farmers, advanced countries increasingly imposed restrictions on imported food. Reducing these restrictions has been one of the main aims of the Doha Development

Agenda (the latest round of WTO trade negotiations: see Box 24.8 on pages 768–9).

Technological developments. Synthetic substitutes have in many cases replaced primaries in the making of consumer durables, industrial equipment and clothing. Also, the process of miniaturisation, as microchips have replaced machines, has meant that less and less raw materials have been required to produce any given amount of output.

Rapid growth in imports. There tends to be a high income elasticity of demand for imported manufactures. This is the result partly of better-off people in developing countries being able to afford luxury goods, and partly of the development of new tastes as people are exposed to the products of the developed world – products such as Coca-Cola®, Levi® jeans, mobile phones and iPods®. In fact, the whole process has been dubbed 'Coca-Colonisation'. Because of a lack of domestic substitutes, the price elasticity of demand for manufactured imports is low. This gives market power to the overseas suppliers of these imports, which tends to raise their price relative to exports.

The terms of trade. Between 1980 and 2000, the prices of many primary products declined. For instance, the nominal price index in 2000 for beverages (coffee and tea) was only one-third of its level in the late 1970s – and even less than that in real terms. This reflected the slow growth in demand for primaries and led to a *decline* in the terms of trade for primary exporters. This is because they were having to export more and more in order to buy any given quantity of imports, such as manufactured goods.

As Figure 26.6 shows, a quite different picture emerged in the 2000s. As the demand for food and raw materials grew rapidly, reflecting the rapid growth of China and various

Figure 26.6 World primary commodity prices for developing countries (2010 = 100)

Source: Based on data from World Bank Commodity Price Data (*The Pink Sheet*), (Commodity Markets, World Bank).

other emerging economies, so primary commodity prices rose sharply.

This was to come to an abrupt halt with the world recession of 2008–9, when primary product prices fell sharply. But, the resumption of global growth saw primary commodity prices climb once more and in many cases to levels considerably higher than before the world recession. But then, with a slowing in global growth, commodity prices fell, so that by January 2016 the aggregate commodity price index had returned to the level of 2006 – before the financial crisis. Nevertheless, this was still some 80 per cent higher than in January 2000 (in nominal terms). It then drifted up slowly over the coming months.

Balance of payments problems: short term

There are also problems for primary exporting countries in the *short term*.

As we have just seen, the prices of primary products can be subject to large fluctuations. This causes great uncertainty for primary exporters. The current account of the balance of payments fluctuates wildly, which tends to cause large swings in exchange rates or requires massive government intervention to stabilise them.

Price fluctuations are caused partly by the low price elasticity of demand and supply of primaries, but also by substantial *shifts* in their demand and supply.

The demand for *food* tends to be relatively stable, but that for minerals varies with the business cycle and tends to vary more than the demand for consumer goods. The reason is the *accelerator principle* (see section 17.4). Since the *level* of investment demand depends on the size of *changes* in consumer demand, investment will fluctuate much more than consumer demand. But since many minerals are inputs into *capital* equipment, their demand is also likely to fluctuate more than consumer demand. For example, with the boom in construction in emerging economies in the mid-2000s and again in 2010–11, the prices of iron ore, copper, nickel and lead shot up.

The supply of minerals is relatively stable. The supply of cash crops, however, varies with the harvest. Many developing countries are subject to drought or flood, which can virtually wipe out their export earnings from the relevant crop.

If a disastrous harvest of rice were confined to a particular country, would (a) the world price and (b) its own domestic price of rice fluctuate significantly? What would happen to the country's export earnings and the earnings of individual farmers?

With a price-inelastic world demand and supply for primaries, shifts in either curve will lead to substantial fluctuations in world prices. Figure 26.6 illustrates the extent of these fluctuations. The problem is most serious for countries that rely on just one or two primary products, such as Ghana, which relies on cocoa, and the Democratic Republic of Congo, which relies on copper and cobalt. Diversification into other primaries would help to reduce their exposure.

Approach 2: Import-substituting industrialisation (ISI)

Dissatisfaction with relying on primary exporting has led most countries to embark on a process of *industrialisation*. The newly industrialised countries (NICs), such as China, Malaysia, Brazil and India, are already well advanced along the industrialisation road. Other developing countries have not yet progressed very far, especially the poorest African countries.

The most obvious way for countries to industrialise was to cut back on the imports of manufactures and substitute them with home-produced manufactures. This could not be done overnight: it had to be done in stages, beginning with assembly, then making some of the components, and finally making all, or nearly all, of the inputs into production. Most developing countries have at least started on the first stage. Several of the more advanced developing countries have component-manufacturing industries. Only a few of the larger NICs, such as China, India, Brazil and South Korea, have built extensive capital goods industries.

The method most favoured by policy makers was *tariff escalation*. Here tariff rates (or other restrictions) increased as one moved from the raw materials to the intermediate product to the finished product stage. Thus finished goods had higher tariffs than intermediate products. This encouraged assembly plants, which were protected by high tariffs from imported finished products, and were able to obtain components at a lower tariff rate.

One of the problems with ISI was that countries were desperately short of resources to invest in industry. As a result, a policy of ISI usually involved encouraging investment by multinational companies. But even without specific 'perks' (e.g. tax concessions, cheap sites, the cutting of red tape), multinationals would still probably be attracted by the protection afforded by the tariffs or quotas.

Adverse effects of import substitution

Some countries, such as South Korea and Taiwan, pursued an inward-looking ISI policy for only a few years. For them it was merely a stage in development, rapidly to be followed by a secondary outward-looking policy. Infant industries were initially given protection, but when they had achieved sufficient economies of scale, the barriers to imports were gradually removed.

The countries that continued to pursue protectionist ISI policies generally had a poorer growth record. They also

Definition

Tariff escalation The system whereby tariff rates increase the closer a product is to the finished stage of production.

BOX 26.4 WHEN DRIVING AND ALCOHOL DO MIX

CASE STUDIES AND APPLICATIONS

A case of import substitution in Brazil

Two major changes in world trade hit Brazil in the 1970s. The first was the fourfold increase in world oil prices. Brazil has very little oil of its own. The second was the slump in the world sugar cane market as a result of northern countries' protection of their sugar beet industries. Brazil was a major cane sugar exporter.

Faced with a resulting large increase in its import bill and a slump in its sugar exports, the Brazilian government came up with an ingenious solution. It could use surplus sugar cane to make alcohol, which could then be used instead of petrol for cars. Farmers were given subsidies to grown sugar cane.

Large distilleries were set up to convert the sugar cane into alcohol. At the same time, cars were produced (e.g. VW Beetles) that could run on alcohol (ethanol) rather than petrol.

Thus by one measure two problems were alleviated. By 1985, more than 90 per cent of cars produced in Brazil were designed to burn alcohol.

Then, with the decline in oil prices from the mid-1980s, the relative cost efficiency of alcohol-powered cars declined: at times it was cheaper to import oil than to produce alcohol. The government cut subsidies and by 1997 less than 1 per cent of cars produced in Brazil were alcohol-powered.

The dual-fuel solution

A more flexible solution was found in 2003 with the introduction of dual-fuel cars that could run on either alcohol or petrol or a mixture of the two. This gave consumers the chance of using whichever fuel was the cheapest at the time. The popularity of these 'flexi-fuel' cars gave a welcome boost to the sugar cane and ethanol industries.

However, despite the number of dual-fuel cars and vans in Brazil reaching over 80 per cent of the total in the early 2010s, the industry began to experience difficulties. The

deteriorating macroeconomic climate depressed car usage and the purchase of new cars. Furthermore, in looking to control inflation the government was subsidising petrol prices and, with the price of oil falling from 2014, the effect was to make the use of ethanol less competitive compared with petrol. Again, the effect was to dampen the demand for ethanol.

The government subsequently took steps to revive the biofuel sector. It terminated its subsidies of petrol and also increased the proportion of ethanol in petrol from 25 per cent to 27.5 per cent.

The story illustrates the danger of basing major schemes on terms of trade existing at a particular time. If these terms of trade subsequently change, the schemes could prove to be uneconomical.

A new era for the biofuels industry

Brazil also increased its support for another import-substituting drive: to displace diesel fuel with fuel produced from soybeans. To do this, parliament approved measures to increase the percentage of biodiesel required in diesel fuel by 1 per cent a year, from 7 per cent in 2016 to 10 per cent in 2019.

Perhaps this support for biodiesel will help to revive the vehicle industry in Brazil. But soya-based biodiesel can have very damaging effects on the environment. It is far less energy-efficient than sugar cane as a source of fuel and it absorbs less carbon per hectare as it grows. In fact, given that rainforest is being cleared to grow soya, the net effect is to reduce carbon capture substantially.

Could a case be made out for a flexible tax on oil imports to ensure that it was always profitable to produce alcohol?

tended to suffer from other problems, such as a deepening of inequality. The development of the modern industrial sector was often to the detriment of the traditional sectors and also to the export sector.

The criticisms of ISI are numerous, and include the following.

It ran directly counter to the principle of comparative advantage. Rather than confining ISI to genuine infant industries and then gradually removing the protection, ISI was applied indiscriminately to a whole range of industries. Countries ended up producing goods in which they had a comparative *disadvantage*.

If a country specialises in a good in which it has a comparative disadvantage, where will it be consuming with respect to its production possibility curve?

It cushioned inefficient practices and encouraged the establishment of monopolies. Without competition from imports, many of the industries were highly inefficient and wasteful of resources. What is more, in all but the largest or most developed of the developing countries the domestic market for many manufactures is small. If a newly established industry is to be large enough to gain the full potential economies of scale, it must be large relative to the market. This means that it will have considerable monopoly power.

It involved artificially low real interest rates. To encourage capital investment in the import-substituting industries, governments often intervened to keep interest rates low. This encouraged the use of capital-intensive technology with a consequent lack of jobs. It also starved other sectors (such as agriculture) of much-needed finance, and it discouraged saving.

K1 38
p190K1 22
p190

It led to urban wages above the market-clearing level. Wage rates in the industrial sector, although still low compared with advanced countries, are often considerably higher than in the traditional sectors.

- They are pushed up by firms seeking to retain labour in which they have invested training.
- Governments, seeking to appease the politically powerful urban industrial working class, have often passed minimum wage laws.
- Trade unions, although less widespread in developing than in advanced countries, are mainly confined to the new industries.

Higher industrial wages again encourage firms to use capital-intensive techniques.

It involved overvalued exchange rates. Restricting imports tends to lead to an appreciation of the exchange rate. This makes non-restricted imports cheaper. This then discourages the production of domestic goods, such as food and component parts, which compete with those imports. Also, a higher exchange rate discourages exports. Exports tend to be priced in dollars. If the exchange rate appreciates, domestic currency will buy more dollars; or put another way, a dollar will exchange for less domestic currency. Thus exporters will earn less domestic currency as the exchange rate appreciates.

Why is an overvalued exchange rate likely to encourage the use of capital-intensive technology?

It did not necessarily save on foreign exchange. Many of the new industries were highly dependent on the importation of raw materials, capital equipment and component parts. These imported inputs, unlike imports of finished goods, were often supplied by a single firm, which could thus charge monopoly prices. What is more, a large proportion of the extra incomes generated by these industries tended to be spent on imports by the new urban elites.

Protection was not applied evenly. Many different tariff rates were used in one country: in fact, a policy of tariff escalation demands this. In addition, governments often used a whole range of other protectionist instruments, such as the licensing of importers, physical and value quotas, and foreign exchange rationing. These were often applied in a haphazard way. The result was that protection was highly uneven.

Income distribution was made less equal. Additional incomes generated by the modern sector tended to be spent on modern-sector goods and imported goods. Thus there was a multiplier effect *within* the modern sector, but virtually none between the sectors. Also, as we saw above, an overvalued exchange rate leads to a bias against agriculture, and thus further deepens the divide between rich and poor. Finally, the relatively high wages of the modern sector encourage workers to migrate to the towns, where many, failing to get a job, live in dire poverty.

Social, cultural and environmental costs. A policy of ISI often involved imposing an alien set of values. Urban life can be harsh, competitive and materialistic. Moreover, a drive for industrialisation may involve major costs to the environment, as a result of waste products from new industries and a lack of sewage systems in poor areas.

Finally, import substitution is necessarily limited by the size of the domestic market. Once that is saturated, ISI can come to an abrupt halt. At that stage, further expansion can come only from exporting; but if these industries have been over-protected, they will be unable to compete in world markets.

This has been a long list of problems and different economists put different emphases on them. Neoclassical economists stress the problems of market distortions, arguing that ISI leads to great inefficiency. Neo-Marxist economists, on the other hand, stress the problems of *dependency*. Many of the new industries will be owned by multinational companies, which import unsuitable technologies. The countries will then become dependent on imported inputs and foreign sources of capital. (See Case Study 26.6 on the student website.)

Approach 3: Exporting manufactures – a possible way forward?

The countries with the highest rates of economic growth are those that have successfully made the transition to being exporters of manufactures. Table 26.6 gives some examples.

The transition from inward-looking to outward-looking industrialisation

How is a country to move from import substituting to being outward-looking? One approach is to take it industry by industry. When an industry has saturated the home market and there is no further scope for import substitution, it should then be encouraged to seek markets overseas. The trouble with this approach is that, if the country is still protecting other industries, there will probably still be an overvalued exchange rate. Thus specific subsidies, tax concessions or other 'perks' would have to be given to this industry to enable it to compete. The country would still be highly interventionist, with all the distortions and misallocation of resources that this tends to bring.

The alternative is to wean the whole economy off protection. Three major things will need doing:

- A devaluation of the currency in order to restore the potential profitability of the export sector.

Definition

Dependency Where the development of a developing country is hampered by its relationships with the industrialised world.

- A dismantling of the various protective measures that had biased production towards the home market.
- A removal or relaxing of price controls.

But these are things that cannot be done 'at a stroke'. Firms may have to be introduced gradually to the greater forces of competition that an outward-looking trade policy brings. Otherwise there may be massive bankruptcies and a corresponding massive rise in unemployment.

The benefits from a secondary outward-looking policy

The advocates of outward-looking industrialisation make a number of points in its favour.

It conforms more closely to comparative advantage. Countries pursuing an open trade regime will be able to export only goods in which they have a comparative advantage. The resources used in earning a unit of foreign exchange from exports will be less than those used in saving a unit of foreign exchange by replacing imports with home-produced goods. In other words, resources will be used more efficiently.

Economies of scale. If the home market is too small to allow a firm to gain all the potential economies of scale, these can be gained by expanding into the export market.

Increased competition. By having to compete with foreign companies, exporters will be under a greater competitive pressure than industries shielded behind protective barriers. This will encourage (a) resource saving in the short run, both through their better *allocation* and through reductions in X inefficiency (see Box 7.5), and (b) innovation and investment, as firms attempt to adopt the latest technology, often obtained from developed countries.

Increased investment. To the extent that outward-looking policies lead to a greater potential for economic growth, they may attract more foreign capital. To the extent that they lead to increased incomes, additional saving will be generated, especially given that the *marginal* propensity to save may be quite high. The extra savings can be used to finance extra investment.

It can lead to more employment and a more equal distribution of income. According to the Heckscher–Ohlin theory, the manufactured goods in which a country will have a comparative advantage are those produced by labour-intensive techniques. Export expansion will thus increase the demand for labour relative to capital, and create more employment. The increased demand for labour will tend to lead to a rise in wages relative to profits.

 *Will the adoption of labour-intensive techniques necessarily lead to a more equal distribution of income?*

It removes many of the costs associated with ISI. Under a policy of ISI, managers may spend a lot of their time lobbying politicians and officials, seeking licences (and sometimes paying bribes to obtain them), adhering to norms and regulations or trying to find ways around them. If an outward-looking

policy involves removing all this, managers can turn their attention to producing goods more efficiently.

Drawbacks of an export-orientated industrialisation strategy

The export of manufactures is seen by many developed countries as very threatening to their own industries. Their response has often been to erect trade barriers. These barriers have tended to be highest in the very industries (such as textiles, footwear and processed food) where developing countries have the greatest comparative advantage. Even if the barriers are *currently* low, developing countries may feel that it is too risky to expand their exports of these products for fear of a future rise in barriers. Recognising this problem, the World Trade Organization is very keen to ensure fair access for developing countries to the markets of the rich world. This has been a core focus of the Doha Round of trade negotiations (see Box 24.8 on pages 768–9).

 *Consider the arguments from the perspective of an advanced country for and against protecting its industries from imports of manufactures from developing countries.*

The successes of developing countries such as China, Malaysia and South Korea in exporting manufactures (see Table 26.6) do not imply that other developing countries will have similar success. As additional developing countries attempt to export their manufactures, they will be facing more and more competition from each other.

Another problem is that, if a more open trade policy involves removing or reducing exchange and capital controls, the country may become more vulnerable to speculative attack. This was one of the major contributing factors to the East Asian crisis of the late 1990s (see Case Study 26.2 on the student website). Grippled by currency and stock market speculation, and by banking and company insolvency, many countries of the region found that economic growth had turned into a major recession. The 'miracle' seemed to be over. Nevertheless, the countries with the fewest distortions fared the best during the crisis. Thus Singapore and Taiwan, which are open and relatively flexible, experienced only a slowdown, rather than a recession.

Exporting manufactures may thus be a very risky strategy for the least developed countries, such as many in Africa. Perhaps the best hope for the future may be for a growth in manufacturing trade *between* such developing countries. That way they can gain the benefits of specialisation and economies of scale that trade brings, while at the same time producing for a growing market. The feasibility of this approach depends on whether developing countries can agree to free trade areas or even customs unions between themselves (see section 24.3).

There does, however, seem to be a strong movement in this direction. The share of trade between developing countries (so-called South–South trade) in total world exports has doubled over the past 20 years, to over 25 per cent. Manufactured goods now account for nearly 60 per cent of South–South trade, respectively.

BOX 26.5 THE EVOLVING COMPARATIVE ADVANTAGE OF CHINA
Riding the dragon

Comparative advantage enables specialisation and trade and this can be one of the key factors that helps a country to grow and develop. During the 1990s and 2000s, China experienced an average rate of growth of just over 10 per cent per year. Its emergence as an economic power is due to many things, but its ability to exploit its *comparative advantage* is certainly one such factor.

A country's comparative advantage often derives from its abundant resources and China used its abundance of cheap labour. With labour costs estimated to be between 60 and 90 per cent lower than in the USA, it was this that attracted many manufacturing companies to China, making a range of products using moderately and low-skilled jobs.

According to the 2016 World Investment Report, China (excluding Hong Kong) was the world's third largest recipient of foreign direct investment (FDI) with investment of \$136 billion (6.3 per cent of the country's gross fixed capital formation). This meant China was the recipient of around 8 per cent of global FDI.

Lu Zheng, the Director of the Institute of Industrial Economics under the Chinese Academy of Social Sciences, said that 'it [China's comparative advantage] will last at least two decades and play an important role in promoting China's economic growth'.

However, it is not just the quantity of labour that explained China's dominance in manufacturing. While many of its workers are low-skilled, many are educated. Furthermore, Paul Krugman notes another key factor:

China's dominant role in the export of many labor-intensive manufactured goods surely reflects its

combination of relatively abundant labor and relatively high manufacturing competence.¹

It is unsurprising that companies would take advantage of lower costs of production and locate factories in China. But while China has benefited from this, many developed nations have seen a decline in their manufactured exports. Countries like the UK and USA gradually adjusted and moved to exploit their comparative advantage in the services sector. They saw a comparative disadvantage emerge in manufactured items. This changing comparative advantage as a country develops is well-documented and could it be that China will soon begin to see its own comparative advantage change?

Rising labour costs

China's low labour costs are crucial, but these have been rising, as workers demand higher wages, shorter hours and greater benefits. Data suggest that labour costs have been growing at some 20 per cent per year.

The first effect of this has been for some labour-intensive businesses to migrate towards inland China, where labour costs are lower.

However, in other cases the move has been more significant. With a comparative advantage in low-cost labour disappearing, some labour-intensive businesses have left China, moving to other nations which can boast cheap labour, such as Bangladesh, Cambodia, Indonesia and Vietnam. This is especially the case for companies specialising in the production of clothes and shoes.

But the story will not stop there. These industries require labour and as long as this remains the case, when a country

Table 26.6 Growth rates and export performance of selected secondary outward-looking countries

Source: Based on data from *Databank* (World Bank).

begins to grow this will lead to higher wage demands, which in turn will raise costs. Production will shift once more.

Moving up the value chain

So, what does this mean for China? When the USA and Europe lost their comparative advantage in the production of manufactured products, they had to look elsewhere. They developed a comparative advantage in the production of products requiring highly skilled labour and increasingly specialised in the services sector. However, with rising costs in emerging economies, more manufacturing, especially of high-value products, is being returned to these developed nations.

Research from 2013 considers the iPhone and electronics manufacturing in terms of comparative advantage and the value chain. Whilst the data on gross trade statistics confirm the decline of US competitiveness in this industry, the 'value-added trade statistics reveal the rising robustness of the United States' comparative advantage in electronics'. The suggestion is that, while China dominates in the sale of many finished exports, the simple sales data actually overstate China's productive capacity. Developed countries, such as the USA, the UK and Japan, often contribute to the value of the final products in terms of intellectual capital, design and technology.²

China will need to follow the pattern of the Western economies; its companies and workers will need to move up the value chain to find products that they can specialise in, which are not easily transferable to lower-wage countries.³ This is no easy task, as moving up the value chain will involve entering into direct competition with countries that have had time to develop their comparative advantage.

China's reliance on cheap labor has powered the country's economy to unprecedented heights. But China's manufacturing sector is running into problems these days: squeezed from one end by places with even lower labor costs, such as Laos and Vietnam, and yet struggling to move to higher ground making more advanced products because of competition from developed nations such as Germany and the United States.⁴

Despite the rising costs of production in China, it does have other factors that will ensure continued investment and production. In particular, the expansion of industrial clusters, such as Shenzhen, may help China to maintain its competitive advantage for many years.⁵

The changing nature of comparative advantage can cause problems for workers, businesses and countries, but benefits also emerge through greater competition, choice and innovation. The next few decades are likely to see some significant changes in the structure of industry in all countries.

Why are countries likely to see their comparative advantage change as they develop?

Section summary

1. Trade is of vital importance for the vast majority of developing countries, and yet most developing countries suffer from chronic balance of trade deficits.
2. Developing countries have traditionally been primary exporters. This has allowed them to exploit their comparative advantage in labour-intensive goods and has provided a market for certain goods that would otherwise have no market at home.
3. There are reasons for questioning the wisdom of relying on traditional primary exports, however. With a low world income elasticity of demand for many primary products, with the development of synthetic substitutes for minerals and with the protection of agriculture in developed countries, the demand for primary exports from the developing world has grown only slowly. At the same time, the demand for manufactured imports into developing countries has grown rapidly. Until recently, the result was a decline in the terms of trade. The rapid growth in demand for primary products from China and India has, to some extent, reversed this trend and the terms of trade have improved for many primary exporters.
4. Import-substituting industrialisation (ISI) was seen to be the answer to the problems of primary exporting. ISI was normally achieved in stages, beginning with the finished goods stage and then working back towards the capital goods stage. ISI, it was hoped, would allow countries to benefit from the various long-term advantages associated with manufacturing.

5. For many countries, however, ISI brought as many problems, if not more, than it solved. It often led to the establishment of inefficient industries, protected from foreign competition and facing little or no competition at home either. It led to considerable market distortions, with tariffs and other forms of protection haphazardly applied; to overvalued exchange rates, with a resulting bias against exports and the agricultural sector generally; to a deepening of inequalities and to large-scale social problems as the cities expanded, as poverty and unemployment grew and as traditional values were undermined; to increased dependency on imported inputs; and to growing environmental problems.
6. The most rapidly growing of the developing countries are those that have pursued a policy of export-orientated industrialisation. This has allowed them to achieve the benefits of economies of scale and foreign competition, and to specialise in goods in which they have a comparative advantage (i.e. labour-intensive goods) and yet which have a relatively high income elasticity of demand. Whether countries that have pursued ISI can successfully turn to an open, export-orientated approach will depend to a large extent on the degree of competition they face not only from advanced countries but also from other developing countries.

26.5 THE PROBLEM OF DEBT

Perhaps the most serious of all balance of payments problems in the world today is that faced by some of the poorest developing countries. Many of them experience massive financial outflows year after year as a result of having to 'service' debt (i.e. pay interest and make the necessary repayments). Much of this debt has been incurred in their attempts to finance development. Figure 26.7 shows the growth of external debt (as a proportion of national income) that began in the early 1970s.

The oil shocks of the 1970s

In 1973–4, oil prices quadrupled and the world went into recession. Oil imports cost much more and export demand was sluggish. The current account deficit of oil-importing developing countries rose from 1.1 per cent of GNY in 1973 to 4.3 per cent in 1975.

It was not difficult to finance these deficits, however. The oil surpluses deposited in commercial banks in the industrialised world provided an important additional source of finance. The banks, flush with money and faced with slack demand in the industrialised world, were very willing to lend. Bank loans to developing countries rose from \$3 billion in 1970 to \$12 billion in 1975. These flows enabled developing countries to continue with policies of growth.

The world recession was short-lived, and with a recovery in the demand for their exports and with their debts being eroded by high world inflation, developing countries found it relatively easy to service these increased debts (i.e. pay interest and make the necessary capital repayments).

In 1979–80 world oil prices rose again (from \$15 to \$38 per barrel). This second oil shock, like the first one, caused a large increase in the import bills of developing countries. But the full effects on their economies this time were very much worse (see Figure 26.7), given the debts that had been

accumulated in the 1970s and given the policies adopted by the industrialised world after 1979.

But why were things so much worse this time?

- The world recession was deeper and lasted longer (1980–83), and when recovery came, it came very slowly. Developing countries' current account balance of payments deteriorated sharply. This was due both to a marked slowing down in the growth of their exports and to a fall in their export prices.
- The tight monetary policies pursued by the industrialised countries led to a sharp increase in interest rates, and the resulting fall in inflation meant, therefore, that there was a very sharp increase in real interest rates. This greatly increased developing countries' costs of servicing their debts as can be seen in Figure 26.8.
- The problem was made worse by the growing proportion of debt that was at variable interest rates. This was largely due to the increasing proportion of debt that was in the form of loans from commercial banks.

Figure 26.8 shows how after 1979 debt servicing costs as a proportion of national income rose across developing countries, making it increasingly difficult for them to service their debts. Then in 1982 Mexico, followed by several other countries such as Brazil, Bolivia, Zaire and Sudan, declared that it would have to suspend payments. There was now a debt crisis, which threatened not only the debtor countries, but also the world banking system.

Coping with debt: rescheduling

There have been two dimensions to tackling the debt problems of developing countries. The first is to cope with difficulties in servicing their debt. This usually involves some form of rescheduling of the repayments. The second

Figure 26.7 External debt as a percentage of gross national income (GNY)

Source: Based on data from *Databank* (World Bank), series DT.DOD.DECT.GN.ZS.

dimension is to deal with the causes of the problem. Here we will focus on rescheduling.

Rescheduling official loans

Official loans are renegotiated through the Paris Club. Industrialised countries are members of the club, which arranges terms for the rescheduling of their loans to developing countries. Agreements normally involve delaying the date for repayment of loans currently maturing, or spreading the repayments over a longer period of time. Paris Club agreements are often made in consultation with the IMF, which works out a programme with the debtor country for tackling its underlying economic problems.

Several attempts have been made since the mid-1980s to make rescheduling terms more generous, with longer periods before repayments start, longer to repay when they do start, and lower interest rates. In return, the developing countries have had to undertake various 'structural adjustment programmes' supervised by the IMF (see below).

But despite the apparent advances made by the Paris Club in making its terms more generous, the majority of low-income countries failed to meet the required IMF conditions, and thus failed to have their debts reduced. What is more, individual Paris Club members were often reluctant to reduce debts unless they were first convinced that other members were 'paying their share'. Nevertheless, some creditor countries unilaterally introduced more generous terms and even cancelled some debts.

The net effect of rescheduling, but only very modest debt forgiveness, can be seen in Figures 26.7 and 26.8. By the mid-1990s average debt service ratios had fallen from the levels of

the mid-1980s and yet the ratio of total debt to GNY was higher. There were thus growing calls for the cancellation of debts (see below).

Rescheduling commercial bank loans

After the declarations by Mexico and other countries of their inability to service their debts, there was fear of an imminent collapse of the world banking system. Banks realised that disaster could be averted only by collective action of the banks to reschedule debts. Banks were prepared to reschedule some of the debts and to provide some additional loans in return for debtor countries undertaking structural adjustment (as described below). Additional loans, however, fell well short of the amount that was needed. Nevertheless, banks were increasingly setting aside funds to cover bad debt, and thus the crisis for the banks began to recede.

As banks felt less exposed to default, so they became less worried about it and less concerned to negotiate deals with debtor countries. Many of the more severely indebted countries, however, found their position still deteriorating rapidly. What is more, many of them were finding that the IMF adjustment programmes were too painful (often involving deep cuts in government expenditure) and were therefore abandoning them. Thus, in 1989, US Treasury Secretary Nicholas Brady proposed measures to *reduce* debt.

The *Brady Plan* involved the IMF and the World Bank lending funds to debtor countries to enable them to repay debts to banks. In return for this instant source of liquidity, the banks would have to be prepared to accept repayment of less than the full sum (i.e. they would sell the debt back to the country at a discount). To benefit from such deals, the debtor

BOX 26.6 A DEBT TO THE PLANET

Developing an agenda for sustainable development

Ecocide

Faced with mounting debts and the need to service them, many developing countries have attempted to increase their export earnings. One way of achieving this is through the intensified extraction of minerals and ores or intensified farming, often by multinational corporations. But a consequence of this may be massive environmental damage.

Brazil. An example of a country forced into what has been called 'ecocide' in response to its huge debt burden is Brazil. One of the most environmentally damaging of all Brazilian projects has been the Grande Carajas iron ore project. Proposed in 1980, the Carajas scheme cost some \$62 billion and has involved massive deforestation of an area larger than France and Britain combined. The Brazilian government has been willing to allow this environmental damage because Carajas is seen as a 'national export project'. Indeed, various plans have been approved for further mining activity in the area. In July 2013, for example, the Carajas Serra Sul S11D Iron Project, the largest iron ore mine project in the world, was approved and production began in December 2016, with supply expected to reach 90 million metric tonnes by 2018.

Venezuela. Another example of ecocide has occurred in Venezuela. The country has huge gold reserves – some 12 per cent of the world total. With the fall in oil prices in the 1990s, and hence a fall in revenues for Venezuela, one of the world's leading oil exporters, the Venezuelan authorities sought to exploit the country's gold reserves more aggressively. By 1994, the state had contracted out some 436 sites, covering 12 839 km². By 2000, this had risen to 30 000 km² (an area the size of Belgium), earning revenue of some \$250 million per year.

The extraction of gold, however, has wrought great environmental damage. The richest gold reserves are in the Guayana region of Venezuela, which makes up part of the Amazon river basin. It is an area rich, and in many respects unique, in its biodiversity. The environmental impact of open-cast mining within the region is already being felt. One of the most serious consequences has been the poisoning of rivers with mercury (used to separate gold from other minerals). In addition to the destruction of the forests and rivers, there are many cases where indigenous peoples have had their human rights violated and have even been murdered to make way for the mines.

Indonesia. The misuse and destruction of rainforests caused dramatic effects in 1997. In large parts of Indonesia (another highly indebted country), it is normal practice to burn land after forests have been felled, either to clear it for crops or for replanting. In 1997, the El Niño effect on ocean currents had caused a major drought and the forest fires got out of hand. As a result, air pollution on a massive scale affected many countries in South East Asia. Most of Indonesia, Malaysia and Singapore became covered with a haze of dense smoke. The international air pollutant index has a scale on which readings above 500 are considered extremely hazardous. In parts of Malaysia readings of 1200 were recorded – equivalent to smoking a couple of packs of cigarettes a day. Schools and airports were closed, and income from tourism was lost throughout the region.

Biodiesel. A recent case of ecocide is the production of palm oil as a biofuel. The environmental justification was that the carbon dioxide given off by burning the fuel is offset by the carbon absorbed by growing the oil palm trees. But this has turned out to be only part of the story. The production of the

countries would have to agree to structural adjustment programmes. Several such agreements were negotiated; much of the debt reduction has involved debt swaps of one sort or another (see Case Study 26.16 on the student website).

What are the relative advantages and disadvantages to a developing country of rescheduling its debts compared with simply defaulting on them (either temporarily or permanently)?

Dealing with debt: structural reform within the developing countries

The IMF has typically demanded that debtor countries pursue severe structural adjustment programmes before it has been prepared to sanction the rescheduling of debts. Such programmes have included:

- Supply-side reforms to encourage greater use of the market mechanism and greater incentives for investment.
 - A more open trade policy and devaluation of the currency in order to encourage more exports and more competition.
- These policies, however, often brought extreme hardship as countries were forced to deflate. Unemployment and poverty increased and growth slowed down or became negative. Even though in the long run some developing countries emerged as more efficient and better able to compete in international trade, in the short run the suffering for many was too great to bear. Popular unrest and resentment against the IMF and the country's government led to riots in many countries and a breakdown of law and order.
- A more 'complete' structural adjustment would extend beyond simple market liberalisation and tough monetary policies to much more open access to the markets of the rich countries (the subject of much of the Doha Round

additional palm oil has involved either cutting down rainforest, which, apart from being a much more efficient carbon absorber than oil palm trees, is habitat for many endangered species, or the draining and burning of peat lands, which sends huge amounts of carbon dioxide into the atmosphere.

The Rio Declaration

In recent years, there has been growing international awareness of the scale of the environmental destruction that is taking place. In particular, the rich countries have begun to realise that they too might suffer from this destruction, with its consequences for global warming and the loss of many unique species of plants and animals. Increasingly, international agencies such as the IMF and the World Bank are taking ecological issues into account when considering appropriate development and adjustment programmes.

Many in the developed world now realise that development must be sustainable. It is no good trying to secure 'development' for the current generation if, in the process, the environment is damaged and future generations suffer. This is a message that has been well understood by indigenous peoples for countless generations, especially those living on marginal lands: from the Aborigines of the Australian outback to the tribes of the African bush. It is seen as a moral imperative that the land bequeathed by one's ancestors should be passed on in just as good a state to one's descendants (see pages 395–6).

In 1992 in Rio de Janeiro, the United Nations Conference on Environment and Development (UNCED) put forward a programme for environmentally responsible development. In Agenda 21 it set out various policies that could be carried out by the international community. The policies, which were approved by 178 countries, included: targeting aid to projects that helped improve the

environment (such as providing clean water); research into environmentally friendly farming methods; and programmes that help reduce population growth (such as family planning and education).

The test of such sentiments, however, is action. To monitor this, a Commission on Sustainable Development (CSD) was established in December 1992. In 2003, it set out a programme until 2015. Every two years from 2004 there was a particular focus for action, including themes around water, sanitation, sustainable development, climate change, forestry and biodiversity.

2030 Agenda for Sustainable Development

In September 2015, the UN adopted the 2030 Agenda for Sustainable Development. This saw a commitment to 17 Sustainable Development Goals and 169 targets, building on the Millennium Development Goals. The aim, the UN argued, is to end poverty, protect the planet and ensure prosperity for all.

The overseer of the progress in meeting the goals and targets of the sustainable development agenda was to be a body known as the High Level Political Forum (HLPF). As with the CSD, the HLPF was to meet periodically, again with meetings arranged around particular themes. For instance, the theme of its 2017 meeting was eradicating poverty and promoting prosperity in a changing world.

1. *If reductions in developing countries' debt are in the environmental interests of the whole world, then why have developed countries not gone much further in reducing or cancelling the debts owed to them?*
2. *Would it be possible to devise a scheme of debt repayments that would both be acceptable to debtor and creditor countries and not damage the environment?*

negotiations: see Box 24.8), to more aid and debt relief being channelled into health and education, and to greater research and development in areas that will benefit poor people (e.g. into efficient labour-intensive technology and into new strains of crops that are suitable for countries' specific climate and soil conditions, and which do not require large amounts of chemicals).

Dealing with debt: debt forgiveness

By the end of the 1990s, the debt burden of many of the poorest countries had become intolerable. Despite portions of their debt being written off under Paris Club terms, the debts of many countries were still rising. Between 1980 and 2000, the debt of sub-Saharan Africa had increased some 3½ times, from \$61 billion to \$212 billion. Some countries, such as Ethiopia and Mozambique, were spending nearly half their export earnings on merely servicing their debt.

Even with substantial debt rescheduling and some debt cancellation, highly indebted countries were being forced to make savage cuts in government expenditure, much of it on health, education and transport. The consequence was a growth in poverty, hunger, disease and illiteracy. African countries on average were paying four times more to rich countries in debt servicing than they were spending on health and education: it was like a patient giving a blood transfusion to a doctor! The majority of these countries had no chance of 'growing their way out of debt'. The only solution for them was for a more substantial proportion of their debt to be written off.

The heavily indebted poor countries (HIPC) initiative

In 1996, the World Bank and the IMF launched the HIPC initiative. A total of 42 countries, mainly in Africa, were identified as being in need of substantial debt relief. This number was subsequently reduced to 39, of which 33 are in

Figure 26.8 Debt servicing costs as a percentage of gross national income (GNY)

Source: Based on data from *Databank* (World Bank), series DT.TDS.DECT.GN.ZS.

Africa. The object of the initiative has been to reduce the debts of such countries to 'sustainable' levels by cancelling debts above 200–250 per cent of GDP (this was reduced to 150 per cent in 1999 and to a lower level still for five countries).

The HIPC process involved countries passing through two stages. In the first stage, eligible countries had to demonstrate a track record of 'good performance'. This means that they had to satisfy the IMF, the World Bank and the Paris Club that they were undertaking adjustment measures, such as cutting government expenditure and liberalising their markets. It also involved the countries preparing a Poverty Reduction Strategy Paper (PRSP) to show how they would use debt relief to tackle poverty, and especially how they would improve health and education. Once the IMF and the World Bank were satisfied that the country was making sufficient progress, the 'decision point' was reached and the level of debt relief would be determined. The country would then enter the second stage. All 39 countries have now reached this stage.

During this second stage, some interim debt relief is provided. Meanwhile the country must establish a 'sound track record' by implementing policies established at the decision point and based on the PRSP. The length of this stage depends on how long it takes the country to implement the policies. At the end of the second stage, the country reaches the 'completion point' and debts are cancelled (as agreed at the decision point) by the various creditors, on a pro rata basis, to bring the debt to the sustainable threshold.

In 2006, debt relief for the HIPCs that reached the completion point was extended under the Multilateral Debt Relief Initiative (MDRI). This involves cancelling multilateral debt incurred before 2004.

By 2017, 36 of the HIPCs had reached the completion point and were receiving MRDI relief, and three were at the pre-decision point. It is estimated that by the end of 2015 \$76 billion had been cancelled under the HIPC programme and a further \$50 billion under MDRI. The debt stocks of the 36 post-decision-point HIPCs had been reduced by over 97 per cent, while poverty-reducing expenditure as a share of government revenue had increased from 42 per cent in 1999 to 45 per cent in 2015. The effect on various debt indicators is shown in Table 26.7. As you can see, the improvement has been dramatic.

Despite this substantial relief, the programme has been heavily criticised for taking too long and imposing excessively harsh conditions on the HIPC countries. The required reductions in government expenditure have led to deep cuts in basic health and education, and deflationary policies have led to reductions in investment.

Then there are the non-HIPCs. Many of these countries are also suffering debts which divert a large percentage of their income from poverty relief. Just because non-HIPCs can manage to service their debts, it does not make it desirable that they should be forced to do so.

Table 26.7 Debt indicators of 36 post-decision-point HIPCs

	1999 (%)	2015 (%)
Present value of debt-to-exports	457	87
Present value of debt-to-GDP	114	22
Debt service-to-exports	18	6
Present value of debt-to-revenue	552	126
Debt service-to-revenue	22	9

Source: *Debt Relief Facts*, April 2017 (The World Bank).

According to many charities, such as Oxfam, a much better approach would be to target debt relief directly at poverty reduction, with the resources released being used for investment in fields such as health, education, rural development and basic infrastructure. The focus, they argue, should be on what countries can afford to pay *after* essential spending on poverty relief and human development.

Imagine that you are an ambassador of a developing country at an international conference. What would you try to persuade the rich countries to do in order to help you and other poor countries overcome the debt problem? How would you set about persuading them that it was in their own interests to help you?

Should all debt be cancelled and aid increased?

In recent years there have been growing calls for the cancellation of debts and a significant increase in aid, especially for the poorest developing countries, many ravaged by war, drought or AIDS. The United Nations has for many years called on wealthy countries to give 0.7 per cent of their GDP in aid.

In 2016 the net flow of aid, i.e. official development assistance (ODA), from the 29 donor countries plus European Union institutions which comprise the OECD's Development Assistance Committee (DAC) amounted to \$143 billion, a mere 0.3 per cent of gross national income (GNY). As

Figure 26.9 shows, many countries fail to meet the UN target. The UK has met the target since 2013. In 2015 the UK parliament passed legislation requiring government to meet the 0.7 per cent foreign aid target.

As we have seen, the HIPC and MDRI relief has reduced such countries' debt dramatically. However, as of 2015 low-income countries' external debt still amounted to close to \$110 billion and developing countries as a whole owed some \$6.7 trillion. Then there is the plight of many non-HIPC countries, such as Kenya, which could be argued to be in greater need of debt relief than some HIPC countries.

The argument against debt cancellation and a substantial increase in aid is that this could represent a 'moral hazard' (see page 135). Once the burden of debt had been lifted and aid had been increased, countries might be tempted to squander the money. It might also encourage them to seek further loans, which might again be squandered.

For this reason, much of the disbursement of funds by donor countries, the IMF and other agencies has been conditional on countries pursuing policies of fiscal restraint and supply-side reform. But also, in recent years, conditionality has required recipient countries to pursue key poverty-reducing projects, such as health, education, clean water and other basic infrastructure projects. (Case Study 26.15 on the student website examines some of the issues surrounding aid.)

Figure 26.9 Official Development Assistance by DAC countries, per cent of GNY, 2016

Source: Based on data from *International Development Statistics* online databases (OECD).

Section summary

1. After the 1973 oil crisis, many developing countries borrowed heavily in order to finance their balance of trade deficits and to maintain a programme of investment. After the 1979 oil price rises the debt problem became much more serious. There was a world recession and real interest rates were much higher. Debt increased dramatically, and much of it at variable interest rates.
2. Rescheduling can help developing countries to cope with increased debt in the short run and various schemes have been adopted by creditor countries and the banks.
3. If the problem is to be tackled, however, then either debts have to be written off – something that banks have been increasingly forced to do – or the developing countries themselves must take harsh corrective measures. The IMF has traditionally favoured ‘structural adjustment’ policies of deflation and market-orientated supply-side policies. An alternative is to use debt relief and aid to invest in health, education, roads and other infrastructure.
4. In 1996, the World Bank and the IMF launched the HIPC initiative to help reduce the debts of heavily indebted poor countries to sustainable levels. HIPC relief has been criticised, however, for being made conditional on the debtor countries pursuing excessively tough IMF adjustment programmes, for having an excessively long qualifying period and debt sustainability thresholds that are too high, and for delays in its implementation. A better approach might be to target debt relief directly at programmes to help the poor.

END OF CHAPTER QUESTIONS

1. Under what circumstances does a growth in financial flows make exchange rates less stable?
2. Assume that countries in the eurozone decide to pursue a deflationary fiscal policy. What effect is this likely to have on the UK economy?
3. It is often argued that international convergence of economic indicators is a desirable objective. Does this mean that countries should all seek to achieve the same rate of economic growth, monetary growth, interest rates and budget deficits as a percentage of their GDP, etc.?
4. Did the exchange rate difficulties experienced by countries under the ERM strengthen or weaken the arguments for progressing to a single European currency?
5. Assume that just some of the members of a common market like the EU adopt full economic and monetary union, including a common currency. What are the advantages and disadvantages to those members joining the full EMU and to those not?
6. Is the eurozone an optimal currency area? Explain your answer.
7. How are asymmetric shocks dealt with within a country? To what extent can this process be mirrored within the eurozone?
8. Would the world benefit from the general imposition of controls on the movement of international finance?
9. Compare the relative merits of using GNY statistics with those of various basic needs indicators when assessing both the level and the rate of a country’s economic development.
10. If a developing country has a comparative advantage in primary products, should the government allow market forces to dictate the pattern of trade?
11. What are the advantages and disadvantages for a developing country of pursuing a policy of ISI?
12. Should all developing countries aim over the long term to become *exporters* of manufactured products?
13. How would you attempt to assess whether the technology used by an industry in a developing country was ‘inappropriate’?
14. To what extent was the debt crisis of the early 1980s caused by inappropriate policies that had been pursued by the debtor countries?
15. Assess the operation and success of the HIPC programme.

Postscript: *The Castaways or Vote for Caliban*

The Pacific Ocean –
A blue demi-globe.
Islands like punctuation marks.

A cruising airliner,
Passengers unwrapping pats of butter.
A hurricane arises,
Tosses the plane into the sea.

Five of them flung onto an island beach,
Survived.

Tom the reporter.
Susan the botanist.
Jim the high-jump champion.
Bill the carpenter.
Mary the eccentric widow.

Tom the reporter sniffed out a stream of drinkable water.
Susan the botanist identified a banana tree.
Jim the high-jump champion jumped up and down and gave them each a bunch.
Bill the carpenter knocked up a table for their banana supper.
Mary the eccentric widow buried the banana skins,
But only after they had asked her twice.

They all gathered sticks and lit a fire.
There was an incredible sunset.

Next morning they held a committee meeting.
Tom, Susan, Jim and Bill
Voted to make the best of things.
Mary, the eccentric widow, abstained.

Tom the reporter killed several dozen wild pigs.
He tanned their skins into parchment
And printed the *Island News* with the ink of squids.

Susan the botanist developed new strains of banana
Which tasted of chocolate, beefsteak, peanut butter,
Chicken and bootpolish.

Jim the high-jump champion organised organised games
Which he always won easily.
Bill the carpenter constructed a wooden water wheel
And converted the water's energy into electricity.
Using iron ore from the hills, he constructed lampposts.

They all worried about Mary, the eccentric widow,
Her lack of confidence and her –
But there wasn't time to coddle her.

The volcano erupted, but they dug a trench
And diverted the lava into the sea
Where it formed a spectacular pier.
They were attacked by pirates but defeated them
With bamboo bazookas firing
Sea-urchins packed with home-made nitro-glycerine.
They gave the cannibals a dose of their own medicine
And survived an earthquake thanks to their skill in jumping.

Tom had been a court reporter
So he became a magistrate and solved disputes.
Susan the botanist established
A university which also served as a museum.
Jim the high-jump champion
Was put in charge of law enforcement –
Jumped on them when they were bad.
Bill the carpenter built himself a church,
Preached there every Sunday.

But Mary the eccentric widow . . .
Each evening she wandered down the island's main street,
Past the Stock Exchange, the Houses of Parliament,
The prison and the arsenal.
Past the Prospero Souvenir Shop,
Past the Robert Louis Stevenson Movie Studios,
Past the Daniel Defoe Motel
She nervously wandered and sat on the end of the pier of lava.

Breathing heavily,
As if at a loss,
As if at a lover,
She opened her eyes wide
To the usual incredible sunset.

Appendix 1: Some Techniques of Economic Analysis

As you will see if you flick back through the pages, there are many diagrams and tables and several equations. But this does not mean that there are many mathematical techniques that you will have to master in order to study this book. In fact there are relatively few techniques, but they are ones which we use many times in many different contexts. You will find that if you are new to the subject, you will very quickly become familiar with these techniques. If you are not new to the subject, perhaps you could reassure your colleagues who are!

On some university courses, however, you will take mathematics to a higher level. To meet your needs there are a number of optional 'Looking at the Maths' sections scattered throughout the book. These use maths to express arguments that have just been covered in words or diagrams. Most of these 'Looking at the Maths' sections also refer to 'Maths Cases' on the student website. These cases consist of worked examples and also have one or more questions at the end for you to test your understanding of the relevant technique. The answers to these questions are also given on the student website.

But please note that the 'Looking at the Maths' sections are purely optional and will not be suitable for many courses. In such cases you can simply ignore them.

can often depict an event much more vividly than any verbal account, so too a diagram in economics can often picture a relationship with a vividness and clarity that could never be achieved by words alone.

For example, we may observe that as people's incomes rise, they spend a lot more on entertainment and only a little more on food. We can picture this relationship very nicely by the use of a simple graph.

In Figure A1.1, an individual's income is measured along the horizontal axis and expenditure on food and entertainment is measured up the vertical axis. There are just two lines on this diagram: one showing how the expenditure on entertainment rises as income rises, the other how the expenditure on food rises as income rises. Now we could use a diagram like this to plot actual data. But we may simply be using it as a sketch – as a picture. In this case we do not necessarily need to put figures on the two axes. We are simply showing the relative *shapes* of the two curves. These shapes tell us that the person's expenditure on entertainment rises more quickly than that on food, and that above a certain level of income the expenditure on entertainment becomes greater than that on food.

Diagrams as pictures

On many occasions, we use diagrams simply to provide a picture of a relationship. Just as a photograph in a newspaper

What else is the diagram telling us?

Representing real-life statistics

In many cases, we will want to depict real-world data. We may want to show, for example, how unemployment has changed over the years in a particular country, or how income is distributed between different groups in the population. In the first we will need to look at *time-series* data. In the second we will look at *cross-section* data.

Time-series data

Table A1.1 shows the level of UK unemployment between the first quarter of 2010 and the second quarter of 2017. A table like this is a common way of representing *time-series data*. It has the advantage of giving the precise figures, and is thus a useful reference if we want to test any theory and see if it predicts accurately.

Notice that in this particular table the figures are given quarterly. Depending on the period of time over which we want to see the movement of a variable, it may be more appropriate to use a different interval of time. For example, if we wanted to see how unemployment had changed over the past 50 years, we might use annual figures or even average figures for longer periods of time. If, however, we wanted to see how unemployment had changed over the course of a year, we would probably use monthly or even weekly figures.

 The table in Box 1.1 shows time-series data for four different variables for four different countries. Would there have been any advantage in giving the figures for each separate year? Would there have been any disadvantage?

Time-series data can also be shown graphically. In fact the data from a table can be plotted directly on to a graph. Figure A1.2 plots the data from Table A1.1. Each dot on the graph

corresponds to one figure from the table. The dots are then joined up to form a single line. Thus if you wanted to find the level of unemployment at any time between 2010 Q1 and 2017 Q2, you would simply find the appropriate date on the horizontal axis, read vertically upward to the line you have drawn, then read across to find the level of unemployment.

Although a graph like this cannot give you quite such an accurate measurement of each point as a table does, it gives a much more obvious picture of how the figures have moved over time and whether the changes are getting bigger (the curve getting steeper) or smaller (the curve getting shallower). We can also read off what the likely figure would be for some point *between* two observations.

 What was the level of unemployment midway between quarter 1 and quarter 2 of 2014?

It is also possible to combine *two* sets of time-series data on one graph to show their relative movements over time. Table A1.2 shows the figures for UK economic growth for the same time period. Figure A1.3 plots these data along with those from Table A1.1. This enables us to get a clear picture of how unemployment and the rate of economic growth moved in relation to each other over the period in question. Note that we use a different vertical scale for the two variables. This is inevitable given that they are measured in different units.

 How would it be possible to show three different lines on the same diagram?

All developed countries publish time-series data for the major macroeconomic variables such as national income, prices, employment and unemployment, interest rates, and imports and exports. Microeconomic data on the distribution of income, the performance of particular industries, the distribution of household expenditure, and so on, appear in the official government statistics. Firms, consumers' associations, charities and other organisations also publish microeconomic statistics.

Source: *The Effects of Taxes and Benefits on Household Income, financial year ending 2016*, Table 29 (ONS, 2017).

There are also several sources of data freely available on the Internet. Section B of Appendix 2 gives a number of websites containing datasets. These websites can be accessed directly from the hotlinks section of this book's own website (www.pearsoned.co.uk/sloman).

Cross-section data

Cross-section data show different observations made at the same point in time. For example, they could show the quantities of food and clothing purchased at various levels of household income, or the costs to a firm or industry of producing various quantities of a product.

Table A1.3 gives an example of cross-section data. It shows the distribution of household income in the UK before the deduction of taxes and the addition of benefits. It puts households into five equal-sized groups (or 'quintiles') according to their income. Thus the poorest 20 per cent of households are in one group, the next poorest 20 per cent are in the next and so on. Looking just at the 2015/16 figures, they show that the poorest 20 per cent earned just 4 per cent of total household incomes, whereas the richest 20 per cent earned 48 per cent.

Figure A1.4 The distribution of UK pre-tax income: the use of a bar chart

Cross-section data like these are often represented in the form of a chart. Figure A1.4 shows the data as a *bar chart*, and Figure A1.5 as two *pie charts*.

It is possible to represent cross-section data at two or more different points in time, thereby presenting the figures as a time series. In Table A1.3, figures are given for just two time periods. With a more complete time series we could graph the movement of the shares of each of the five groups over time.

Definition

Cross-section data Information showing how a variable (e.g. the consumption of eggs) differs between different groups or different individuals at a given time.

Could bar charts or pie charts be used for representing time-series data?

Figure A1.5 The distribution of UK pre-tax income: the use of a pie chart

Getting a true picture from the statistics

'There are lies, damned lies and statistics.' This well-known saying highlights the abuse of statistics – abuse, unfortunately, that is commonplace. Have you noticed how politicians always seem to be able to produce statistics to 'prove' that they are right and that their opponents are wrong? And it's not just politicians. Newspapers frequently present statistics in the most 'newsworthy' way; companies try to show their performance in the most flattering way; pressure groups fighting for a cause (such as the protection of the environment) again present statistics in the way that best supports their case.

It is not difficult to present data in such a way as to give a grossly distorted picture of a situation. Let us have a look at some of the most common examples.

Selective use of data

This is where people select only those statistics that support their case and ignore those that do not. For example, assume that unemployment has risen but inflation has fallen. The government highlights the inflation statistics to show how successful its policies have been. The opposition parties do the opposite: they concentrate on the unemployment statistics to demonstrate the failure of government policy.

Graphical presentation of data

Two graphs may present exactly the same data and yet convey a quite different impression about them. Figure A1.6 shows how the amount that people buy of a particular foodstuff varies with their income. It is based on the information in Table A1.4.

Diagram (a) shows *exactly the same* information as diagram (b), and yet at a glance it would seem from diagram (a) that

people buy a lot more as their incomes rise, whereas from diagram (b) it would seem that people only buy a little more.

Clearly the choice of *scales* for the two axes will determine the shape of the graph.

1. If the vertical scale for Figure A1.2 ran from 0 to 5 million, how would this alter your impression of the degree to which unemployment had changed?
2. What are the advantages and disadvantages of presenting data graphically with the axes starting from zero?

Use of absolute or proportionate values

'People are paying more taxes now than they did when the government came to office', claims the opposition.

'Since coming into office we have cut taxes substantially', claims the government.

So who is right? Do we pay more or less tax? Quite possibly they are both right. If incomes have risen, we probably do pay more tax in total. After all, the more we earn, the greater the sum of money we will be paying in income tax; and the more we spend, the more we will be paying out in VAT. Thus in *absolute* terms we probably are paying more in taxes.

On the other hand, if the government has cut the rates of tax, we may be paying a smaller *proportion* of our income. In other words, a smaller proportion of a larger total can still represent an absolute increase.

Ignoring questions of distribution

'The average person has become better off under this government', claims a minister.

'Poverty has increased steeply under this government', claims the opposition. 'More than half the population are worse off now than when the government came to office.'

Figure A1.6 The relationship between consumer income and the consumption of a particular foodstuff, using graphs with different scales

Table A1.4 Annual purchases per person of a particular foodstuff

Consumer income (£ per year)	0	10 000	20 000	30 000	40 000
Foodstuff purchased per person (kg per year)	10	25	45	70	100

Surely, this time one of the claims must be wrong? But again, both could be right. The term 'average' normally refers to the **mean**. The mean income is simply the total national income divided by the number in the population: i.e. income *per head*. If this is what is meant by the average, then the government may well be correct. Income per head may have risen.

If, however, a small number of people have got a lot richer and the rest have got a little poorer, the **median** income will have fallen. The median income is the income of the *middle* person. For example, if the population were 50 million, the median income would be the income of the 25 millionth richest person. This person's income may have fallen.

Real or nominal values

'Incomes have risen by 2 per cent this last year', claims the government.

'The standard of living has fallen', claims the opposition.

One of the most common abuses of statistics is deliberately switching between real and nominal figures, depending on what message you want to give your audience. **Nominal** figures are the simple monetary values at the prices ruling at the time. For example, if you earned a wage of £500 per week last year and are earning £510 per week this year, then in nominal terms your wage has risen by 2 per cent.

But what if prices have risen by 3 per cent? Your 2 per cent increase in wages will in fact buy you 1 per cent *less*. Your **real** wages have gone down by 1 per cent. In other words, to show how much better or worse off a person or nation is, the nominal figure must be corrected for inflation.

Thus:

$$\text{Real growth} = \text{Nominal growth} - \text{Inflation}$$

1. If a bank paid its depositors 3 per cent interest and inflation was 5 per cent, what would be the real rate of interest?
2. Has your real income gone up or down this last year?

The distinction between nominal and real figures

Nominal figures are those using current prices, interest rates, etc. Real figures are figures corrected for inflation.

The time chosen for comparison

'Between 1982 and 1990, Britain's real growth rate averaged 3.5 per cent per year', boasted the Conservative government of the time.

'Between 1979 and 1993, Britain could only manage a real growth rate of 1.6 per cent per year', chided the opposition.

Again, both were correct, but they had chosen either to include or to ignore the periods from 1979 to 1982 and from 1990 to 1993 when the real growth rate was negative.

Index numbers

Time-series data are often expressed in terms of **index numbers**. Consider the data in Table A1.5. It shows index numbers of manufacturing output in the UK from 1985 to 2013.

One year is selected as the **base year** and this is given the value of 100. In our example this is 2013. The output for other years is then shown by their percentage variation from 100. For 1987 the index number is 90.0. This means that manufacturing output was 10.0 per cent lower in 1987 than in 2013. The index number for 2007 is 108.9. This means that manufacturing output was 8.9 per cent higher in 2007 than in 2013.

Does this mean that the value of manufacturing output in 2007 was 8.9 per cent higher than 2013 in money terms?

The use of index numbers allows us to see clearly any upward and downward movements and to make an easy comparison of one year with another. For example, Table A1.5 shows quite clearly that manufacturing output fell from

Definitions

Mean (or arithmetic mean) The sum of the values of each of the members of the sample divided by the total number in the sample.

Median The value of the middle member of the sample.

Nominal values Money values measured at *current* prices.

Real values Money values corrected for inflation.

Index number The value of a variable expressed as 100 plus or minus its percentage deviation from a base year.

Base year (for index numbers) The year whose index number is set at 100.

Table A1.5 UK manufacturing output (2013 = 100)

1987	1988	1989	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001
90.0	96.6	100.4	100.3	95.2	95.2	96.6	101.1	102.6	103.4	105.2	105.6	106.2	108.5	106.9
2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016
104.6	104.0	105.9	105.9	108.2	108.9	105.8	95.9	100.3	102.5	101.0	100.0	102.9	102.7	103.5

1990 to 1991 and did not surpass its 1989 level until 1994. It fell again from 2007 to 2009 and from 2011 to 2013.

Using index numbers to measure percentage changes

To find the annual percentage growth rate in any one year we simply look at the percentage change in the index from the previous year. To work this out we use the following formula:

$$\left(\frac{I_t - I_{t-1}}{I_{t-1}} \right) \times 100$$

where I_t is the index in the year in question and I_{t-1} is the index in the previous year.

Thus to find the growth rate in manufacturing output from 1987 to 1988 we first see how much the index has risen ($I_t - I_{t-1}$). The answer is $96.6 - 90.0 = 6.6$. But this does *not* mean that the growth rate is 6.6 per cent. According to our formula, the growth rate is equal to

$$\begin{aligned} & \frac{96.6 - 90.0}{90.0} \times 100 \\ &= 6.6/90.0 \times 100 \\ &= 7.3 \end{aligned}$$

 What was the growth rate in manufacturing output from (a) 2005 to 2006; (b) 2008 to 2009?

The price index

Perhaps the best known of all price indices is the **consumer prices index (CPI)**. It is an index of the prices of goods and services purchased by the average household. Movements in this index, therefore, show how the cost of living has changed. Annual percentage increases in the CPI are the commonest definition of the rate of inflation. Thus if the CPI went up from 100 to 110 over a 12 month period, we would say that the rate of inflation was 10 per cent.

 If the CPI went up from 150 to 162 over 12 months, what would be the rate of inflation?

The use of weighted averages

The CPI is a **weighted average** of the prices of many items. The index of manufacturing output that we looked at previously was also a weighted average, an average of the output of many individual products.

To illustrate how a weighted average works, consider the case of a weighted average of the output of just three industries, A, B and C. Let us assume that in the base year (year 1) the output of A was £7 million, of B £2 million and of C £1 million, giving a total output of the three industries of £10 million. We now attach weights to the output of each industry to reflect its proportion of total output. Industry A is given a weight of 0.7 because it produces seven-tenths of total output. Industry B is given a weight of 0.2 and industry C a weight of 0.1. We then simply multiply each industry's index by its weight and add up all these figures to give the overall industry index.

The index for each industry in year 1 (the base year) is 100. This means that the weighted average index is also 100. Table A1.6 shows what happens to output in year 2. Industry A's output falls by 10 per cent, giving it an index of 90 in year 2. Industry B's output rises by 10 per cent and industry C's output rises by 30 per cent, giving indices of 110 and 130, respectively. But as you can see from the table, despite the fact that two of the three industries have had a rise in output, the total industry index has *fallen* from 100 to 98. The reason is that industry A is so much larger than the other two that its decline in output outweighs their increase.

The consumer prices index is a little more complicated. This is because it is calculated in two stages. First, products are grouped into categories such as food, clothing and services. A weighted average index is worked out for each group. Thus the index for food would be the weighted average of the indices for bread, potatoes, cooking oil, etc. Second, a weight is attached to each of the groups in order to work out an overall index.

Functional relationships

Throughout economics we examine how one economic variable affects another: how the purchases of cars are affected

Definitions

Consumer prices index (CPI) An index of the prices of goods bought by a typical household.

Weighted average The average of several items where each item is ascribed a weight according to its importance. The weights must add up to 1.

Table A1.6 Constructing a weighted average index

Industry	Weight	Year 1		Year 2	
		Index	Index times weight	Index	Index times weight
A	0.7	100	70	90	63
B	0.2	100	20	110	22
C	0.1	100	10	130	13
Total	1.0		100		98

by their price; how consumer expenditure is affected by taxes, or by incomes; how the cost of producing washing machines is affected by the price of steel; how the rate of unemployment is affected by the level of government expenditure. These relationships are called **functional relationships**. We will need to express these relationships in a precise way, preferably in the form of a table or a graph or an equation.

Simple linear functions

These are relationships which produce a straight line when plotted on a graph. Let us take an imaginary example of the relationship between total value added tax receipts in an economy (V) and the level of consumer expenditure (C). This functional relationship can be written as:

$$V = f(C)$$

This is simply shorthand for saying that VAT receipts are a function of (i.e. depend on) the level of consumer expenditure.

If we want to know just *how much* VAT revenue will be at any given level of consumer expenditure, we will need to spell out this functional relationship. Let us do this in each of the three ways.

As a table. Table A1.7 gives a selection of values of C and the corresponding level of V . It is easy to read off from the table the level of VAT receipts at one of the levels of consumer expenditure listed. It is clearly more difficult to work out the level of VAT receipts if consumer expenditure is £23.4 billion or £47.6 billion.

As a graph. Figure A1.7 plots the data from Table A1.7. Each of the dots corresponds to one of the points in the table. By joining the dots up into a single line we can easily read off the value for VAT receipts at some level of consumption other than those listed in the table. A graph also

Figure A1.7 A graph of the VAT function: $V = 0.2C$

has the advantage of allowing us to see the relationship at a glance.

It is usual to plot the *independent variable* (i.e. the one that does not depend on the other) on the horizontal or x -axis, and the *dependent variable* on the vertical or y -axis. In our example, VAT receipts *depend* on consumer expenditure. Thus VAT receipts are the dependent variable and consumer expenditure is the independent variable.

As an equation. The data in the table can be expressed in the equation

$$V = 0.2C$$

This would be the equation if the VAT rate were 20 per cent on all goods and services.

An equation has the major advantage of being precise. We could work out *exactly* how much would be paid in VAT at any given level of consumption.

This particular function starts at the origin of the graph (i.e. the bottom left-hand corner). This means that when the value of the independent variable is zero, so too is the value of the dependent variable.

When a graph does not pass through the origin its equation will have the form

$$y = a + bx$$

where y stands for the dependent variable and x for the independent variable, and a and b will have numbers assigned in an actual equation. For example, the equation might be

$$y = 4 + 2x$$

This would give Table A1.8 and Figure A1.8.

Definition

Functional relationships The mathematical relationships showing how one variable is affected by one or more others.

Table A1.7 A VAT function

Consumer expenditure (£bn per year)	VAT receipts (£bn per year)
0	0
10	2
20	4
30	6
40	8
50	10

Table A1.8 $y = 4 + 2x$

x	y
0	4
1	6
2	8
3	10
4	12
5	14

Figure A1.8 $y = 4 + 2x$ 

Notice two things about the relationship between the equation and the graph:

- The point where the line crosses the vertical axis (at a value of 4) is given by the constant (a) term. If the a term is negative, the line will cross the vertical axis *below* the horizontal axis.
- The slope of the line is given by the b term. The slope is 2/1: for every 1 unit increase in x there is a 2 unit increase in y .

? On a diagram like Figure A1.8 draw the graphs for the following equations: $y = -3 + 4x$; $y = 15 - 3x$.

Note that in the second equation of the question, the x term is negative. This means that y and x are *inversely related*. As x increases, y decreases.

Non-linear functions

With these functions the equation involves a squared term (or other power terms). Such functions will give a curved line when plotted on a graph. As an example, consider the following equation:

$$y = 4 + 10x - x^2$$

Table A1.9 and Figure A1.9 are based on it.

Table A1.9 $y = 4 + 10x - x^2$

x	y
0	4
1	13
2	20
3	25
4	28
5	29
6	28
7	25

Figure A1.9 $y = 4 + 10x - x^2$ 

As you can see, y rises at a decelerating rate and eventually begins to fall. This is because the negative x^2 term is becoming more and more influential as x rises and eventually begins to outweigh the $10x$ term.

? What shaped graph would you get from the equations $y = -6 + 3x + 2x^2$ and $y = 10 - 4x + x^2$?

(If you cannot work out the answer, construct a table like Table A1.9 and then plot the figures on a graph.)

*Elementary differentiation

In several starred boxes and *Looking at the Maths* sections we use some elementary calculus. The part of calculus we use is called **differentiation**. This is a technique to enable us to calculate the rate of change of a variable. The purpose of this section is not to explain why differentiation involves the procedures it does, but simply to state the rules that are necessary for our purposes. You will need to consult a maths book if you want to know how these rules are derived.

First, let us see when we would be interested in looking at the rate of change of a variable. Take the case of a firm thinking of expanding. It will want to know how much its costs will increase as its output increases. It will want to know the rate of change of costs with respect to changes in output.

Let us assume that it faces a cost function of the form

$$C = 20 + 5Q + Q^2 \quad (1)$$

where C is the total cost of production and Q is the quantity produced. Table A1.10 and Figure A1.10 are derived from this equation.

The rate of increase in its costs with respect to increases in output is given by the *slope* of the cost curve in Figure A1.10. The steeper the slope, the more rapidly costs increase. At

Definition

Differentiation A mathematical technique to find the rate of change of one variable with respect to another.

point *a* the slope of the curve is 11. This is found by drawing the tangent to the curve and measuring the slope of the tangent. At this point on the curve, what we are saying is that for each one unit increase in output there is an £11 increase in costs. (Obviously as the graph is curved, this rate of increase will vary at different outputs.)

This rate of increase in costs is known as the **marginal cost**. It is the same with other variables that increase with quantity: their rate of increase is known as *marginal*. For example, *marginal revenue* is the rate of increase of sales revenue with respect to output.

We can use the technique of differentiation to derive a marginal from a total equation: in other words, to derive the slope of the total curve. Let us assume that we have an equation:

$$y = 10 + 6x - 4x^2 + 2x^3 \tag{2}$$

When we differentiate it, we call the new equation dy/dx : this stands for the rate of increase in y (dy) with respect to the increase in x (dx).

The rules for differentiating a simple equation like equation (2) are very straightforward.

1. You delete the constant term (10). The reason for this is that, being constant, by definition it will not cause an

increase in y as x increases, and it is the *increase* in y that we are trying to discover.

2. You delete the x from the x term which has no power attached, and just leave the number. Thus the term $6x$ becomes simply 6.
3. For any term with a power in it (a square, a cube, etc.), its value should be *multiplied* by the power term and the power term reduced by one. Thus in the term $4x^2$, the 4 would be multiplied by 2 (the power term), and the power term would be reduced from 2 to 1 (but x to the power of 1 is simply x). After differentiation, therefore, the term becomes $8x$. In the term $2x^3$, the 2 would be multiplied by 3 (the power term), and the power term would be reduced from 3 to 2. After differentiation, therefore, the term becomes $6x^2$.

Applying these three rules to the equation

$$y = 10 + 6x - 4x^2 + 2x^3 \tag{2}$$

gives

$$dy/dx = 6 - 8x + 6x^2 \tag{3}$$

To find the rate of change of y with respect to x at any given value of x , therefore, you simply substitute that value of x into equation (3).

Thus when $x = 4$, $dy/dx = 6 - (8 \times 4) + (6 \times 16) = 70$. In other words, when $x = 4$, for every 1 unit increase in x , y will increase by 70.

Returning to our cost function in equation (1), what is the marginal cost equation? Applying the three rules to the equation

$$C = 20 + 5Q + Q^2 \tag{1}$$

gives

$$dC/dQ = 5 + 2Q \tag{4}$$

Thus at an output of 3, the marginal cost (dC/dQ) is $5 + (2 \times 3) = 11$, which is the slope of the tangent to point *a*.

? What would be the marginal cost equation if the total cost equation were

$$C = 15 + 20Q - 5Q^2 + Q^3?$$

What would be the marginal cost at an output of 8?

Finding the maximum or minimum point of a curve

The other important use we can make of calculus is to find the maximum or minimum point of a curve. This has a number of important applications. For example, a firm may want to know the minimum point on its average cost curve (a curve which

***BOX A1.1 WHEN IS GOOD NEWS REALLY GOOD?**
CASE STUDIES AND APPLICATIONS
Are things getting better or merely getting worse more slowly?

From the second quarter of 2008 unemployment rose continuously for several months. By the third quarter of 2009 unemployment had increased by some 0.75 million. What good news could the government possibly draw from this?

Governments, always in search of any glimmer of good economic news, proclaimed that unemployment was rising more slowly (in other words, that the rate of increase in unemployment was *falling*). This was perfectly correct.

To show this, let us assume that N is the number of people out of work. The rate of change of unemployment is therefore given by dN/dt (where t is time). A positive figure for dN/dt represents a rise in unemployment, a negative figure a fall. Its value is given by the slope of the green line in the diagram. From the second quarter of 2008 this figure was positive. Bad news!

But the government sought a rosier interpretation. By using a second-order derivative, d^2N/dt^2 , it could show that the rate of increase in unemployment from early 2009 had been falling. The value of this is given by the *slope* of the red line in the diagram and by the level of the green line. The government proclaimed that this was evidence that the economy was beginning to recover. Good news!

The use of calculus in this manner is a two-edged sword and such statistical sophistry is open to the political opposition, who could at a later date, if they so wished, claim that a fall in unemployment was bad economic news. Dare they?

If the opposition were indeed to claim that a fall in unemployment was bad news, what would have to be the value of d^2N/dt^2 : positive or negative?

shows how costs per unit of output vary as output increases). Also it is likely to want to know the output at which it will earn maximum profit. Let us examine this particular case.

Assume that the equation for total profit (Π) is:

$$\Pi = -20 + 12Q - Q^2 \quad (5)$$

This gives profit at various outputs as shown in Table A1.11. The corresponding graph is plotted in Figure A1.11.

What is the meaning of a negative profit?

It can be seen at a glance that profits are maximised at an output of 6 units. But we could have worked this out directly

from the profit equation without having to draw up a table or graph. How is this done?

Remember that when we differentiate a curve, the equation we get (known as 'the first derivative') gives us the slope of the curve. You can see that at the point of maximum profit (the top of the curve) its slope is zero: the tangent is horizontal. So all we have to do to find the top of the curve is to differentiate its equation and set it equal to zero.

Given that

$$\Pi = -20 + 12Q - Q^2 \quad (5)$$

then:

$$d\Pi/dQ = 12 - 2Q \quad (6)$$

Setting this equal to zero gives:

$$12 - 2Q = 0$$

$$\therefore 2Q = 12$$

$$\therefore Q = 6$$

Thus profits are maximised at an output of 6 units: the result we obtained from the table and graph.

The second derivative test

There is a problem with this technique, however. How can we tell from equation (6) that we have found the *maximum* rather than the *minimum*? The problem is that *both* the maximum *and* the minimum points of a curve have a zero slope.

The answer is to conduct a **second derivative test**. This involves differentiating the equation a second time. This gives the rate of change of the *slope* of the original curve. If you look at Figure A1.11, as output increases, the tangent moves from being upward sloping, to horizontal, to downward sloping. In other words, the slope is getting less and less. Its rate of change is *negative*. Thus if we differentiate the equation for the slope (i.e. the first derivative), we should get a negative figure.

When we differentiate a second time we get what is called the **second derivative**. It is written d^2y/dx^2 .

If we differentiate equation (6):

$$d^2\Pi/dQ^2 = 12 - 2Q \tag{6}$$

we get:

$$d^2\Pi/dQ^2 = -2 \tag{7}$$

(Note that the rules for differentiating a second time are the same as for the first time.) Given that the second derivative in this case is negative, we have demonstrated that we have indeed found the maximum profit point (at $Q = 6$), and not the minimum.

Given the following equation for a firm's average cost (AC), i.e. the cost per unit of output (Q):

$$AC = 60 - 16Q + 2Q^2$$

- (a) At what output is AC at a minimum?
- (b) Use the second derivative test to prove that this is a minimum and not a maximum.

Partial differentiation

Many relationships in economics involve more than two variables. For example, the demand for a product depends not just on its price, but also on income, the price of substitutes, the price of complements, etc. Similarly, a firm's cost of production depends not just on the quantity of output it produces, but also on wage rates, the prices of the various materials it uses, the productivity of its workers and machinery, and so on.

Such relationships can be expressed as a function as follows:

$$y = f(x_1, x_2, x_3, \dots, x_n)$$

where x_1, x_2 , etc. are the various determinants of y .

Let us take a simple example where a firm's total cost (TC) depends on just two things: the quantity produced (Q) and the wage rate (W). The cost function will be of the form

$$TC = f(Q, W)$$

Assume that in the case of a particular firm the function is

$$TC = 20 + 10Q - 4Q^2 + 2Q^3 + 6W \tag{8}$$

What we are likely to want to know is how this firm's total cost changes as quantity changes, assuming the wage rate is held constant. Alternatively we may wish to know how its total cost changes as the wage rate changes, assuming that output is held constant. To do this we use the technique of

Table A1.11 $\Pi = -20 + 12Q - Q^2$

Definitions

Second derivative test If on differentiating an equation a second time the answer is negative (positive), the point is a maximum (minimum).

Second derivative The rate of change of the first derivative, found by differentiating the first derivative.

partial differentiation. This involves the same technique as simple differentiation but applied to just the one variable that is not held constant.

Thus to find the rate of change of costs with respect to quantity in equation (8), we differentiate the equation with respect to Q and ignore the W term. We ignore it as it is held constant and is thus treated like the constant (20) term in the equation. Using the rules of differentiation, the **partial derivative** is thus

$$\frac{\partial TC}{\partial Q} = 10 - 8Q + 6Q^2 \quad (9)$$

Note that instead of using the symbol 'd' that we used in simple differentiation, we now use the symbol ' ∂ '. Apart from that, the rules for partial differentiation are exactly the same as with simple differentiation.

If we now wanted to see how this firm's costs vary with the wage rate for any given output, then we would partially differentiate equation (8) with respect to W , giving

$$\frac{\partial TC}{\partial W} = 6$$

In other words, for each £1 rise in the wage rate, total cost would rise by £6.

Assume that the demand for a product is given by the following function:

$$Q_d = 1000 - 50P + 2P^2 + 10P_s + P_s^2$$

where Q_d is the quantity demanded, P is the price of the good and P_s is the price of a substitute good. What is the partial derivative of this demand function with respect to (a) the price of the good; (b) the price of the substitute good? Interpret the meaning of each partial derivative.

Definitions

Partial differentiation A mathematical technique used with functions containing two or more independent variables. The technique is used to find the rate of change of the dependent variable with respect to a single independent variable assuming that the other independent variables are held constant.

Partial derivative The partial derivative of a function of two or more independent variables is the derivative with respect to just one of those variables, while holding the others constant.

Appendix summary

- Diagrams in economics can be used as pictures: to sketch a relationship so that its essentials can be perceived at a glance.
- Tables, graphs and charts are also used to portray real-life data. These can be time-series data or cross-section data or both.
- In order to get a true picture from economic data it is important to be aware of various ways that statistics can be abused: these include a selective use of data, a choice of axes on a graph to make trends seem more or less exaggerated or to make a curve more or less steep, confusing absolute and relative values, ignoring questions of distribution, confusing nominal and real values, and selecting the time period to make the statistics look the most favourable or unfavourable.
- Presenting time-series data as index numbers gives a clear impression of trends and is a good way of comparing how two or more series (perhaps originally measured in different units) have changed over the same time period. A base year is chosen and the index for that year is set at 100. The percentage change in the value of a variable is given by the percentage change in the index (I). The formula is

$$\left(\frac{I_t - I_{t-1}}{I_{t-1}} \right) \times 100$$

Several items can be included in one index by using a weighted value for each of the items. The weights must add up to 1, and each weight will reflect the relative importance of that particular item in the index.

- Functional relationships can be expressed as an equation, a table or a graph. In the linear (straight-line) equation $y = a + bx$, the a term gives the vertical intercept (the point where the graph crosses the vertical axis) and the b term gives the slope. When there is a power term (e.g. $y = a + bx + cx^2$), the graph will be a curve.
- Differentiation can be used to obtain the rate of change of one variable with respect to another. The rules of differentiation require that in an equation of the form $y = a + bx + cx^2 + dx^3$ the a term disappears, the bx term simply becomes b , the cx^2 term becomes $2cx$, the dx^3 becomes $3dx^2$ and so on, with each extra term being multiplied by its power term and its power term being reduced by 1.
- To find the value of the x term at which the y term is at a maximum or minimum, the equation should be differentiated and set equal to zero. To check which it is – maximum or minimum – the second derivative should be calculated. If it is negative, then setting the first derivative equal to zero has yielded a maximum. If the second derivative is positive, then setting the first derivative to zero has yielded a minimum value.

Appendix 2: Websites

All the following websites can be accessed from this book's own website (<http://www.pearsoned.co.uk/sloman>). When you enter the site, click on **Hot Links**. You will find all the following sites listed. Click on the one you want and the 'hot link' will take you straight to it.

The sections and numbers below refer to the ones used in the websites listed at the end of each chapter. Thus if the list contained the number A21, this would refer to the *Conversation* site.

(A) General news sources

As the title of this section implies, the websites here can be used for finding material on current news issues or tapping into news archives. Most archives are offered free of charge. However, some do require you to register. As well as key UK and American news sources, you will also notice some slightly different places from where you can get your news, such as *The Moscow Times* and *The Japan Times*. Check out site numbers 38. *Refdesk*, 43. *Guardian World News Guide* and 44. *Online newspapers* for links to newspapers across the world. Try searching for an article on a particular topic by using site number 41. *Google News Search*.

(B) Sources of economic and business data

Using websites to find up-to-date data is of immense value to the economist. The data sources below offer you a range of specialist and non-specialist data information. Universities have free access to the *UK Data Service* site (site 35 in this set), which is a huge database of statistics. Site 34, the *Treasury Pocket Databank*, is a very useful source of key UK and world statistics, and is updated monthly; it can be saved as an Excel file. The Economics Network's *Economic data freely available online* (site 1) gives links to various sections in over 40 UK and international sites.

1. Economics Network gateway to economic data
2. Office for Budget Responsibility
3. Office for National Statistics

(D) Economic models, simulations and classroom experiments

Economic modelling is an important aspect of economic analysis. There are several sites that offer access to a model or simulation for you to use, e.g. *Virtual Chancellor* (where you can play being Chancellor of the Exchequer). Using such models can be a useful way of finding out how economic theory works within a specific environment. Other sites link to games and experiments, where you can play a particular role, perhaps competing with other students.

(E) UK government and UK organisations' sites

If you want to see what a government department is up to, then look no further than the list below. Government departments' websites are an excellent source of information and data. They are particularly good at offering information on current legislation and policy initiatives.

1. Gateway site (GOV.UK)
2. Department for Communities and Local Government
3. Prime Minister's Office
4. Competition & Markets Authority
5. Department for Education
6. Department for International Development
7. Department for Transport
8. Department of Health
9. Department for Work and Pensions
10. Department for Business, Energy & Industrial Strategy
11. Environment Agency
12. Department of Energy and Climate Change
13. Low Pay Commission
14. Department for Environment, Food & Rural Affairs (Defra)
15. Office of Communications (Ofcom)
16. Office of Gas and Electricity Markets (Ofgem)
17. Official Documents OnLine
18. Office for Budget Responsibility
19. Office of Rail and Road (ORR)
20. The Takeover Panel
21. Sustainable Development Commission
22. Ofwat
23. National Statistics (ONS)
24. List of ONS releases from UK Data Explorer
25. HM Revenue & Customs
26. UK Intellectual Property Office
27. Parliament website
28. Scottish Government

29. Scottish Environment Protection Agency
30. HM Treasury
31. Equality and Human Rights Commission
32. Trades Union Congress (TUC)
33. Confederation of British Industry (CBI)
34. Adam Smith Institute
35. Chatham House
36. Institute for Fiscal Studies
37. Advertising Standards Authority
38. Businesses and Self-employed
39. Campaign for Better Transport
40. New Economics Foundation
41. Financial Conduct Authority
42. Prudential Regulation Authority

(F) Sources of monetary and financial data

As the title suggests, here are listed useful websites for finding information on financial matters. You will see that the list comprises mainly central banks, both within Europe and further afield. The links will take you to English language versions of non-English speaking countries' sites.

1. Bank of England
2. Bank of England Monetary and Financial Statistics
3. Banque de France (in English)
4. Bundesbank (German central bank)
5. Central Bank of Ireland
6. European Central Bank
7. Eurostat
8. US Federal Reserve Bank
9. Netherlands Central Bank (in English)
10. Bank of Japan (in English)
11. Reserve Bank of Australia
12. Bank Negara Malaysia (in English)
13. Monetary Authority of Singapore
14. Bank of Canada
15. National Bank of Denmark (in English)
16. Reserve Bank of India
17. Links to central bank websites from the Bank for International Settlements
18. The London Stock Exchange

(G) European Union and related sources

For information on European issues, the following is a wide range of useful sites. The sites maintained by the European Union are an excellent source of information.

1. Business, Economy, Euro (EC DG)
2. European Central Bank
3. EU official website
4. Eurostat
5. Employment, Social Affairs and Inclusion (EC DG)
6. Reports, Studies and Booklets on the EU

7. Internal Market, Industry, Entrepreneurship and SMEs (EC DG)
8. Competition (EC DG)
9. Agriculture and Rural Development (EC DG)
10. Energy (EC DG)
11. Environment (EC DG)
12. Regional Policy (EC DG)
13. Taxation and Customs Union (EC DG)
14. Education, Youth, Sport and Culture (EC DG)
15. European Patent Office
16. European Commission
17. European Parliament
18. European Council
19. Mobility and Transport (EC DG)
20. Trade (EC DG)
21. Maritime Affairs and Fisheries (EC DG)
22. International Cooperation and Development (EC DG)
23. Financial Stability, Financial Services and Capital Markets Union (EC DG)

(H) International organisations

This section casts its net beyond Europe and lists the Web addresses of the main international organisations in the global economy. You will notice that some sites are run by charities, such as Oxfam, while others represent organisations set up to manage international affairs, such as the International Monetary Fund and the United Nations.

1. UN Food and Agriculture Organization (FAO)
2. United Nations Conference on Trade and Development (UNCTAD)
3. International Labour Organization (ILO)
4. International Monetary Fund (IMF)
5. Organisation for Economic Co-operation and Development (OECD)
6. OPEC
7. World Bank
8. World Health Organization (WHO)
9. United Nations (UN)
10. United Nations Industrial Development Organization (UNIDO)
11. Friends of the Earth
12. Institute of International Finance
13. Oxfam
14. Christian Aid (reports on development issues)
15. European Bank for Reconstruction and Development (EBRD)
16. World Trade Organization (WTO)
17. United Nations Development Programme
18. UNICEF

21. South American Free Trade Areas

22. ASEAN
23. APEC

(I) Economics search and link sites

If you are having difficulty finding what you want from the list of sites above, the following sites offer links to other sites and are a very useful resource when you are looking for something a little bit more specialist. Once again, it is worth having a look at what these sites have to offer in order to judge their usefulness.

1. Gateway for UK official sites
2. Alta Plana
3. Data Archive Search
4. Inomics (information on economics courses and jobs)
5. Ideas: RePEc bibliographic database
6. Wikidata
7. Portal site with links to other sites (Economics Network)
8. EcEdWeb
9. Global goals 2030 (link to economic development resources)
10. Development Data Hub
11. DMOZ Open Directory: Economics (legacy site)
12. Web links for economists from the Economics Network
13. EconData.Net
14. Yale university: 75 Sources of Economic Data, Statistics, Reports, and Commentary
15. Excite Economics Links
16. Internet Resources for Economists
17. Trade Map (trade statistics)
18. Resources for Economists on the Internet
19. UK University Economics Departments
20. Economics education links
21. Development Gateway
22. Find the Data
23. Data on the Net
24. National Bureau of Economic Research links to data sources

(J) Internet search engines

The following search engines have been found to be useful.

1. Google
2. Bing
3. Whoosh UK
4. Excite
5. Zanran (search engine for data and statistics)
6. Search.com
7. MSN
8. Economics search engine (from RFE)
9. Yahoo
10. Ask
11. Lycos
12. Webcrawler
13. Metacrawler: searches several search engines

Threshold Concepts and Key Ideas

THRESHOLD CONCEPTS

	Page
1. Choice and opportunity cost	11
2. People gain from voluntary economic interaction	26
3. Markets may fail to meet social objectives	26
4. Markets equate demand and supply	47
5. People respond to incentives	50
6. Elasticity: of a variable to a change in a determinant	68
7. Governments can sometimes improve market outcomes	81
8. Rational decision making involves choices at the margin	109
9. People's actions depend on their expectations	129
10. General equilibrium: when all markets are in balance	350
11. Allocative efficiency: private and social	353
12. Short-term growth in a country's output tends to fluctuate	447
13. The distinction between real and nominal values	453
14. Long-term growth in a country's output depends on a growth in the quantity and/or productivity of its resources	458
15. Cumulative causation: economic effects can snowball	535

KEY IDEAS

	Page
1. Scarcity is the excess of human wants over what can actually be produced. Because of scarcity, various choices have to be made between alternatives.	7
2. The opportunity cost of any activity is the sacrifice made to do it. It is the best thing that could have been done as an alternative.	10
3. Economic efficiency is thus achieved when each good is produced at the minimum cost and where individual people and firms get the maximum benefit from their resources.	13
4. Equity is where income is distributed in a way that is considered to be fair or just. Note that an equitable distribution is not the same as an equal distribution and that different people have different views on what is equitable.	14
5. Changes in demand or supply cause markets to adjust. Whenever such changes occur, the resulting 'disequilibrium' will bring an automatic change in prices, thereby restoring equilibrium (i.e. a balance of demand and supply).	22
6. The importance of the positive/normative distinction. Economics can only contribute to policy issues in a positive way. Economists, as scientists, should not make normative judgements. They can make them only as individual people, with no more moral right than any other individual.	29
7. The income and substitution effects are useful concepts as they help to explain why people react to a price rise by buying less. The size of these effects depends on a range of factors. These factors determine the shape of the demand curve.	36
8. Equilibrium is the point where conflicting interests are balanced. Only at this point is the amount that demanders are willing to purchase the same as the amount that suppliers are willing to supply. It is a point that will be automatically reached in a free market through the operation of the price mechanism.	46
9. Elasticity. The responsiveness of one variable (e.g. demand) to a change in another (e.g. price). This concept is fundamental to understanding how markets work. The more elastic variables are, the more responsive is the market to changing circumstances.	66

10. **People's actions are influenced by their expectations.** People respond not just to what is happening now (such as a change in price), but to what they anticipate will happen in the future. 70
11. **People's actions are influenced by their attitudes towards risk.** Many decisions are taken under conditions of risk or uncertainty. Generally, the lower the probability of (or the more uncertain) the desired outcome of an action, the less likely people will be to undertake the action. 76
12. **The fallacy of composition.** What applies in one case will not necessarily apply when repeated in all cases. 97
13. **The principle of diminishing marginal utility.** The more of a product a person consumes, the less will be the additional utility gained from one more unit. 105
14. **The equi-marginal principle.** The optimum amount of two alternatives consumed (or produced) will be where the marginal benefit ratios of the two alternatives are equal to their marginal cost ratios:
- $$\frac{MU_A}{MU_B} = \frac{P_A}{P_B}$$
- 111
15. **Good decision making requires good information.** Where information is poor, decisions and their outcomes may be poor. 129
16. **Adverse selection.** A market process whereby buyers, sellers or products with certain unobservable characteristics (e.g. high risk or low quality) are more likely to enter the market at the current market price. This process can have a negative impact on economic efficiency and cause some potentially profitable markets to collapse. 135
17. **Moral hazard.** Following a deal, the actions/behaviour of one party to a transaction may change in a way that reduces the pay-off to the other party. In the context of insurance, it refers to customers taking more risks when they have insurance than when they do not have insurance. 135
18. **Output depends on the amount of resources and how they are used.** Different amounts and combinations of inputs will lead to different amounts of output. If output is to be produced efficiently, then inputs should be combined in the optimum proportions. 149
19. **The law of diminishing marginal returns** states that when increasing amounts of a variable factor are used with a given amount of a fixed factor, there will come a point when each extra unit of the variable factor will produce less extra output than the previous unit. 151
20. The **'bygones' principle** states that sunk (fixed) costs should be ignored when deciding whether to produce or sell more or less of a product. Only variable costs should be taken into account. 156
21. **Fixed costs and the time period.** Fixed costs occur only in the short run, since in the long run all inputs can be varied. 172
22. **Market power.** When firms have market power over prices, they can use this to raise prices and profits above the perfectly competitive level. Other things being equal, the firm will gain at the expense of the consumer. Similarly, if consumers or workers have market power, they can use this to their own benefit. 190
23. **People often think and behave strategically.** How you think others will respond to your actions is likely to influence your own behaviour. Firms, for example, when considering a price or product change will often take into account the likely reactions of their rivals. 222
24. **The nature of institutions and organisations is likely to influence behaviour.** There are various forces influencing people's decisions in complex organisations. Assumptions that an organisation will follow one simple objective (e.g. short-run profit maximisation) is thus too simplistic in many cases. 252
25. **The principal-agent problem.** Where people (principals), as a result of a lack of knowledge, cannot ensure that their best interests are served by their agents. Agents may take advantage of this situation to the disadvantage of the principals. 267
26. **Stocks and flows.** A stock is a quantity of something at a given point in time. A flow is an increase or decrease in something over a specified period of time. This is an important distinction and a common cause of confusion. 303
27. **The principle of discounting.** People generally prefer to have benefits today rather than in the future. Thus future benefits have to be reduced (discounted) to give them a present value. 304
28. **Allocative efficiency (simple formulation) in any activity** is achieved where marginal benefit equals marginal cost. Private efficiency is achieved where marginal private benefit equals marginal private cost ($MB = MC$). Social efficiency is achieved where marginal social benefit equals marginal social cost ($MSB = MSC$). 348
29. **Social efficiency (equi-marginal formulation)** is achieved where the marginal social benefit ratios are equal to the marginal social cost ratios for any two alternatives. In the case of two alternatives X and Y, this will be where:
- $$\frac{MSB_x}{MSB_y} = \frac{MSC_x}{MSC_y}$$
- 353
30. **Markets generally fail to achieve social efficiency.** There are various types of market failure. Market failures provide one of the major justifications for government intervention in the economy. 356
31. **Externalities are spillover costs or benefits.** Where these exist, even an otherwise perfect market will fail to achieve social efficiency. 356

32. **The free-rider problem.** People are often unwilling to pay for things if they can make use of things other people have bought. This problem can lead to people not purchasing things that would be to the benefit of them and other members of society to have. 363
33. **The problem of time lags.** Many economic actions can take a long time to take effect. This can cause problems of instability and an inability of the economy to achieve social efficiency. 368
34. **Economies suffer from inherent instability.** As a result, economic growth and other macroeconomic indicators tend to fluctuate. 445
35. **Balance sheets affect people's behaviour.** The size and structure of governments', institutions' and individuals' liabilities (and assets too) affect economic well-being and can have significant effects on behaviour and economic activity. 451
36. **Societies face trade-offs between economic objectives.** For example, the goal of faster growth may conflict with that of greater equality; the goal of lower unemployment may conflict with that of lower inflation (at least in the short run). This is an example of opportunity cost: the cost of achieving one objective may be achieving less of another. The existence of trade-offs means that policy makers must make choices. 451
37. **Goodhart's law:** Controlling a symptom (i.e. an indicator) of a problem will not cure the problem. Instead, the indicator will merely cease to be a good indicator of the problem. 700
38. **The law of comparative advantage.** Provided opportunity costs of various goods differ in two countries, both of them can gain from mutual trade if they specialise in producing (and exporting) those goods that have relatively low opportunity costs compared with the other country. 752
39. **The competitive advantage of nations.** The ability of countries to compete in the market for exports and with potential importers to their country. The competitiveness of any one industry depends on the availability and quality of resources, demand conditions at home in that industry, the strategies and rivalry of firms within the industry and the quality of supporting industries and infrastructure. It also depends on government policies and there is also an element of chance. 760
40. **The distinction between nominal and real figures.** Nominal figures are those using current prices, interest rates, etc. Real figures are figures corrected for inflation. A:6

[The page contains extremely faint, illegible text, likely bleed-through from the reverse side of the document. The text is arranged in several paragraphs and is not readable.]

Glossary

- Abduction** Using pieces of evidence to develop a plausible explanation. This can then be tested by gathering more evidence.
- Absolute advantage** A country has an absolute advantage over another in the production of a good if it can produce it with less resources than the other country can.
- Accelerationist hypothesis/theory** The theory that unemployment can only be reduced below the natural rate at the cost of accelerating inflation.
- Accelerator coefficient** The level of induced investment as a proportion of a rise in national income: $\alpha = I_i/\Delta Y$.
- Accelerator theory** The *level* of investment depends on the *rate of change* of national income, and as result tends to be subject to substantial fluctuations.
- Active balances** Money held for transactions and precautionary purposes.
- Actual growth** The percentage increase in national output actually produced.
- Ad valorem tariffs** Tariffs levied as a percentage of the price of the import.
- Ad valorem tax** A tax on a good levied as a percentage of its value. It can be a single-stage tax or a multi-stage tax (such as VAT).
- Adaptive expectations hypothesis** The theory that people base their expectations of inflation on past inflation rates.
- Adjustable peg** A system whereby exchange rates are fixed for a period of time, but may be devalued (or revalued) if a deficit (or surplus) becomes substantial.
- Adverse selection (in general)** A market process whereby either buyers, sellers or products with certain unobservable characteristics (e.g. high risk or low quality) are more likely to enter the market at the current market price. This process can have a negative impact on economic efficiency and cause some potentially profitable markets to collapse.
- Adverse selection in the insurance market** Where customers with the least desirable characteristics from the sellers' point of view are more likely to purchase an insurance policy at a price based on the average risk of all the potential customers.
- Aggregate demand** Total spending on goods and services made in the economy. It consists of four elements, consumer spending (C), investment (I), government spending (G) and the expenditure on exports (X), less any expenditure on imports of goods and services (M): $AD = C + I + G + X - M$.
- Aggregate demand for labour curve** A curve showing the total demand for labour in the economy at different levels of real wage rates.
- Aggregate expenditure (E)** Aggregate demand in the Keynesian model: i.e. $C_d + J$.
- Aggregate supply of labour curve** A curve showing the total number of people willing and able to work at different average real wage rates.
- Aggregate supply** The total amount of output in the economy.
- Allocative efficiency** A situation where the current combination of goods produced and sold gives the maximum satisfaction for each consumer at their current levels of income. Note that a redistribution of income would lead to a different combination of goods that was allocatively efficient.
- Alternative theories of the firm** Theories of the firm based on the assumption that firms have aims other than profit maximisation.
- Ambient-based standards** Pollution control that requires firms to meet minimum standards for the environment (e.g. air or water quality).
- Appreciation (of a currency)** A rise in the free-market exchange rate of the domestic currency with foreign currencies.
- Arbitrage** The practice of taking advantage of price differentials in markets by buying in the low-priced markets and selling in the high-priced ones. The practice of buying and selling will tend to eliminate the price differentials. Interest rate arbitrage involves borrowing at low interest rates and lending at high rates. This will tend to eliminate the interest rate differentials.
- Arc elasticity** The measurement of elasticity between two points on a curve.
- Assets** Possessions of an individual or institution, or claims held on others.
- Asymmetric information** Where one party in an economic relationship (e.g. an agent) has more information than another (e.g. the principal).
- Asymmetric shocks** Shocks (such as an oil price increase or a recession in another part of the world) that have different-sized effects on different industries, regions or countries.
- Automatic fiscal stabilisers** Tax revenues that rise and government expenditure that falls as national income rises. The more they change with income, the bigger the stabilising effect on national income.

- Average (total) cost** Total cost (fixed plus variable) per unit of output: $AC = TC/Q = AFC + AVC$.
- Average cost pricing or mark-up pricing** Where firms set the price by adding a profit mark-up to average cost.
- Average fixed cost** Total fixed cost per unit of output: $AFC = TFC/Q$.
- Average physical product** Total output (TPP) per unit of the variable factor in question: $APP = TPP/Q_v$.
- Average rate of income tax** Income taxes as a proportion of a person's total (gross) income: T/Y .
- Average revenue** Total revenue per unit of output. When all output is sold at the same price average revenue will be the same as price: $AR = TR/Q = P$.
- Average variable cost** Total variable cost per unit of output: $AVC = TVC/Q$.
- Backwards induction** A process by which firms think through the most likely outcome in the last period of competition and then work backwards step by step, thinking through the most likely outcomes in earlier periods of competition.
- Balance of payments account** The record of all the economic transactions between the residents of a specific country with the rest of the world for a specific time period, typically a year or a quarter. It records all the inflows and outflows of money under various headings. Inflows are recorded as credits; outflows are recorded as debits.
- Balance of payments on current account** The balance on trade in goods and services plus net investment income and current transfers.
- Balance on trade in goods or balance of visible trade or merchandise balance** Exports of goods minus imports of goods.
- Balance on trade in goods and services (or balance of trade)** Exports of goods and services minus imports of goods and services.
- Balance on trade in services** Exports of services minus imports of services.
- Balance sheet** A record of the stock of assets and liabilities of an individual or institution.
- Balance-sheet recession** A recession or economic slowdown caused by a collapse in aggregate demand arising from the actions of financially distressed people and businesses.
- Bank bills** Bills that have been accepted by another institution and hence insured against default.
- Bank (or deposits) multiplier** The number of times greater the expansion of bank deposits is than the additional liquidity in banks that causes it: $1/L$ (the inverse of the liquidity ratio).
- Barometric firm price leadership** Where the price leader is the one whose prices are believed to reflect market conditions in the most satisfactory way.
- Barriers to entry** Anything that prevents or impedes the entry of firms into an industry and thereby limits the amount of competition faced by existing firms.
- Barter economy** An economy where people exchange goods and services directly with one another without any payment of money. Workers would be paid with bundles of goods.
- Base year (for index numbers)** The year whose index number is set at 100.
- Basic needs approach** The attempt to measure development in terms of a country's ability to meet the basic requirements for life.
- Basic rate of tax** The main marginal rate of tax, applying to most people's incomes.
- Behavioural theories of the firm** Theories that attempt to predict the actions of firms by studying the behaviour of various groups of people within the firm and their interactions under conditions of potentially conflicting interests.
- Benefit principle of taxation** The principle that people ought to pay taxes in proportion to the amount they use government services.
- Benefits in kind** Goods or services which the state provides directly to the recipient at no charge or at a subsidised price. Alternatively, the state can subsidise the private sector to provide them.
- Bid rigging** Where two or more firms secretly agree on the prices they will tender for a contract. These prices will be above those that would have been submitted under a genuinely competitive tendering process.
- Bilateral monopoly** Where a monopsony buyer faces a monopoly seller.
- Bill of exchange** A certificate promising to repay a stated amount on a certain date, typically three months from the issue of the bill. Bills pay no interest as such, but are sold at a discount and redeemed at face value, thereby earning a rate of discount for the purchaser.
- Bounded rationality** When the ability to make rational decisions is limited by lack of information or the time necessary to obtain such information or by a lack of understanding of complex situations.
- Bretton Woods system** An adjustable peg system whereby currencies were pegged to the US dollar. The USA maintained convertibility of the dollar into gold at the rate of \$35 to an ounce.
- Broad money in UK (M4)** Cash in circulation plus retail and wholesale bank and building society deposits.
- Budget deficit** The excess of central government's spending over its tax receipts.
- Budget line** A graph showing all the possible combinations of two goods that can be purchased at given prices and for a given budget.
- Budget surplus** The excess of central government's tax receipts over its spending.
- Buffer stocks** Stocks of a product used to stabilise its price. In years of abundance, the stocks are built up. In years of low supply, stocks are released on to the market.
- Business cycle or trade cycle** The periodic fluctuations of national output round its long-term trend.

- Capital** All inputs into production that have themselves been produced: e.g. factories, machines and tools.
- Capital account of the balance of payments** The record of the transfers of capital to and from abroad.
- Capital adequacy ratio (CAR)** The ratio of a bank's capital (reserves and shares) to its risk-weighted assets.
- Capital expenditure** Investment expenditure; expenditure on assets.
- Capital market** A financial market where longer-term debt instruments, like government bonds (gilts), can be bought and sold.
- Carry trade** Borrowing at low interest rates and then using it to buy assets that earn higher rates. In foreign exchange markets, the carry trade involves borrowing money in a currency of a country where interest rates are low and exchanging it for another currency where the country pays higher interest rates.
- Cartel** A formal collusive agreement.
- Central bank** Banker to the banks and the government. It oversees the banking system, implements monetary policy and issues currency.
- Centrally planned or command economy** An economy where all economic decisions are taken by the central authorities.
- Certainty equivalent** The guaranteed amount of money that an individual would view as equally desirable as the expected value of a gamble. Where a person is risk averse, the certainty equivalent is less than the expected value.
- Certificates of deposit (CDs)** Certificates issued by banks for fixed-term interest-bearing deposits. They can be resold by the owner to another party.
- Ceteris paribus** Latin for 'other things being equal'. This assumption has to be made when making deductions from theories.
- Change in demand** This is the term used for a shift in the demand curve. It occurs when a determinant of demand *other* than price changes.
- Change in supply** The term used for a shift in the supply curve. It occurs when a determinant *other* than price changes.
- Change in the quantity demanded** The term used for a movement along the demand curve to a new point. It occurs when there is a change in price.
- Change in the quantity supplied** The term used for a movement along the supply curve to a new point. It occurs when there is a change in price.
- Claimant unemployment** Those in receipt of unemployment-related benefits.
- Classical model** A macroeconomic model that assumes prices and wages are fully flexible.
- Clearing system** A system whereby inter-bank debts are settled.
- Closed shop** Where a firm agrees to employ only union members.
- Club good** A good which has a low degree of rivalry but is easily excludable.
- Coase theorem** When there are well-defined property rights and zero bargaining costs, then negotiations between the party creating the externality and the party affected by the externality can bring about the socially efficient market quantity.
- Cobb–Douglas production function** Like other production functions, this shows how output (*TPP*) varies with inputs of various factors (F_1, F_2, F_3 , etc.). In the simple two-factor case it takes the following form:
- $$TPP = f(F_1, F_2) = aF_1^\alpha F_2^\beta$$
- If $\alpha + \beta = 1$, there are constant returns to scale; if $\alpha + \beta > 1$, there are increasing returns to scale; if $\alpha + \beta < 1$, there are decreasing returns to scale.
- Collateralised debt obligations (CDOs)** These are a type of security consisting of a bundle of fixed-income assets, such as corporate bonds, mortgage debt and credit card debt.
- Collusive oligopoly** Where oligopolists agree (formally or informally) to limit competition between themselves. They may set output quotas, fix prices, limit product promotion or development, or agree not to 'poach' each other's markets.
- Collusive tendering** Where two or more firms secretly agree on the prices they will tender for a contract. These prices will be above those which would be put in under a genuinely competitive tendering process.
- Command-and-control (CAC) systems** The use of laws or regulations backed up by inspections and penalties (such as fines) for non-compliance.
- Command economy** An economy where all economic decisions are made by a central planning process.
- Commercial bills** Bills of exchange issued by firms.
- Common good or resource** A good or resource that has a high degree of rivalry but the exclusion of non-payers is difficult.
- Common market** A customs union where the member countries act as a single market with free movement of labour and capital, common taxes and common trade laws.
- Comparative advantage** A country has a comparative advantage over another in the production of a good if it can produce it at a lower opportunity cost: i.e. if it has to forgo less of other goods in order to produce it.
- Competition for corporate control** The competition for the control of companies through takeovers.
- Complementary goods** A pair of goods consumed together. As the price of one goes up, the demand for both goods will fall.
- Compounding** The process of adding interest each year to an initial capital sum.
- Compromise strategy** A strategy whose worst outcome is better than under a high-risk strategy and whose best outcome is better than under a low-risk strategy.
- Conglomerate merger** When two firms in different industries merge.

- Consortium** Where two or more firms work together on a specific project and create a separate company to run the project.
- Constant-cost industry** An industry where average costs stay constant as the size of the industry expands.
- Constrained discretion** A set of principles or rules within which economic policy operates. These can be informal or enshrined in law.
- Consumer durable** A consumer good that lasts a period of time, during which the consumer can continue gaining utility from it.
- Consumer prices index (CPI)** An index of the weighted average of the prices of goods and services bought by a typical household. Its annual rate of change gives CPI inflation and is the measure used by most countries, including the UK, for their inflation target.
- Consumer sovereignty** A situation where firms respond to changes in consumer demand without being in a position in the long run to charge a price above average cost.
- Consumer surplus** The excess of what a person would have been prepared to pay for a good (i.e. the utility) over what that person actually pays.
- Consumers' share of a tax on a good** The proportion of the revenue from a tax on a good that arises from an increase in the price of the good.
- Consumption** The act of using goods and services to satisfy wants. This will normally involve purchasing the goods and services.
- Consumption function** The relationship between consumption and national income. It can be expressed algebraically or graphically.
- Consumption of domestically produced goods and services (C_d)** The direct flow of money payments from households to firms.
- Consumption smoothing** The act by households of smoothing their levels of consumption over time despite facing volatile incomes.
- Contingent convertible debt instruments (Co-Cos)** Debt instruments, like corporate bonds, which may be converted into equity capital when a trigger point, such as the level of financial distress of a corporation, is reached.
- Continuous market clearing** The new classical assumption that all markets in the economy continuously clear so that the economy is permanently in equilibrium.
- Convergence in GDP per head** The tendency for less rich developed countries to catch up the richer ones. Convergence does not apply to many of the poorer developing countries, however, where the gap between them and richer countries has tended to widen.
- Convergence of economies** When countries achieve similar levels of growth, inflation, budget deficits as a percentage of GDP, balance of payments, etc.
- Co-ordination failure** When a group of firms (e.g. banks) acting independently could have achieved a more desirable outcome if they had co-ordinated their decision making.
- Core workers** Workers, normally with specific skills, who are employed on a permanent or long-term basis.
- Cost-benefit analysis** The identification, measurement and weighing up of the costs and benefits of a project in order to decide whether or not it should go ahead.
- Cost-plus pricing (full-cost pricing)** (another name for mark-up pricing) When firms price their product by adding a certain profit 'mark-up' to average cost.
- Cost-push inflation** Inflation caused by persistent rises in costs of production (independently of demand).
- Countervailing power** When the power of a monopolistic/oligopolistic seller is offset by powerful buyers who can prevent the price from being pushed up.
- Cournot equilibrium** Where each of two firm's actual output is the same as what the other firm predicted it would produce: where the two firms' reaction curves cross.
- Cournot model of duopoly** A model where each firm makes its price and output decisions on the assumption that its rival will produce a particular quantity.
- Crawling peg** A system whereby the government allows a gradual adjustment of the exchange rate.
- Credibility (of policies)** Policies that people believe the government will carry out once they have been announced.
- Credible threat (or promise)** One that is believable to rivals because it is in the threatener's interests to carry it out.
- Credit-constrained households** Households which are limited in their ability to borrow against expected future incomes.
- Credit crunch** A sudden reduction in the availability of loans or credit from banks and other financial institutions.
- Cross-price elasticity of demand** The percentage (or proportionate) change in quantity demanded of one good divided by the percentage (or proportionate) change in the price of another.
- Cross-price elasticity of demand (arc formula)**
 $\Delta Q_{DA} / \text{average } Q_{DA} + \Delta P_B / \text{average } P_B$
- Cross-section data** Information showing how a variable (e.g. the consumption of eggs) differs between different groups or different individuals at a given time.
- Cross-subsidise** To use profits in one market to subsidise prices in another.
- Crowding out** Where increased public expenditure diverts money or resources away from the private sector.
- Cumulative causation (principle of)** When an initial change causes an eventual change that is larger.
- Currency union** A group of countries (or regions) using a common currency.
- Current account balance of payments** Exports of goods and services minus imports of goods and services plus net incomes and current transfers from abroad. If inflows of money (from the sale of exports, etc.) exceed outflows of money (from the purchase of imports, etc.) there is a 'current account surplus' (a positive figure). If outflows exceed inflows there is a 'current account deficit' (a negative figure).

- Current expenditure (by the government)** Recurrent spending on goods and factor payments.
- Customs union** A free trade area with common external tariffs and quotas.
- Deadweight loss of an indirect tax** The loss of consumers' plus producers' surplus from the imposition of an indirect tax.
- Deadweight welfare loss of monopoly** The loss of consumers' plus producers' surplus in monopoly or other imperfect markets (when compared with perfect competition).
- Deadweight welfare loss from externalities** The loss of social surplus at the competitive market equilibrium compared with the social optimum where $MSC = MSB$.
- Debentures (company bonds)** Fixed-interest loans to firms. These assets can be traded on the stock market and their market price is determined by demand and supply.
- Debt servicing** Paying the interest and capital repayments on debt.
- Debt-servicing costs** The costs incurred when repaying debt, including debt interest payments.
- Deciles** Divisions of the population into ten equal-sized groups (an example of a quantile).
- Decision tree (or game tree)** A diagram showing the sequence of possible decisions by competitor firms and the outcome of each combination of decisions.
- Decreasing-cost industry** An industry where average costs decrease as the size of the industry expands.
- Deduction** Using a theory to draw conclusions about specific circumstances.
- Deficit bias** The tendency for frequent fiscal deficits and rising debt-to-GDP ratios because of the reluctance of policy makers to tighten fiscal policy.
- Deflationary (or recessionary) gap** The shortfall of national expenditure below national income (and injections below withdrawals) at the full-employment level of national income.
- Deflationary policy** Fiscal or monetary policy designed to reduce the rate of growth of aggregate demand.
- Demand curve** A graph showing the relationship between the price of a good and the quantity of the good demanded over a given time period. Price is measured on the vertical axis; quantity demanded is measured on the horizontal axis. A demand curve can be for an individual consumer or group of consumers, or more usually for the whole market.
- Demand function** An equation which shows the mathematical relationship between the quantity demanded of a good and the values of the various determinants of demand.
- Demand-management policies** Demand-side policies (fiscal and/or monetary) designed to smooth out the fluctuations in the business cycle.
- Demand schedule (market)** A table showing the different total quantities of a good that consumers are willing and able to buy at various prices over a given period of time.
- Demand schedule for an individual** A table showing the different quantities of a good that a person is willing and able to buy at various prices over a given period of time.
- Demand-deficient or cyclical unemployment** Disequilibrium unemployment caused by a fall in aggregate demand with no corresponding fall in the real wage rate.
- Demand-pull inflation** Inflation caused by persistent rises in aggregate demand.
- Demand-side policies** Policies designed to affect aggregate demand: fiscal policy and monetary policy.
- Demand-side policy** Government policy designed to alter the level of aggregate demand, and thereby the level of output, employment and prices.
- Dependency** Where the development of a developing country is hampered by its relationships with the industrialised world.
- Depreciation (of a currency)** A fall in the free-market exchange rate of the domestic currency with foreign currencies.
- Depreciation (of capital)** The decline in value of capital equipment due to age, or wear and tear.
- Deregulation** Where the government removes official barriers to competition (e.g. licences and minimum quality standards).
- Derived demand** The demand for a factor of production depends on the demand for the good which uses it.
- Destabilising speculation** Where the actions of speculators tend to make price movements larger.
- Devaluation** Where the government re-pegs the exchange rate at a lower level.
- Differentiation** A mathematical technique to find the rate of change of one variable with respect to another.
- Diminishing marginal rate of substitution** The more a person consumes of good X and the less of good Y, the less additional Y will that person be prepared to give up in order to obtain an extra unit of X: i.e. $\Delta Y/\Delta X$ diminishes.
- Diminishing marginal returns** When one or more factors are held fixed, there will come a point beyond which the extra output from additional units of the variable factor will diminish.
- Diminishing marginal utility** As more units of a good are consumed, additional units will provide less additional satisfaction than previous units.
- Diminishing marginal utility of income** Where each additional pound earned yields less additional utility than the previous pound.
- Direct income support or direct aid** A fixed grant to farmers that does not vary with current output. It may be based on acreage, number of livestock or past output.
- Direct monetary transmission mechanism** A change in money supply having a direct effect on aggregate demand.
- Direct taxes** Taxes on income and wealth. Paid directly to the tax authorities on that income or wealth.

- Dirty floating (managed flexibility)** A system of flexible exchange rates but where the government intervenes to prevent excessive fluctuations or even to achieve an unofficial target exchange rate.
- Discount factor** The value today of deciding to consume a good one period in the future as a proportion of the value when it is actually consumed.
- Discount market** An example of a money market in which new or existing bills, such as Treasury bills or commercial bills, are bought and sold at a discount below their face value: i.e. the value at which they will be redeemed on maturity.
- Discounting** The process of reducing the value of future flows to give them a present valuation.
- Discounting: exponential** A method of reducing future benefits and costs to a present value. The discount rate depends on just how much less, from the consumer's perspective, *future* utility and costs (from a decision made today) are than gaining the utility/incurring the costs *today*.
- Discretionary fiscal policy** Deliberate changes in tax rates or the level of government expenditure in order to influence the level of aggregate demand.
- Diseconomies of scale** Where costs per unit of output increase as the scale of production increases.
- Disequilibrium unemployment** Unemployment resulting from real wage rates in the economy being above the equilibrium level.
- Disguised unemployment** Where the same work could be done by fewer people.
- Disintermediation** The diversion of business away from financial institutions which are subject to controls.
- Disposable income** Household income after the deduction of taxes and the addition of benefits.
- Distribution of income by class of recipient** Measurement of the distribution of income between the classes of person who receive it (e.g. homeowners and non-homeowners or those in the North and those in the South).
- Diversification** This is where a firm expands into new types of business.
- Dominant firm price leadership** When firms (the followers) choose the same price as that set by a dominant firm in the industry (the leader).
- Dominant strategy game** Where the firm's optimal strategy remains the same irrespective of what it assumes its rivals are going to do.
- Downward causation** The name given to the impact on individual behaviour or well-being of aggregate or group effects. This is an example of cumulative causation (Threshold Concept 15).
- Dumping** When exports are sold at prices below marginal cost – often as a result of government subsidy.
- Duopoly** An oligopoly where there are just two firms in the market.
- Dynamic stochastic general equilibrium (DSGE) models** Models that seek to explain macroeconomic phenomena by examining the microeconomic behaviour of rational forward-looking individual economic agents acting in a variety of market conditions. The microeconomic equilibria are subject to random shocks, such as technological change, political events or changes in the supply of natural resources.
- Econometrics** The science of applying statistical techniques to economic data in order to identify and test economic relationships.
- Economic agents** People or institutions making economic decisions. These could be individuals as consumers, workers, borrowers or savers, or firms, governments or other public institutions.
- Economic and monetary union (EMU)** The adoption by a group of countries of a single currency with a single central bank and a single monetary policy. In the EU the term applies to the countries that have adopted the euro.
- Economic discrimination** When workers of identical *ability* are paid different wages or are otherwise discriminated against because of race, age, sex, etc.
- Economic efficiency** A situation where each good is produced at the minimum cost and where individual people and firms get the maximum benefit from their resources.
- Economic model** A formal presentation of an economic theory.
- Economic rent** The excess that a factor is paid over the amount necessary to keep it in its current employment.
- Economies of scale** When increasing the scale of production leads to a lower long-run cost per unit of output.
- Economies of scope** When increasing the range of products produced by a firm reduces the cost of producing each one.
- ECU (European Currency Unit)** The predecessor to the euro: a weighted average of EU currencies. It was used as a reserve currency and for the operation of the exchange rate mechanism (ERM).
- Effective rate of protection** The percentage increase in an industry's domestic value added resulting from protection given to that industry.
- Efficient (capital) market hypothesis** The hypothesis that new information about a company's current or future performance will be quickly and accurately reflected in its share price.
- Efficiency (technical)** The firm is producing as much output as is technologically possible given the quantity of factor inputs it is using.
- Efficiency wage hypothesis** The hypothesis that the productivity of workers is affected by the wage rate that they receive.
- Efficiency wage rate** The profit-maximising wage rate for the firm after taking into account the effects of wage rates on worker motivation, turnover and recruitment.
- Elastic demand (with respect to price)** Where quantity demanded changes by a larger percentage than price. Ignoring the negative sign, it will have a value greater than 1.

- Elasticity** A measure of the responsiveness of a variable (e.g. quantity demanded or quantity supplied) to a change in one of its determinants (e.g. price or income).
- EMS (The European Monetary System, mark 1)** A system, prior to the euro, whereby EU countries co-operated to achieve greater exchange rate stability. It involved use of the exchange rate mechanism (the ERM).
- Endogenous growth models** Models which demonstrate that the rate of economic growth depends on the rate of technological progress and diffusion, both of which depend on institutions, incentives and the role of government.
- Endogenous money supply** Money supply that is determined (at least in part) by the demand for money.
- Endogenous variable** A variable whose value is determined by the model of which it is part.
- Endowment effect (or divestiture aversion)** The hypothesis that people ascribe more value to things when they own them than when they are merely considering purchasing or acquiring them – in other words, when the reference point is one of ownership rather than non-ownership.
- Engel curve** A line derived from indifference analysis showing how much of a good people will demand at different levels of income.
- Entrepreneurship** The initiating and organising of the production of new goods, or the introduction of new techniques, and the risk taking associated with it.
- Envelope curve** A long-run average cost curve drawn as the tangency points of a series of short-run average cost curves.
- Environmental charges** Charges for using natural resources (e.g. water or national parks), or for using the environment as a dump for waste (e.g. factory emissions or sewage).
- Equation of exchange** $MV = PY$. The total level of spending on GDP (MV) equals the total value of goods and services produced (PY) that go to make up GDP.
- Equilibrium** A position of balance. A position from which there is no inherent tendency to move away.
- Equilibrium price** The price where the quantity demanded equals the quantity supplied: the price where there is no shortage or surplus.
- Equilibrium ('natural') unemployment** The difference between those who would like employment at the current wage rate and those willing and able to take a job.
- Equi-marginal principle** Consumers will maximise total utility from their incomes by consuming that combination of goods where $MU_a/P_a = MU_b/P_b = MU_c/P_c \dots = MU_n/P_n$.
- Equities** Company shares. Holders of equities are owners of the company and share in its profits by receiving dividends.
- Equity** A distribution of income that is considered to be fair or just. Note that an equitable distribution is not the same as an equal distribution and that different people have different views on what is equitable.
- ERM (the exchange rate mechanism)** A system of semi-fixed exchange rates used by most of the EU countries prior to adoption of the euro. Members' currencies were allowed to fluctuate against each other only within agreed bands. Collectively they floated against all other currencies.
- Excess burden (of a tax on a good)** The amount by which the loss in consumer plus producer surplus exceeds the government surplus.
- Excess capacity (under monopolistic competition)** In the long run, firms under monopolistic competition will produce at an output below their minimum-cost point.
- Exchange equalisation account** The gold and foreign exchange reserves account in the Bank of England.
- Exchange rate** The rate at which one national currency exchanges for another. The rate is expressed as the amount of one currency that is necessary to purchase *one unit* of another currency (e.g. €1.20 = £1).
- Exchange rate band** Where a currency is allowed to float between an upper and lower exchange rate, but is not allowed to move outside this band.
- Exchange rate index** A weighted average exchange rate expressed as an index where the value of the index is 100 in a given base year. The weights of the different currencies in the index add up to 1.
- Exchange rate mechanism** See *ERM*.
- Exchange rate overshooting** Where a fall (or rise) in the long-run equilibrium exchange rate causes the actual exchange rate to fall (or rise) by a greater amount before eventually moving back to the new long-run equilibrium level.
- Exchange rate: real** A country's exchange rate adjusted for changes in the domestic currency prices of its exports relative to the foreign currency prices of its imports. If a country's prices rise (fall) relative to those of its trading partners, its real exchange rate will rise (fall) relative to the nominal exchange rate.
- Exchange rate regime** The system under which the government allows the exchange rate to be determined.
- Exchange rate transmission mechanism** How a change in money supply affects aggregate demand via a change in exchange rates.
- Exclusionary abuses (in business)** Business practices that limit or prevent effective competition from either actual or potential rivals.
- Exogenous money supply** Money supply that does not depend on the demand for money but is set by the authorities.
- Exogenous variable** A variable whose value is determined independently of the model of which it is part.
- Expansion path** The line on an isoquant map that traces the minimum-cost combinations of two factors as output increases. It is drawn on the assumption that both factors can be varied. It is thus a long-run path.
- Expected value** The average value of an outcome of an activity when the same activity takes place many times.

Expectations-augmented Phillips curve A (short-run) Phillips curve whose position depends on the expected rate of inflation.

Expenditure changing (increasing) from depreciation: the income effect Where depreciation, via the substitution effect, will alter the demand for imports and exports, and this will, via the multiplier, affect the level of national income and hence the demand for imports.

Expenditure changing (reducing) from deflation: the income effect Where deflationary policies lead to a reduction in national income and hence a reduction in the demand for imports.

Expenditure switching from deflation: the substitution effect Where deflationary policies lead to a reduction in inflation and thus cause a switch in expenditure away from imports and also towards exports.

Expenditure switching from depreciation: the substitution effect Where a lower exchange rate reduces the price of exports and increases the price of imports. This will increase the sale of exports and reduce the sale of imports.

Exploitative abuse (in business) A business practice that directly harms the customer. Examples include high prices and poor quality.

Exponential discounting A method of reducing future benefits and costs to a present value. The discount rate depends on just how much less, from the consumer's perspective, *future* utility and costs (from a decision made today) are than gaining the utility/incurring the costs *today*.

Explicit costs The payments to outside suppliers of inputs.

External balance (in the economy) Narrow definition: where the current account of the balance of payments is in balance (and thus also the capital plus financial accounts). Loose definition: where there is a total currency flow balance at a given exchange rate.

External benefits Benefits from production (or consumption) experienced by people *other* than the producer (or consumer) directly involved in the transaction.

External costs Costs of production (or consumption) borne by people *other* than the producer (or consumer) directly involved in the transaction.

External diseconomies of scale Where a firm's costs per unit of output increase as the size of the whole *industry* increases.

External economies of scale Where a firm's costs per unit of output decrease as the size of the whole *industry* grows.

External policy objectives Objectives relating to the economy's international economic relationships.

Externalities Costs or benefits of production or consumption experienced by people *other* than the producers and consumers directly involved in the transaction. They are sometimes referred to as 'spillover' or 'third-party' costs or benefits.

Factor price equalisation The tendency for international trade to reduce factor price inequalities both between and within countries.

Factors of production (or resources) The inputs into the production of goods and services: labour, land and raw materials, and capital.

Fallacy of composition What applies to the individual does not necessarily apply to the whole.

Final expenditure Expenditure on goods and services. This is included in GDP and is part of aggregate demand.

Financial accelerator The amplification of effects on the macroeconomy from economic shocks because of changes in the pricing and supply of credit by financial institutions.

Financial account of the balance of payments The record of the flows of money into and out of the country for the purposes of investment or as deposits in banks and other financial institutions.

Financial crowding out When an increase in government borrowing diverts money away from the private sector.

Financial deregulation The removal of or reduction in legal rules and regulations governing the activities of financial institutions.

Financial flexibility Where employers can vary their wage costs by changing the composition of their workforce or the terms on which workers are employed.

Financial instability hypothesis During periods of economic growth, economic agents (firms and individuals) tend to borrow more and MFIs are more willing to lend. This fuels the boom. In a period of recession, economic agents tend to cut spending in order to reduce debts and MFIs are less willing to lend. This deepens the recession. Behaviour in financial markets thus tends to amplify the business cycle.

Financial instruments Financial products resulting in a financial claim by one party over another.

Financial intermediaries The general name for financial institutions (banks, building societies, etc.) which act as a means of channelling funds from depositors to borrowers.

Financialisation A term used to describe the process by which financial markets, institutions and instruments becoming increasingly significant in economies.

Fine-tuning The use of demand management policy (fiscal or monetary) to smooth out cyclical fluctuations in the economy.

First-best solution The solution of correcting a specific market distortion by ensuring that the whole economy operates under conditions of social efficiency (Pareto optimality).

First-degree price discrimination Where the seller of the product charges each consumer the maximum price he or she is prepared to pay for each unit.

First-mover advantage When a firm gains from being the first one to take action.

Fiscal drag The tendency of automatic fiscal stabilisers to reduce the recovery of an economy from recession.

Fiscal policy Policy to affect aggregate demand by altering the balance between government expenditure and taxation.

- Fiscal stance** How deflationary or reflationary the Budget is.
- Fixed costs** Total costs that do not vary with the amount of output produced.
- Fixed exchange rate (totally)** Where the government takes whatever measures are necessary to maintain the exchange rate at some stated level.
- Fixed factor** An input that cannot be increased in supply within a given time period.
- Flat organisation** Where the senior management communicate directly with those lower in the organisational structure, bypassing middle management.
- Flexible firm** A firm that has the flexibility to respond to changing market conditions by changing the composition of its workforce.
- Floating exchange rate** When the government does not intervene in the foreign exchange markets, but simply allows the exchange rate to be freely determined by demand and supply.
- Flow** An amount of something occurring over a *period of time*: e.g. production per week, income per year, demand per week. (Contrasts with *stock*.)
- Flow-of-funds equation** The various items making up an increase (or decrease) in money supply.
- Forward exchange market** Where contracts are made today for the price at which currency will be exchanged at some specified future date.
- Framing** The way in which a choice is presented or understood. A person may make different decisions depending on whether a choice is presented optimistically or pessimistically.
- Franchising** Where a firm is given the licence to operate a given part of an industry for a specified length of time.
- Free trade area** A group of countries with no trade barriers between themselves.
- Freely floating exchange rate** Where the exchange rate is determined entirely by the forces of demand and supply in the foreign exchange market with no government intervention whatsoever.
- Free-market economy** An economy where all economic decisions are taken by individual households and firms and with no government intervention.
- Free-rider problem** When it is not possible to exclude other people from consuming a good that someone has bought.
- Frictional (search) unemployment** Equilibrium unemployment which occurs as a result of imperfect information in the labour market. It often takes time for workers to find jobs (even though there are vacancies) and in the meantime they are unemployed.
- Full-employment level of national income** The level of national income at which there is no deficiency of demand.
- Functional distribution of income** Measurement of the distribution of income according to the source of income (e.g. from employment, from profit, from rent, etc.).
- Functional flexibility** Where employers can switch workers from job to job as requirements change.
- Functional relationships** The mathematical relationship showing how one variable is affected by one or more others.
- Funding (in monetary policy)** Where the authorities alter the balance of bills and bonds for any given level of government borrowing.
- Future price** A price agreed today at which an item (e.g. commodities) will be exchanged at some set date in the future.
- Futures or forward market** A market in which contracts are made to buy or sell at some future date at a price agreed today.
- Gaia philosophy** The respect for the rights of the environment to remain unharmed by human activity. Humans should live in harmony with the planet and other species. We have a duty to be stewards of the natural environment, so that it can continue to be a self-maintaining and self-regulating system.
- Game theory (or the theory of games)** A mathematical method of decision making in which alternative strategies are analysed to determine the optimal course of action for the interested party, depending on assumptions about rivals' behaviour. Widely used in economics, game theory is also used as a tool in biology, psychology and politics.
- GDP (gross domestic product at market prices)** The value of output (or income or expenditure) in terms of the prices actually paid. $GDP = GVA + \text{taxes on products} - \text{subsidies on products}$.
- GDP deflator** The price index of all final domestically produced goods and services: i.e. all those items that contribute towards GDP.
- Gearing or leverage** (US term) The ratio of debt capital to equity capital: in other words, the ratio of borrowed capital (e.g. bonds) to shares.
- General equilibrium** A situation where all the millions of markets throughout the economy are in a simultaneous state of equilibrium.
- General equilibrium diagrams (in trade theory)** Indifference curve/production possibility curve diagrams that show a country's production and consumption of both imports and exports.
- General government debt** The accumulated deficits of central plus local government. It is the total amount owed by general government, both domestically and internationally.
- General government deficit (or surplus)** The combined deficit (or surplus) of central and local government.
- Geographical immobility** The lack of ability or willingness of people to move to jobs in other parts of the country.
- Giffen good** An inferior good whose demand increases as its price increases as a result of a positive income effect larger than the normal negative substitution effect.
- Gini coefficient** The area between the Lorenz curve and the 45° line divided by the total area under the 45° line.

- Global systemically important banks (SIBs)** Banks identified by a series of indicators as being significant players in the global financial system.
- GNY (gross national income)** GDP plus net income from abroad.
- Gold standard** The system whereby countries' exchange rates were fixed in terms of a certain amount of gold and whereby balance of payments deficits were paid in gold.
- Golden-rule saving rate** The rate of saving that maximises the level of long-run consumption.
- Goodhart's law** Controlling a symptom of a problem or only one part of the problem will not *cure* the problem: it will simply mean that the part that is being controlled now becomes a poor indicator of the problem.
- Government bonds or 'gilt-edged securities'** A government security paying a fixed sum of money each year. It is redeemed by the government on its maturity date at its face value.
- Government surplus (from a tax on a good)** The total tax revenue earned by the government from sales of a good.
- Grandfathering** Where the number of emission permits allocated to a firm is based on its *current* levels of emission (e.g. permitted levels for all firms could be 80 per cent of their current levels).
- Green tax** A tax on output designed to charge for the adverse effects of production on the environment. The socially efficient level of a green tax is equal to the marginal environmental cost of production.
- Gross domestic product (GDP)** The value of output produced within the country over a 12-month period.
- Gross national income (GNY)** GDP plus net income from abroad.
- Gross value added at basic prices (GVA)** The sum of all the values added by all industries in the economy over a year. The figures exclude taxes on products (such as VAT) and include subsidies on products.
- Growth maximisation** An alternative theory that assumes that managers seek to maximise the growth in sales revenue (or the capital value of the firm) over time.
- Harrod-Domar model** A model that relates a country's rate of economic growth to the proportion of national income saved and the ratio of capital to output.
- Heckscher-Ohlin version of comparative advantage** A country has a comparative advantage in those goods that are intensive in the country's relatively abundant factor.
- Heterodox economists** Economists who reject the assumptions of neoclassical economics, in particular the assumptions of rational optimising behaviour. They highlight the importance of institutional behaviour and factors influencing human behaviour.
- Heuristics** A mental short-cut or rule of thumb that people use when trying to solve complex problems. Heuristics reduce the computational effort required but sometimes lead to systematic errors.
- H-form organisation (holding company)** Where the parent company holds interests in a number of subsidiary companies.
- Historic costs** The original amount the firm paid for factors it now owns.
- Hit-and-run competition** A strategy whereby a firm is willing to enter a market and make short-run profits and then leave again when the existing firm(s) cut prices. Costless exit makes hit-and-run behaviour more likely.
- Horizontal equity** The equal treatment of people in the same situation.
- Horizontal merger** When two firms in the same industry at the same stage in the production process merge.
- Households' disposable income** The income available for households to spend: i.e. personal incomes after deducting taxes on incomes and adding benefits.
- Human capital** The qualifications, skills and expertise that contribute to a worker's productivity.
- Human Development Index (HDI)** A composite index made up of three elements: an index for life expectancy, an index for school enrolment and adult literacy, and an index for GDP per capita (in PPP\$).
- Hysteresis** The persistence of an effect even when the initial cause has ceased to operate. In economics, it refers to the persistence of unemployment even when the demand deficiency that caused it no longer exists.
- Identification problem** The problem of identifying the relationship between two variables (e.g. price and quantity demanded) from the evidence when it is not known whether or how the variables have been affected by *other* determinants. For example, it is difficult to identify the shape of a demand curve simply by observing price and quantity when it is not known whether changes in other determinants have *shifted* the demand curve.
- Idle balances** Money held for speculative purposes: money held in anticipation of a fall in asset prices.
- Illegal (or shadow or underground) markets** Where people ignore the government's price and/or quantity controls and sell illegally at whatever price equates illegal demand and supply.
- Imperfect competition** The collective name for monopolistic competition and oligopoly.
- Implicit costs** Costs which do not involve a direct payment of money to a third party, but which nevertheless involve a sacrifice of some alternative.
- Import-substituting industrialisation (ISI)** A strategy of restricting imports of manufactured goods and using the foreign exchange saved to build up domestic substitute industries.
- Impulse response functions** The time paths of key macro-economic variables following economic shocks.
- Impure public good** A good that is partially non-rivalrous and non-excludable.
- Incidence of tax** The distribution of the burden of tax between sellers and buyers.

- Income and expenditure account or profit and loss account** A record of the flows of incomes, expenditure and saving of an individual or institution.
- Income effect (of a price change)** The effect of a change in price on quantity demanded arising from the consumer becoming better or worse off as a result of the price change.
- Income effect of a rise in wage rates** Workers get a higher income for a given number of hours worked and may thus feel they need to work *fewer* hours as wage rates rise.
- Income effect of a tax rise** Tax increases reduce people's incomes and thus encourage people to work more.
- Income elasticity of demand** The percentage (or proportionate) change in quantity demanded divided by the percentage (or proportionate) change in income.
- Income elasticity of demand (arc formula)** $\Delta Q_D / \text{average } Q_D \Delta Y / \text{average } Y$.
- Income-consumption curve** A line showing how a person's optimum level of consumption of two goods changes as income changes (assuming the price of the goods remains constant).
- Increasing-cost industry** An industry where average costs increase as the size of the industry expands.
- Increasing opportunity costs of production** When additional production of one good involves ever increasing sacrifices of another.
- Independence (of firms in a market)** Where the decisions of one firm in a market will not have any significant effect on the demand curves of its rivals.
- Independent risks** Where two risky events are unconnected. The occurrence of one will not affect the likelihood of the occurrence of the other.
- Index number** The value of a variable expressed as 100 plus or minus its percentage deviation from a base year.
- Indifference curve** A line showing all those combinations of two goods between which a consumer is indifferent: i.e. those combinations that give the same level of utility.
- Indifference map** A graph showing a whole set of indifference curves. The further away a particular curve is from the origin, the higher the level of satisfaction it represents.
- Indifference set** A table showing the same information as an indifference curve.
- Indirect monetary transmission mechanism** A change in money supply affecting aggregate demand indirectly via some other variable.
- Indirect taxes** Taxes on expenditure (e.g. VAT). They are paid to the tax authorities, not by the consumer, but indirectly by the suppliers of the goods or services.
- Indivisibilities** The impossibility of dividing a factor into smaller units.
- Induced investment** Investment that firms make to enable them to meet extra consumer demand.
- Induction** Constructing general theories on the basis of specific observations.
- Industrial policies** Policies to encourage industrial investment and greater industrial efficiency.
- Industry's infrastructure** The network of supply agents, communications, skills, training facilities, distribution channels, specialised financial services, etc., that supports a particular industry.
- Inelastic demand (with respect to price)** Where quantity demanded changes by a smaller percentage than price. Ignoring the negative sign, it will have a value less than 1.
- Infant industry** An industry that has a potential comparative advantage, but which is as yet too underdeveloped to be able to realise this potential.
- Inferior goods** Goods whose demand *decreases* as consumer incomes increase. Such goods have a negative income elasticity of demand.
- Inflation** A general rise in the level of prices throughout the economy.
- Inflation bias** Excessive inflation that results from people raising their expectations of the inflation rate following expansionary demand management policy, encouraging government to loosen policy even further.
- Inflation rate (annual)** The percentage increase in prices over a 12-month period.
- Inflationary gap** The excess of national expenditure over income (and injections over withdrawals) at the full-employment level of national income.
- Informal sector** The parts of the economy that involve production and/or exchange, but where there are no money payments.
- Infrastructure (industry's)** The network of supply agents, communications, skills, training facilities, distribution channels, specialised financial services, etc. that supports a particular industry.
- Injections (J)** Expenditure on the production of domestic firms coming from outside the inner flow of the circular flow of income. Injections equal investment (I) plus government expenditure (G) plus expenditure on exports (X).
- (Injections) multiplier** The number of times by which a rise in income exceeds the rise in injections that caused it: $k = \Delta Y / \Delta J$.
- (Injections) multiplier formula** The formula for the multiplier: $k = 1/mpw$ or $1/(1-mpc_d)$.
- Input-output analysis** This involves dividing the economy into sectors where each sector is a user of inputs from and a supplier of outputs to other sectors. The technique examines how these inputs and outputs can be matched to the total resources available in the economy.
- Insiders** Those in employment who can use their privileged position (either as members of unions or because of specific skills) to secure pay rises despite an excess supply of labour (unemployment).
- Interdependence (under oligopoly)** One of the two key features of oligopoly. Each firm will be affected by its rivals' decisions. Likewise its decisions will affect its rivals. Firms recognise this interdependence. This recognition will affect their decisions.

- Interest rate transmission mechanism** How a change in money supply affects aggregate demand via a change in interest rates.
- Intermediate exchange rate regimes** Where the government intervenes to influence movements in the exchange rate.
- Internal balance (of an economy)** Where the equilibrium level of national income is at the desired level.
- Internal policy objectives (national)** Objectives relating solely to the domestic economy.
- Internal rate of return** The rate of return of an investment: the discount rate that makes the net present value of an investment equal to zero.
- International harmonisation of economic policies** Where countries attempt to co-ordinate their macroeconomic policies so as to achieve common goals.
- International liquidity** The supply of currencies in the world acceptable for financing international trade and investment.
- International substitution effect** As prices rise, people at home and abroad buy less of this country's products and more of products from abroad.
- International trade multiplier** The effect on national income in Country B of a change in exports (or imports) of Country A.
- Inter-temporal substitution effect** Higher prices may lead to higher interest rates and thus less borrowing and more saving. Current consumption falls; future consumption (from the higher savings) rises.
- Intervention price (in the CAP)** The price at which the EU is prepared to buy a foodstuff if the market price were to be below it.
- Interventionist supply-side policies** Policies to increase aggregate supply by government intervention to counteract the deficiencies of the market.
- Investment** The production of items that are not for immediate consumption. This can include investment in plant and equipment; such investment builds the stock of firms' capital and yields a flow of future output. Investment also includes adding to stocks of goods or resources which are not sold or used in the current period, but will be in the future.
- Irrational exuberance** Where banks and other economic agents are over confident about the economy and/or financial markets and expect economic growth to remain stronger and/or asset prices to rise further than warranted by evidence.
- IS/LM model** A model showing simultaneous equilibrium in the goods market ($I = S$) and the money market ($L = M$).
- Isocost** A line showing all the combinations of two factors that cost the same to employ.
- Isoquant** A line showing all the alternative combinations of two factors that can produce a given level of output.
- J-curve effect** Where a devaluation causes the balance of trade first to deteriorate and then to improve. The graph of the balance of trade over time thus looks like a letter J.
- Joint float** Where a group of currencies pegged to each other jointly float against other currencies.
- Joint supply** Where the production of more of one good leads to the production of more of another.
- Joint venture** Where two or more firms set up and jointly own a new independent firm.
- Just-in-time methods** Where a firm purchases supplies and produces both components and finished products as they are required. This minimises stock holding and its associated costs. It does, however, put pressure on the supply chain and increases the probability that on occasion firms may not be able to meet demand – for example in times of bad weather.
- Kinked demand theory** The theory that oligopolists face a demand curve that is kinked at the current price, demand being significantly more elastic above the current price than below. The effect of this is to create a situation of price stability.
- Labour** All forms of human input, both physical and mental, into current production.
- Labour force** The number employed plus the number unemployed.
- Land (and raw materials)** Inputs into production that are provided by nature: e.g. unimproved land and mineral deposits in the ground.
- Law of comparative advantage** Trade can benefit all countries if they specialise in the goods in which they have a comparative advantage.
- Law of demand** The quantity of a good demanded per period of time will fall as price rises and will rise as price falls, other things being equal (*ceteris paribus*).
- Law of diminishing (marginal) returns** When one or more factors are held fixed, there will come a point beyond which the extra output from additional units of the variable factor will diminish.
- Law of large numbers** The larger the number of events of a particular type, the more predictable will be their average outcome.
- Lender of last resort** The role of the Bank of England as the guarantor of sufficient liquidity in the monetary system.
- Leverage (US term) or gearing** The ratio of debt capital to equity capital: in other words, the ratio of borrowed capital (e.g. bonds) to shares.
- Liability** Claim by others on an individual or institution; debt of that individual or institution.
- Liabilities** All legal claims for payment that outsiders have on an institution.
- Libertarian school** A school of thought that advocates maximum liberty for economic agents to pursue their own interests and to own property.
- Limit pricing** Where a monopolist (or oligopolist) charges a price below the short-run profit-maximising level in order to deter new entrants.
- Liquidity** The ease with which an asset can be converted into cash without loss.

- Liquidity preference** The demand for holding assets in the form of money.
- Liquidity ratio** The proportion of a bank's total assets held in liquid form.
- Liquidity trap** The absorption of any additional money supply into idle balances at very low rates of interest, leaving aggregate demand unchanged.
- Lock-outs** Union members are temporarily laid off until they are prepared to agree to the firm's conditions.
- Long run** The period of time long enough for *all* factors to be varied.
- Long run under perfect competition** The period of time that is long enough for new firms to enter the industry.
- Long-run average cost curve** A curve that shows how average cost varies with output on the assumption that *all* factors are variable. (It is assumed that the least-cost method of production will be chosen for each output.)
- Long-run marginal cost** The extra cost of producing one more unit of output assuming that all factors are variable. (It is assumed that the least-cost method of production will be chosen for this extra output.)
- Long-run neutrality of money** Changes in money supply over the long run will only affect prices and not real output or employment
- Long-run profit maximisation** An alternative theory of the firm which assumes that managers aim to *shift* cost and revenue curves so as to maximise profits over some longer time period.
- Long-run shut-down point** This is where the *AR* curve is tangential to the *LRAC* curve. The firm can just make normal profits. Any fall in revenue below this level will cause a profit-maximising firm to shut down once all costs have become variable.
- Lorenz curve** A curve showing the proportion of national income earned by any given percentage of the population (measured from the poorest upwards).
- Macro-prudential regulation** Regulation which focuses not on a single financial institution but on the financial system as a whole and which monitors its overall stability, its resilience to shocks and its impact on the wider economy.
- Macroeconomics** The branch of economics that studies economic aggregates (grand totals): e.g. the overall level of prices, output and employment in the economy.
- Managed flexibility (dirty floating)** A system of flexible exchange rates but where the government intervenes to prevent excessive fluctuations or even to achieve an unofficial target exchange rate.
- Margin squeeze** Where a vertically integrated firm with a dominant position in an upstream market deliberately charges high prices for an input required by firms in a downstream market to drive them out of business.
- Marginal benefit** The additional benefit of doing a little bit more (or 1 unit more if a unit can be measured) of an activity.
- Marginal capital/output ratio** The amount of extra capital (in money terms) required to produce a £1 increase in national output. Since $I_1 = \Delta K$, the marginal capital/output ratio $\Delta K/\Delta Y$ equals the accelerator coefficient α .
- Marginal consumer surplus** The excess of utility from the consumption of one more unit of a good (*MU*) over the price paid: $MCS = MU - P$.
- Marginal cost (of an activity)** The additional cost of doing a little bit more (or 1 unit more if a unit can be measured) of an activity.
- Marginal cost (of production)** The cost of producing one more unit of output: $MC = \Delta TC/\Delta Q$.
- Marginal disutility of work** The extra sacrifice/hardship to a worker of working an extra unit of time in any given time period (e.g. an extra hour per day).
- Marginal efficiency of capital or internal rate of return** The rate of return of an investment: the discount rate that makes the net present value of an investment equal to zero.
- Marginal physical product** The extra output gained by the employment of one more unit of the variable factor: $MPP = \Delta TPP/\Delta Q_v$.
- Marginal productivity theory** The theory that the demand for a factor depends on its marginal revenue product.
- Marginal propensity to consume** The proportion of a rise in national income that goes on consumption: $mpc = \Delta C/\Delta Y$.
- Marginal propensity to import** The proportion of an increase in national income that is spent on imports: $mpm = \Delta M/\Delta Y$.
- Marginal propensity to save** The proportion of an increase in national income saved: $mps = \Delta S/\Delta Y$.
- Marginal propensity to withdraw** The proportion of an increase in national income that is withdrawn from the circular flow: $mpw = \Delta W/\Delta Y$, where $mpw = mps + mpt + mpm$.
- Marginal rate of factor substitution** The rate at which one factor can be substituted by another while holding the level of output constant: $MRS = \Delta F_1/\Delta F_2 = MPP_{F_2}/MPP_{F_1}$.
- Marginal rate of income tax** The income tax rate. The rate paid on each *additional* pound earned: $\Delta T/\Delta Y$.
- Marginal rate of substitution (between two goods in consumption)** The amount of one good (*Y*) that a consumer is prepared to give up in order to obtain one extra unit of another good (*X*): i.e. $\Delta Y/\Delta X$.
- Marginal revenue** The extra revenue gained by selling one more unit per time period: $MR = \Delta TR/\Delta Q$.
- Marginal revenue product (of a factor)** The extra revenue a firm earns from employing one more unit of a variable factor: $MRP_{\text{factor}} = MPP_{\text{factor}} MR_{\text{good}}$.
- Marginal tax propensity** The proportion of an increase in national income paid in tax: $mpt = \Delta T/\Delta Y$.
- Marginal utility** The extra satisfaction gained from consuming one extra unit of a good within a given time period.

- Market** The interaction between buyers and sellers.
- Market clearing** A market clears when supply matches demand, leaving no shortage or surplus.
- Market demand schedule** A table showing the different total quantities of a good that consumers are willing and able to buy at various prices over a given period of time.
- Market for loanable funds** The market for loans from and deposits into the banking system.
- Market loans** Short-term loans (e.g. money at call and short notice).
- Market-orientated supply-side policies** Policies to increase aggregate supply by freeing up the market.
- Mark-up** A profit margin added to average cost to arrive at price.
- Marshall-Lerner condition** Depreciation will improve the balance of payments only if the sum of the price elasticities of demand for imports and exports is greater than 1.
- Maturity gap** The difference in the average maturity of loans and deposits.
- Maturity transformation** The transformation of deposits into loans of a longer maturity.
- Maximax** The strategy of choosing the policy that has the best possible outcome. Maximax is usually a high-risk strategy.
- Maximin** The strategy of choosing the policy whose worst possible outcome is the least bad. Maximin is usually a low-risk strategy.
- Maximum price** A price ceiling set by the government or some other agency. The price is not allowed to rise above this level (although it is allowed to fall below it).
- Mean (or arithmetic mean)** The sum of the values of each of the members of the sample divided by the total number in the sample.
- Means-tested benefits** Benefits whose amount depends on the recipient's income or assets.
- Median** The value of the middle member of the sample.
- Medium of exchange** Something that is acceptable in exchange for goods and services.
- Menu costs of inflation** The costs associated with having to adjust price lists or labels.
- Merchandise balance** See *Balance of trade in goods*.
- Merit goods** Goods which the government feels that people will underconsume and which therefore ought to be subsidised or provided free.
- M-form (multi-divisional form) of corporate organisation** Where the firm is split into a number of separate divisions (e.g. different products or countries), with each division then split into a number of departments.
- Microeconomics** The branch of economics that studies individual units: e.g. households, firms and industries. It studies the interrelationships between these units in determining the pattern of production and distribution of goods and services.
- Minimum price** A price floor set by the government or some other agency. The price is not allowed to fall below this level (although it is allowed to rise above it).
- Minimum reserve ratio** A minimum ratio of cash (or other specified liquid assets) to deposits (either total or selected) that the central bank requires banks to hold.
- Minsky moment** A turning point in a credit cycle where a period of easy credit and rising debt is replaced by one of tight credit and debt consolidation.
- Mixed command economy** A planned economy that nevertheless makes some use of markets.
- Mixed economy** An economy where economic decisions are made partly by the government and partly through the market. In practice all economies are mixed.
- Mixed market economy** A market economy where there is some government intervention.
- Mobility of labour** The willingness and ability of labour to move to another job.
- Monetarists** Those who attribute inflation solely to rises in money supply.
- Monetary base** Notes and coin outside the central bank.
- Monetary base control** Monetary policy that focuses on controlling the monetary base (as opposed to broad liquidity).
- Monetary financial institutions (MFIs)** Deposit-taking institutions including banks, building societies and the Bank of England.
- Monetary policy** Where the central bank alters the supply of money in the economy and/or manipulates interest rates.
- Money illusion** When people believe that a *money* change in wages or prices represents a *real* change: in other words, they ignore or underestimate inflation.
- Money market** The market for short-term debt instruments, such as government bills (Treasury bills), in which financial institutions are active participants.
- Money multiplier** The number of times greater the expansion of money supply is than the expansion of the monetary base that caused it: $\Delta Ms / \Delta Mb$.
- Monopolistic competition** A market structure where, like perfect competition, there are many firms and freedom of entry into the industry, but where each firm produces a differentiated product and thus has some control over its price.
- Monopoly** A market structure where there is only one firm in the industry.
- Monopsony** A market with a single buyer or employer.
- Moral hazard** Where one party to a transaction has an incentive to behave in a way which reduces the pay-off to the other party: for example, the temptation to take more risks when you know that someone else will cover the risks if you get into difficulties. In the case of banks taking risks, the 'someone else' may be another bank, the central bank or the government.
- Moral hazard (in insurance)** Customers taking more risks when they have insurance than when they don't have insurance.
- Multiplier (injections multiplier)** The number of times a rise in income exceeds the rise in injections that caused it. $k = \Delta Y / \Delta J$.

- Multiplier effect** An initial increase in aggregate demand of £x million leads to an eventual rise in national income that is greater than £x million.
- Multiplier formula (injections multiplier)** The formula for the multiplier is $k = 1/mpw$ or $1/(1-mpc_d)$.
- Mutual recognition** The EU principle that one country's rules and regulations must apply throughout the EU. If they conflict with those of another country, individuals and firms should be able to choose which to obey.
- Nash equilibrium** The position resulting from everyone making their optimal decision based on their assumptions about their rivals' decisions. Without collusion, there is no incentive for any firm to move from this position.
- National debt** The accumulated deficits of central government. It is the total amount owed by central government, both domestically and internationally.
- National expenditure on domestic product (E)** Aggregate demand in the Keynesian model: i.e. $C_d + J$.
- Nationalised industries** State-owned industries that produce goods or services that are sold in the market.
- Natural level of real income or output** The level of output in monetarist analysis where the vertical long-run aggregate supply curve cuts the horizontal axis.
- Natural level of unemployment** The level of equilibrium unemployment in monetarist and new classical analysis measured as the difference between the (vertical) long-run gross labour supply curve (N) and the (vertical) long-run effective labour supply curve (AS_t).
- Natural monopoly** A situation where long-run average costs would be lower if an industry were under monopoly than if it were shared between two or more competitors.
- Natural rate hypothesis** The theory that, following fluctuations in aggregate demand, unemployment will return to a natural rate. This rate is determined by supply-side factors, such as labour mobility.
- Natural rate of unemployment** The rate of unemployment at which there is no excess or deficiency of demand for labour. The rate of unemployment consistent, therefore, with a constant rate of inflation: the rate of unemployment at which the vertical long-run Phillips curve cuts the horizontal axis.
- Natural wastage** When a firm wishing to reduce its workforce does so by not replacing those who leave or retire.
- Near money** Highly liquid assets (other than cash).
- Negative income tax** A combined system of tax and benefits. As people earn more they gradually lose their benefits until beyond a certain level they begin paying taxes.
- Neo-Austrian/libertarian school** A school of thought that advocates maximum liberty for economic agents to pursue their own interests and to own property.
- Net investment** Total investment minus depreciation.
- Net national income (NNY)** GNY minus depreciation.
- Net present value of an investment** The discounted benefits of an investment minus the cost of the investment.
- Net worth** The market value of a sector's stock of financial and non-financial wealth.
- Network (business)** An informal arrangement between businesses to work together towards some common goal.
- Network economies (or network externalities)** The benefits a consumer obtains from consuming a good or service increase with the number of other people who use the same good or service.
- Neutrality of money (long run)** Changes in money supply over the long run will only affect prices and not real output or employment.
- New classical school** The school of economists which believes that markets clear virtually instantaneously and that expectations are formed 'rationally'. Any expansion of demand will feed through virtually instantaneously into higher prices, giving a vertical short-run as well as a vertical long-run Phillips curve.
- New Keynesians** Economists who seek to explain how market imperfections and frictions can result in fluctuations in real GDP and the persistence of unemployment. They argue that governments may have to expand aggregate demand when demand-deficient unemployment is persistent.
- Nominal GDP** GDP measured at current prices.
- Nominal national income** National income measured at current prices.
- Nominal values** Money values measured at *current* prices.
- Non-accelerating-inflation rate of unemployment (NAIRU)** The rate of unemployment consistent with steady inflation in the near term, say, over the next 12 months.
- Non-bank private sector** Households and non-bank firms: in other words, everyone in the country other than banks and the government (central and local).
- Non-collusive oligopoly** Where oligopolists have no agreement between themselves either formal, informal or tacit.
- Non-excludability** Where it is not possible to provide a good or service to one person without it thereby being available free for others to enjoy.
- Non-price competition** Competition in terms of product promotion (advertising, packaging, etc.) or product development.
- Non-rivalry** Where the consumption of a good or service by one person will not prevent others from enjoying it.
- Normal-form game** Where the possible pay-offs from different strategies or decisions are presented as a matrix.
- Normal goods** Goods whose demand increases as consumer incomes increase. They have a positive income elasticity of demand. Luxury goods will have a higher income elasticity of demand than more basic goods.
- Normal profit** The opportunity cost of being in business: the profit that could have been earned in the next best alternative business. It is counted as a cost of production.
- Normal rate of return** The rate of return (after taking risks into account) that could be earned elsewhere.
- Normative statement** A value judgement.

- Nudge theory** The theory that positive reinforcement or making the decision easy can persuade people to make a particular choice. They are 'nudged' into so doing.
- Numerical flexibility** Where employers can change the size of their workforce as their labour requirements change.
- Occupational immobility** The lack of ability or willingness of people to move to other jobs irrespective of location.
- Okun's law** The name given to the negative statistical relationship between the unemployment rate and deviations of output from potential output.
- Oligopoly** A market structure where there are few enough firms to enable barriers to be erected against the entry of new firms.
- Oligopsony** A market with just a few buyers or employers.
- Open economy** One that trades with and has financial dealings with other countries.
- Open-market operations** The sale (or purchase) by the authorities of government securities in the open market in order to reduce (or increase) money supply or influence interest rates.
- Operational standing facilities** Central bank facilities by which individual banks can deposit reserves or borrow reserves.
- Opportunity cost** Cost measured in terms of the value of the best alternative forgone.
- Optimal currency area** The optimal size of a currency area is the one that maximises the benefits from having a single currency relative to the costs. If the area were increased or decreased in size, the costs would rise relative to the benefits.
- Optimum tariff** A tariff that reduces the level of imports to the point where the country's marginal social cost equals marginal social benefit.
- Organisational slack** Where managers allow spare capacity to exist, thereby enabling them to respond more easily to changed circumstances.
- Output gap** The difference between actual and potential output. When actual output exceeds potential output, the gap is positive. When actual output is less than potential output, the gap is negative.
- Outsiders** Those out of work or employed on a casual, part-time or short-term basis, who have little or no power to influence wages or employment.
- Overheads** Costs arising from the general running of an organisation, and only indirectly related to the level of output.
- Paradox of debt (or paradox of deleveraging)** The paradox that one individual can increase his or her net worth by selling assets, but if this is undertaken by a large number of people aggregate net worth declines because asset prices fall.
- Paradox of thrift** If society saves more, this may *reduce* its future income and consumption. The reason is that as people save more, they will spend less. Firms will thus produce less. There will thus be a multiplied *fall* in income.
- Pareto improvement** Where changes in production or consumption can make at least one person better off without making anyone worse off.
- Pareto optimality** Where all possible Pareto improvements have been made: where, therefore, it is impossible to make anyone better off without making someone else worse off.
- Partial derivative** The partial derivative of a function of two or more independent variables is the derivative with respect to just one of those variables, while holding the others constant.
- Partial differentiation** A mathematical technique used with functions containing two or more independent variables. The technique is used to find the rate of change of the dependent variable with respect to a single independent variable assuming that the other independent variables are held constant.
- Participation rate** The percentage of the working-age population that is part of the workforce.
- Partnership** A firm owned by two or more people. They each have unlimited liability for the firm's debts.
- Peak-load pricing** Price discrimination (second or third degree) where a higher price is charged in peak periods and a lower price in off-peak periods.
- Perfect competition** A market structure where there are many firms, none of which is large; where there is freedom of entry into the industry; where all firms produce an identical product; and where all firms are price takers.
- Perfectly contestable market** A market where there is free and costless entry and exit and the monopolist cannot immediately respond to entry.
- Phillips curve** A curve showing the relationship between (price) inflation and unemployment. The original Phillips curve plotted *wage* inflation against unemployment for the years 1861–1957.
- Picketing** When people on strike gather at the entrance to the firm and attempt to persuade workers or delivery vehicles from entering.
- Pigouvian tax (or subsidy)** A tax (or subsidy) designed to 'internalise' an externality. The marginal rate of a Pigouvian tax (or subsidy) should be equal to the marginal external cost (or benefit).
- Plant economies of scale** Economies of scale that arise because of the large size of the factory.
- Point elasticity** The measurement of elasticity at a point on a curve. The formula for price elasticity of demand using the point elasticity method is: $dQ/dP \times P/Q$, where dQ/dP is the inverse of the slope of the tangent to the demand curve at the point in question.
- Policy ineffectiveness proposition** The conclusion drawn from new classical models that when economic agents anticipate changes in economic policy, output and employment remain at their equilibrium (or natural) levels.
- Political business cycle** The theory that governments, after being elected, will engineer an economic contraction, designed to squeeze out inflation. They will then later engineer a pre-election boom to appeal to the electorate.

- Poll tax** A lump-sum tax per head of the population. Since it is a fixed *amount*, it has a marginal rate of zero with respect to both income and wealth.
- Polluter pays principle** The principle that polluters ought to be charged (e.g. through green taxes) for the external environmental costs that they generate.
- Pooling risks (for an insurance company)** The more policies and insurance company issues and the more independent the risks of claims from these policies are, the more predictable will be the number of claims.
- Portfolio balance** The balance of assets, according to their liquidity, that people choose to hold in their portfolios.
- Positive statement** A value-free statement which can be tested by an appeal to the facts.
- Post-Keynesians** Economists who stress the importance of institutional and behavioural factors, and the role of business confidence in explaining the state of the economy. They argue that firms are more likely to respond to changes in demand by changing output rather than prices.
- Potential growth** The percentage increase in the capacity of the economy to produce.
- Potential output** The sustainable level output that could be produced in the economy: i.e. one that involves a 'normal' level of capacity utilisation and does not result in rising inflation.
- Poverty trap (for developing countries)** When countries are too poor to save and invest enough to achieve real per capita growth.
- Poverty trap (for individuals)** Where poor people are discouraged from working or getting a better job because any extra income they earn will be largely taken away in taxes and lost benefits.
- Predatory pricing** Where a firm sets its prices below average cost in order to drive competitors out of business.
- Preferential trading arrangements** A trade agreement whereby trade between the signatories is freer than trade with the rest of the world.
- Present bias** Time-inconsistent behaviour whereby people give greater weight to present pay-offs relative to future ones than would be predicted by standard discounting techniques.
- Present value approach to appraising investment** This involves estimating the value *now* of a flow of future benefits (or costs).
- Present value (in consumption)** The value a person places today on a good that will not be consumed until some point in the future.
- Price benchmark** A price which is typically used. Firms, when raising prices will usually raise it from one benchmark to another.
- Price discrimination** Where a firm sells the same product at different prices.
- Price elasticity of demand (arc formula)** $\Delta Q/\text{average } Q \div \Delta P/\text{average } P$. The average in each case is the average between the two points being measured.
- Price elasticity of demand ($P\epsilon_D$)** The percentage (or proportionate) change in quantity demanded divided by the percentage (or proportionate) change in price: $\% \Delta Q_D \div \% \Delta P$.
- Price elasticity of supply ($P\epsilon_S$)** The percentage (or proportionate) change in quantity supplied divided by the percentage (or proportionate) change in price: $\% \Delta Q_S \div \% \Delta P$.
- Price elasticity of supply (arc formula)** $\Delta Q_S/\text{average } Q_S \div \Delta P/\text{average } P$.
- Price mechanism** The system in a market economy whereby changes in price in response to changes in demand and supply have the effect of making demand equal to supply.
- Price taker** A person or firm with no power to be able to influence the market price.
- Price-cap regulation** Where the regulator puts a ceiling on the amount by which a firm can raise its price.
- Price-consumption curve** A line showing how a person's optimum level of consumption of two goods changes as the price of one of the two goods changes (assuming that income and the price of the other good remain constant).
- Prices and incomes policy** When the government seeks to restrain price and wage increases. This may be in the form of a voluntary agreement with firms and/or unions, or there may be statutory limits imposed.
- Primary labour market** The market for permanent full-time core workers.
- Primary market in capital** Where shares are sold by the issuer of the shares (i.e. the firm) and where, therefore, finance is channelled directly from the purchasers (i.e. the shareholders) to the firm.
- Primary surplus (or deficit)** The situation when the sum of public-sector expenditures excluding interest payments on public-sector debt is less than (greater than) public-sector receipts.
- Principal-agent problem** Where people (principals), as a result of lack of knowledge, cannot ensure that their best interests are served by their agents.
- Principle of cumulative causation** An initial event can cause an ultimate effect that is much larger.
- Prisoners' dilemma** Where two or more firms (or people), by attempting independently to choose the best strategy for whatever the other(s) are likely to do, end up in a worse position than if they had co-operated in the first place.
- Private efficiency** Where a person's marginal benefit from a given activity equals the marginal cost.
- Private limited company** A company owned by its shareholders. Shareholders' liability is limited to the value of their shares. Shares can only be bought and sold privately.
- Producers' share of a tax on a good** The proportion of the revenue from a tax on a good that arises from a reduction in the price to the producer (after the payment of the tax).

Product differentiation When one firm's product is sufficiently different from its rivals' to allow it to raise the price of the product without customers all switching to the rivals' products. A situation where a firm faces a downward-sloping demand curve.

Production The transformation of inputs into outputs by firms in order to earn profit (or meet some other objective).

Production function The mathematical relationship between the output of a good and the inputs used to produce it. It shows how output will be affected by changes in the quantity of one or more of the inputs used in production, holding the level of technology constant.

Production possibility curve A curve showing all the possible combinations of two goods that a country can produce within a specified time period with all its resources fully and efficiently employed.

Productive efficiency A situation where firms are producing the maximum output for a given amount of inputs, or producing a given output at the least cost. The least-cost combination of factors for a given output.

Productivity deal When, in return for a wage increase, a union agrees to changes in working practices that will increase output per worker.

Profit (rate of) Total profit (T) as a proportion of the total capital employed (K): $r = T/K$.

Profit and loss account or income and expenditure account A record of the flows of incomes, expenditure and saving of an individual or institution.

Profit satisficing Where decision makers in a firm aim for a target level of profit rather than the absolute maximum level.

Profit-maximising rule Profit is maximised where marginal revenue equals marginal cost.

Progressive tax A tax whose average rate with respect to income rises as income rises.

Proportional tax A tax whose average rate with respect to income stays the same as income rises.

Prudential control The insistence by the Bank of England that recognised banks maintain adequate liquidity.

Public good A good or service that has the features of non-rivalry and non-excludability and as a result would not be provided by the free market.

Public limited company A company owned by its shareholders. Shareholders' liability is limited to the value of their shares. Shares may be bought and sold publicly – on the Stock Exchange.

Public-sector current budget deficit The amount by which public-sector expenditures classified as current expenditures exceed public-sector receipts

Public-sector net borrowing (PSNB) The difference between the expenditures of the public sector and its receipts from taxation and the revenues from public corporations.

Public-sector net cash requirement (PSNCR) The (annual) deficit of the public sector, and thus the amount that the public sector must borrow. This can differ from the PSNB because of the timing of receipts and expenditures. The term is only used in the UK.

Public-sector net debt Gross public-sector debt minus liquid financial assets.

Public-sector surplus or public-sector debt repayment (PSDR) The (annual) surplus of the public sector, and thus the amount of debt that can be repaid when public-sector income exceeds public-sector expenditures.

Purchasing-power parity (PPP) exchange rate An exchange rate corrected to take into account the purchasing power of a currency. \$1 would buy the same in each country after conversion into its currency at the PPP rate.

Purchasing-power parity theory The theory that the exchange rate will adjust so as to offset differences in countries' inflation rates, with the result that the same quantity of internationally traded goods can be bought at home as abroad with a given amount of the domestic currency.

Purchasing-power standard (PPS) GDP GDP measured as a country's PPP exchange rate.

Pure fiscal policy Fiscal policy which does not involve any change in money supply.

Pure public good A good or service that has the characteristics of being perfectly non-rivalrous and completely non-excludable and as a result, would not be provided by the free market.

Quantiles Divisions of the population into equal-sized groups.

Quantitative easing (QE) A deliberate attempt by the central bank to increase the money supply by buying large quantities of securities through open-market operations. These securities could be securitised mortgage and other private sector debt or government bonds. When banks and other financial institutions lend the money, broad money expands by a multiple of this through the process of credit creation.

Quantity demanded The amount of a good a consumer is willing and able to buy at a given price over a given period of time.

Quantity theory of money The price level (P) is directly related to the quantity of money in the economy (M).

Quasi-rent Temporary economic rent arising from short-run supply inelasticity.

Quintiles Divisions of the population into five equal-sized groups (an example of a quantile).

Quota (set by a cartel) The output that a given member of a cartel is allowed to produce (production quota) or sell (sales quota).

Random walk Where fluctuations in the value of a share away from its 'correct' value are random: i.e. have no systematic pattern. When charted over time, these share price movements would appear like a 'random walk': like the path of someone staggering along drunk!

Rate of discount The rate that is used to reduce future values to present values.

Rate of economic growth The percentage increase in output, normally expressed over a 12-month or 3-month period.

- Rate of inflation (annual)** The percentage increase in the level of prices over a 12-month period.
- Rate of profit** Total profit (T) as a proportion of the capital employed (K): $r = T/K$.
- Rational choices** Choices that involve weighing up the benefit of any activity against its opportunity cost so that the decision maker successfully maximises his or her objective: e.g. happiness or profits.
- Rational consumer** A person who weighs up the costs and benefits to themselves of each additional unit of a good purchased.
- Rational consumer behaviour** The attempt to maximise total consumer surplus.
- Rational economic behaviour** Doing more of activities whose marginal benefit exceeds their marginal cost and doing less of those activities whose marginal cost exceeds their marginal benefit.
- Rational expectations** Expectations based on the *current* situation. These expectations are based on the information people have to hand. Whilst this information may be imperfect and therefore people will make errors, these errors will be random.
- Rational producer behaviour** When a firm weighs up the costs and benefits of alternative courses of action and then seeks to maximise its net benefit.
- Rationalisation** The reorganising of production (often after a merger) so as to cut out waste and duplication and generally to reduce costs.
- Rationing** Where the government restricts the amount of a good that people are allowed to buy.
- Reaction function (or curve)** This shows how a firm's optimal output varies according to the output chosen by its rival (or rivals).
- Real balance effect** As the price level rises, so the value of people's money balances will fall. They will therefore *spend* less in order to increase their money balances and go some way to protecting their real value.
- Real business cycle theory** The new classical theory which explains cyclical fluctuations in terms of shifts in aggregate supply, rather than aggregate demand.
- Real exchange rate** A country's exchange rate adjusted for changes in the domestic currency prices of its exports relative to the foreign currency prices of its imports. If a country's prices rise (fall) relative to those of its trading partners, its real exchange rate will rise (fall) relative to the nominal exchange rate.
- Real GDP** GDP after allowing for inflation: i.e. GDP measured in *constant* prices, in other words in terms of the prices ruling in some base year.
- Real income** Income measured in terms of how much it can buy. If your *money* income rises by 10 per cent, but prices rise by 8 per cent, you can only buy 2 per cent more goods than before. Your *real* income has risen by 2 per cent.
- Real national income** National income after allowing for inflation: i.e. national income measured in constant prices: i.e. in terms of the prices ruling in some base year.
- Real values** Money values corrected for inflation.
- Real-wage unemployment** Disequilibrium unemployment caused by real wages being driven up above the market-clearing level.
- Recession** A period where national output falls for two successive quarters or more.
- Recessionary (or deflationary) gap** The shortfall of national expenditure below national income (and injections below withdrawals) at the full-employment level of national income.
- Reciprocity (in economics)** Where people's behaviour is influenced by the effects it will have on others.
- Recognised banks** Banks licensed by the Bank of England. All financial institutions using the word 'bank' in their title have to be recognised by the Bank of England. This requires them to have paid-up capital of at least £5 million and to meet other requirements about their asset structure and range of services.
- Rediscounting bills of exchange** Buying bills before they reach maturity.
- Reference dependent loss aversion** Where people value (or 'code') outcomes as either losses or gains in relation to a reference point. This can mean that losses are disliked more than would be predicted by standard diminishing marginal utility.
- Reflationary policy** Fiscal or monetary policy designed to increase the rate of growth of aggregate demand.
- Regional Development Agencies (RDAs)** Nine agencies, based in English regions, which initiate and administer regional policy within their area.
- Regional multiplier effects** When a change in injections into or withdrawals from a particular region causes a multiplied change in income in that region. The regional multiplier (k_r) is given by $1/mpw_r$, where the import component of mpw , consists of imports into that region either from abroad or from other regions of the economy.
- Regional unemployment** Structural unemployment occurring in specific regions of the country.
- Regression analysis** A statistical technique which allows a functional relationship between two or more variables to be estimated.
- Regressive tax** A tax whose average rate with respect to income falls as income rises.
- Regulatory capture** Where the regulator is persuaded to operate in the industry's interests rather than those of the consumer.
- Relative price** The price of one good compared with another (e.g. good X is twice the price of good Y).
- Replacement costs** What the firm would have to pay to replace factors it currently owns.
- Resale (or retail) price maintenance** Where the manufacturer of a product (legally) insists that the product should be sold at a specified retail price.

- Reserve averaging** The process whereby individual banks manage their average level of overnight reserves between MPC meetings using the Bank of England's operational standing facilities and/or the inter-bank market.
- Residual demand curve** A firm's residual demand curve illustrates the relationship between the output it produces and the market price for the product, holding constant the output produced by other firms.
- Restrictive practice** Where two or more firms agree to adopt common practices to restrict competition.
- Retail banks** 'High street banks'. Banks operating extensive branch networks and dealing directly with the general public, with published interest rates and charges.
- Retail deposits and loans** Deposits and loans made through bank/building society branches at published interest rates.
- Retail price index (RPI)** An index of the prices of goods bought by a typical household.
- Revaluation** Where the government re-pegs the exchange rate at a higher level.
- Reverse repos** When gilts or other assets are *purchased* under a sale and repurchase agreement. They become an asset to the purchaser.
- Risk** When a (desirable) outcome of an action may or may not occur, but the probability of its occurring is known. The lower the probability, the greater the risk involved in taking the action.
- Risk averse** Where a person is not prepared to take a gamble even if the odds of gaining are favourable.
- Risk loving** Where a person is willing to take a gamble even if the odds of gaining are unfavourable.
- Risk neutral** Where a person is willing to take a gamble if the odds are favourable and is unwilling if the odds are unfavourable.
- Risk premium** The expected value of a gamble minus a person's certainty equivalent.
- Risk transformation** The process whereby banks can spread the risks of lending by having a large number of borrowers.
- Sale and repurchase agreement (repos)** An agreement between two financial institutions whereby one in effect borrows from another by selling its assets, agreeing to buy them back (repurchase them) at a fixed price and on a fixed date.
- Sales revenue maximisation** An alternative theory of the firm based on the assumption that managers aim to maximise the firm's short-run total revenue.
- Say's law** Supply creates its own demand. In other words, the production of goods will generate sufficient demand to ensure that they are sold.
- Scarcity** The excess of human wants over what can actually be produced to fulfil these wants.
- Search theory** This examines people's behaviour under conditions of ignorance where it takes time to search for information.
- Seasonal unemployment** Unemployment associated with industries or regions where the demand for labour is lower at certain times of the year.
- Second best (problem of)** The difficulty of working out the best way of correcting a specific market distortion if distortions in other parts of the market continue to exist.
- Second derivative** The rate of change of the first derivative: found by differentiating the first derivative.
- Second derivative test** If on differentiating an equation a second time the answer is negative (positive), the point is a maximum (minimum).
- Secondary action** Industrial action taken against a company not directly involved in a dispute (e.g. a supplier of raw materials to a firm whose employees are on strike).
- Secondary labour market** The market for peripheral workers, usually employed on a temporary or part-time basis, or a less secure 'permanent' basis.
- Secondary market in capital** Where shareholders sell shares to others. This is thus a market in 'second-hand' shares.
- Secondary marketing** Where assets are sold before maturity to another institution or individual. The possibility of secondary marketing encourages people or institutions to buy assets/grant loans in the primary market, knowing that they can sell them if necessary in the secondary market. The sale of existing shares and bonds on the stock market is an example of secondary marketing.
- Second-best solution** The solution to a specific market distortion that recognises distortions elsewhere and seeks to minimise the overall distortionary effects to the economy of tackling this specific distortion.
- Second-degree price discrimination** Where a firm offers consumers a range of different pricing options for the same or similar product. Consumers are then free to choose whichever option they wish but the price is often dependent on some factor such as the quantity purchased.
- Securitisation** Where future cash flows (e.g. from interest rate or mortgage payments) are turned into marketable securities, such as bonds. The sellers (e.g. banks) get cash now rather than having to wait and can use it to fund loans to customers. The buyers make a profit by buying below the discounted value of the future income. Such bonds can be very risky, however, as the future cash flows may be less than anticipated.
- Self-fulfilling speculation** The actions of speculators tend to cause the very effect that they had anticipated.
- Semi-strong efficiency (of share markets)** Where share prices adjust quickly, fully and accurately to publicly available information.
- Sensitivity analysis** Where a range of possible values of uncertain costs and benefits are given to see whether the project's desirability is sensitive to these different values.
- Sequential move game** One firm (the first mover) makes and implements a decision. Rival firms (second movers) can observe the actions taken by the first mover before making their own decisions.

- Set-aside** A system in the EU of paying farmers not to use a certain proportion of their land.
- Shadow (or illegal or underground) markets** Where people ignore the government's price and/or quantity controls and sell illegally at whatever price equates illegal demand and supply.
- Shares (equities)** A part ownership of a company. Companies' distributed profits are paid to shareholders in the form of dividends according to the number of shares held.
- Short run (in production)** The period of time over which at least one factor is fixed.
- Short run under perfect competition** The period during which there is insufficient time for new firms to enter the industry.
- Short-run shut-down point** This is where the *AR* curve is tangential to the *AVC* curve. The firm can only just cover its variable costs. Any fall in revenue below this level will cause a profit-maximising firm to shut down immediately.
- Short selling** The practice of borrowing an asset (for a fee) and selling it, hoping that the price will fall so that it can then be purchased and returned to the lender. The difference between the sale and purchase price (minus the fee) is thus profit to the short seller.
- Short-termism** Where firms and investors take decisions based on the likely short-term performance of a company, rather than on its long-term prospects. Firms may thus sacrifice long-term profits and growth for the sake of a quick return.
- Sight deposits** Deposits that can be withdrawn on demand without penalty.
- Simultaneous single-move game** A game where each player has just one move, where each player plays at the same time and acts without knowledge of the actions chosen by other players.
- Size distribution of income** Measurement of the distribution of income according to the levels of income received by individuals (irrespective of source).
- Social benefit** Private benefit plus externalities in consumption.
- Social capital (OECD definition)** Networks, together with shared norms, values and understandings, that facilitate co-operation within or among groups.
- Social cost** Private cost plus externalities in production.
- Social efficiency** A situation of Pareto optimality: where all possible Pareto improvements have been made: where, therefore, it is impossible to make anyone better off without making someone else worse off.
- Social efficiency (improvement in)** A Pareto improvement: where changes in production or consumption can make at least one person better off without making anyone worse off.
- Social rate of discount** A rate of discount that reflects *society's* preferences for present benefits over future ones.
- Social surplus** Total social benefits minus total social costs.
- Social-impact standards** Pollution control that focuses on the effects on people (e.g. on health or happiness).
- Socially optimal output** The output where $MSC = MSB$: the output where total social surplus is maximised.
- Sole proprietorship** A firm owned by one person. That person has unlimited liability.
- Sovereign debt crisis** The financial and economic problems caused by excessive public-sector debt and by the fear that governments will be unable to raise sufficient finance to repay maturing debt.
- Special drawing rights (SDRs)** Additional liquidity created by the IMF. SDRs give countries the right to borrow a certain amount of additional funds from the IMF, with no requirement for extra deposits (quotas).
- Special purpose vehicle (SPV)** Legal entities created by financial institutions for conducting specific financial functions, such as bundling assets together into fixed interest bonds and selling them.
- Specialisation and division of labour** Where production is broken down into a number of simpler, more specialised tasks, thus allowing workers to acquire a high degree of efficiency.
- Specific tax** A tax on a good levied at a fixed amount per unit of the good, irrespective of the price of that unit.
- Speculation** Where people make buying or selling decisions based on their anticipations of future prices.
- Speculators** People who buy (or sell) commodities or financial assets with the intention of profiting by selling them (or buying them back) at a later date at a higher (lower) price.
- Spot price** The current market price.
- Spreading risks (for an insurance company)** The more policies an insurance company issues and the more independent the risks of claims from these policies are, the more predictable will be the number of claims.
- Stabilising speculation** Where the actions of speculators tend to reduce the magnitude of price fluctuations.
- Stagflation** A term used to refer to the combination of stagnation (low growth and high unemployment) and high inflation.
- Stakeholders (in a company)** People who are affected by a company's activities and/or performance (customers, employees, owners, creditors, people living in the neighbourhood, etc.). They may or may not be in a position to take decisions, or influence decision taking, in the firm.
- Standardised unemployment rate** The measure of the unemployment rate used by the ILO and OECD. The unemployed are defined as persons of working age who are without work, available to start work within two weeks and either have actively looked for work in the last four weeks or are waiting to take up an appointment.
- Steady-state growth path** The growth path for a given saving rate (where growth results from technological progress).
- Steady-state level of national income** The long-run equilibrium level of national income. The level at which all investment is used to maintain the existing capital stock at its current level.

- Sterilisation** Actions (e.g. open-market operations) taken by a central bank to offset the effects of foreign exchange flows or its own bond transactions so as to leave money supply unchanged.
- Stochastic shocks** Shocks that are random and hence unpredictable, or predictable only as occurring within a range of values.
- Stock** An amount of something (inputs, goods, money, etc.) existing at a point of time. (Contrasts with *flow*.)
- Stock (or inventory) appreciation** The increase in monetary value of stocks due to increased prices. Since this does not represent increased output, it is not included in GDP.
- Stop-go policies** Alternate deflationary and reflationary policies to tackle the currently most pressing of the four problems which fluctuate with the business cycle.
- Strategic alliance** Where two firms work together, formally or informally, to achieve a mutually desirable goal.
- Strategic trade theory** The theory that protecting/supporting certain industries can enable them to compete more effectively with large monopolistic rivals abroad. The effect of the protection is to increase long-run competition and may enable the protected firms to exploit a comparative advantage that they could not have done otherwise.
- Strong efficiency (of share markets)** Where share prices adjust quickly, fully and accurately to all available information, both public and that only available to insiders.
- Structural public-sector deficit (or surplus)** The public-sector deficit (or surplus) that would occur if the economy were operating at the potential level of national income: i.e. one where there is a zero output gap.
- Structural unemployment** Equilibrium unemployment that arises from changes in the pattern of demand or supply in the economy. People made redundant in one part of the economy cannot immediately take up jobs in other parts (even though there are vacancies).
- Structuralists** Economists who focus on specific barriers to development and how to overcome them.
- Subcontracting** Where a firm employs another firm to produce part of its output or some of its input(s).
- Sub-prime debt** Debt where there is a high risk of default by the borrower (e.g. mortgage holders who are on low incomes facing higher interest rates and falling house prices).
- Subsistence production** Where people produce things for their own consumption.
- Substitute goods** A pair of goods which are considered by consumers to be alternatives to each other. As the price of one goes up, the demand for the other rises.
- Substitutes in supply** These are two goods where an increased production of one means diverting resources away from producing the other.
- Substitution effect of a price change** The effect of a change in price on quantity demanded arising from the consumer switching to or from alternative (substitute) products.
- Substitution effect of a rise in wage rates** Workers will tend to substitute income for leisure as leisure now has a higher opportunity cost. This effect leads to *more* hours being worked as wage rates rise.
- Substitution effect of a tax rise** Tax increases reduce the opportunity cost of leisure and thus encourage people to work less.
- Substitution effect - international** As prices rise, people at home and abroad buy less of this country's products and more of products from abroad.
- Sunk costs** Costs that cannot be recouped (e.g. by transferring assets to other uses). Examples include specialised machinery or the costs of an advertising campaign.
- Supernormal profit** also known as **pure profit, economic profit, abnormal profit**, or simply **profit**) The excess of total profit above normal profit.
- Supply curve** A graph showing the relationship between the price of a good and the quantity of the good supplied over a given period of time.
- Supply schedule** A table showing the different quantities of a good that producers are willing and able to supply at various prices over a given time period. A supply schedule can be for an individual producer or group of producers, or for all producers (the market supply schedule).
- Supply-side economics** An approach which focuses directly on aggregate supply and how to shift the aggregate supply curve outwards.
- Supply-side policies** Government policies that attempt to alter the level of aggregate supply directly (rather than through changes in aggregate demand). Such policies aim to increase *potential* output. They focus on increasing the quantity and/or productivity of resources.
- Surplus on the current budget** The amount by which public-sector receipts exceed those expenditures classified as current expenditures.
- Sustainability (environmental)** The ability of the environment to survive its use for economic activity.
- Sustainable output** The level of national output corresponding to no excess or deficiency of aggregate demand.
- Switching costs** The costs to a consumer of switching to an alternative supplier.
- Systemically important banks (SIBs)** Banks identified by a series of indicators as being significant players in the global financial system.
- Tacit collusion** Where oligopolists take care not to engage in price cutting, excessive advertising or other forms of competition. There may be unwritten 'rules' of collusive behaviour such as price leadership.
- Takeover bid** Where one firm attempts to purchase another by offering to buy the shares of that company from its shareholders.
- Takeover constraint** The effect that the fear of being taken over has on a firm's willingness to undertake projects that reduce distributed profits.
- Target real wage theory** The theory that unions bargain for target real wage increases each year irrespective of the level of real growth in the economy.

- Tariff escalation** The system whereby tariff rates increase the closer a product is to the finished stage of production.
- Tariffs (or import levies)** Taxes on imported products: i.e. customs duties.
- Tax allowance** An amount of income that can be earned tax-free. Tax allowances vary according to a person's circumstances.
- Tax avoidance** The rearrangement of one's affairs so as to reduce one's tax liability.
- Tax evasion** The illegal non-payment of taxes (e.g. by not declaring income earned).
- Taylor rule** A rule adopted by a central bank for setting the rate of interest. It will raise the interest rate if (a) inflation is above target or (b) real national income is above the sustainable level (or unemployment is below the natural rate). The rule states how much interest rates will be changed in each case.
- Technical efficiency** The firm is producing as much output as is technologically possible given the quantity of factor inputs it is using.
- Technological unemployment** Structural unemployment that occurs as a result of the introduction of labour-saving technology.
- Technology-based standards** Pollution control that requires firms' emissions to reflect the levels that could be achieved from using the best available pollution control technology.
- Terms of trade** The price index of exports divided by the price index of imports and then expressed as a percentage. This means that the terms of trade will be 100 in the base year.
- Theory of the firm (traditional)** The analysis of pricing and output decisions of the firm under various market conditions, assuming that the firm wishes to maximise profit.
- Third-degree price discrimination** Where a firm divides consumers into different groups based on some characteristic that is relatively easy to observe and informative about how much consumers are willing to pay. The firm then charges a different price to consumers in different groups, but the same price to all the consumers within a group.
- Tie-in sales** Where a firm is only prepared to sell a first product on the condition that its customers buy a second product from it.
- Time consistency** Where a person's preferences remain the same over time. For example, it is time consistent if you plan to buy a book when your student loan arrives and then actually do so when it does.
- Time-consistent policy announcement** A policy announcement where there is an incentive for the policy maker to stick to it over time.
- Time deposits** Deposits that require notice of withdrawal or where a penalty is charged for withdrawals on demand.
- Time-inconsistent policy announcement** A policy announcement where there is an incentive for the policy maker to renege on it at a future date.
- Time-series data** Information depicting how a variable (e.g. the price of eggs) changes over time.
- Total consumer expenditure on a product (*TE*) (per period of time)** The price of the product multiplied by the quantity purchased: $TE = PQ$.
- Total consumer surplus** The excess of a person's total utility from the consumption of a good (*TU*) over the amount that person spends on it (*TE*): $TCS = TU - TE$.
- Total cost** The sum of total fixed costs and total variable costs: $TC = TFC + TVC$.
- Total currency flow on the balance of payments** The current plus capital plus financial account balance but excluding the reserves.
- Total physical product** The total output of a product per period of time that is obtained from a given amount of inputs.
- Total (private) surplus** Total consumer surplus ($TU - TE$) plus total producer surplus ($TR - TVC$).
- Total producer surplus (*TPS*)** Total revenue minus total variable cost ($TR - TVC$): in other words, total profit plus total fixed cost ($T + TFC$).
- Total revenue** A firm's total earnings from a specified level of sales within a specified period: $TR = P \times Q$.
- Total revenue (*TR*) (per period of time)** The total amount received by firms from the sale of a product, before the deduction of taxes or any other costs. The price multiplied by the quantity sold. $TR = P \times Q$.
- Total social surplus** Total benefits to society from consuming a good minus total costs to society from producing it. In the absence of externalities, total social surplus is the same as total (private) surplus.
- Total utility** The total satisfaction a consumer gets from the consumption of all the units of a good consumed within a given time period.
- Tradable permits** Firms are issued or sold permits by the authorities that give them the right to produce a given level of pollution. Firms that do not have sufficient permits to match their pollution levels can purchase additional permits to cover the difference, while those that reduce their pollution levels can sell any surplus permits for a profit.
- Trade creation** Where a customs union leads to greater specialisation according to comparative advantage and thus a shift in production from higher-cost to lower-cost sources.
- Trade cycle or business cycle** The periodic fluctuations of national output round its long-term trend.
- Trade diversion** Where a customs union diverts consumption from goods produced at a lower cost outside the union to goods produced at a higher cost (but tariff free) within the union.
- Traditional theory of the firm** The analysis of pricing and output decisions of the firm under various market conditions, assuming that the firm wishes to maximise profit.
- Tragedy of the commons** When resources are commonly available at no charge people are likely to overexploit them.

Transfer payments Moneys transferred from one person or group to another (e.g. from the government to individuals) without production taking place.

Transfers (by the government) Transfers of money from taxpayers to recipients of benefits and subsidies. They are not an injection into the circular flow but are the equivalent of a negative tax (i.e. a negative withdrawal).

Treasury bills Bills of exchange issued by the Bank of England on behalf of the government. They are a means whereby the government raises short-term finance.

Trigger strategy Once a firm observes that its rival has broken some agreed behaviour it never co-operates with them ever again.

Tying Where a firm is only prepared to sell a first product (the tying good) on the condition that its consumers buy a second product from it (the tied good).

U-form (unitary form) of corporate organisation Where the managers of the various departments of a firm are directly responsible to head office, normally to a chief executive.

Uncertainty When an outcome may or may not occur and its probability of occurring is not known.

Underemployment Where people who want full-time work are only able to find part-time work.

Underground (or illegal or shadow) markets Where people ignore the government's price and/or quantity controls and sell illegally at whatever price equates illegal demand and supply.

Unemployment The number of people of working age who are actively looking for work but are currently without a job. (Note that there is much debate as to who should officially be counted as unemployed.)

Unemployment rate The number unemployed expressed as a percentage of the labour force.

Unit elastic demand Where quantity demanded changes by the same percentage as price. Ignoring the negative sign, it will have a value equal to 1.

Universal benefits Benefits paid to everyone in a certain category irrespective of their income or assets.

Util An imaginary unit of satisfaction from the consumption of a good.

Value added tax (VAT) A tax on goods and services, charged at each stage of production as a percentage of the value added at that stage.

Variable costs Total costs that vary with the amount of output produced.

Variable factor An input that can be increased in supply within a given time period.

Velocity of circulation The number of times annually that money on average is spent on goods and services that make up GDP.

Vent for surplus When international trade enables a country to exploit resources that would otherwise be unused.

Vertical equity The redistribution from the better off to the worse off. In the case of taxes, this means the rich paying proportionately more taxes than the poor.

Vertical merger When two firms in the same industry at different stages in the production process merge.

Vertical restraints Conditions imposed by one firm on another which is either its supplier or its customer.

Wage-price spiral Wages and prices chasing each other as the aggregate demand curve continually shifts to the right and the aggregate supply curve continually shifts upwards.

Wage taker An employer or employee who has no power to influence the market wage rate.

Weak efficiency (of share markets) Where share dealing prevents cyclical movements in shares.

Weighted average The average of several items where each item is ascribed a weight according to its importance. The weights must add up to 1.

Wholesale banks Banks specialising in large-scale deposits and loans and dealing mainly with companies.

Wholesale deposits and loans Large-scale deposits and loans made by and to firms at negotiated interest rates.

Withdrawals (W) (or leakages) Incomes of households or firms that are not passed on round the inner flow. Withdrawals equal net saving (S) plus net taxes (T) plus expenditure on imports (M): $W = S + T + M$.

Working to rule Workers do the bare minimum they have to, as set out in their job descriptions.

Yield on a share The dividend received per share expressed as a percentage of the current market price of the share.
